The general design of the machine is the same as those we have previously illustrated. The spindles are of high carbon steel, running in phosphor-bronze bearings with ball thrust collars. They will be provided with either No. 4 or No. 5 Morse taper sockets as desired. The table is fed upward with steel feed-screws, operated by carefully-made worm-gearing. The feed-screw nuts are of phosphor-bronze, opened and closed by a hand-lever on the front of the table; the feed throw-out is automatic. The pilot-wheel controls the rapid movement or adjustment of the feed. The table itself is made extra heavy, is provided with T-slots, and is counterbalanced. The three spindle speeds are designed to be suited to the different diameters of holes in the work in automobile cylinder operations.

GANG RADIAL DRILLING MACHINE

The radial drill made by the Wm. E. Gang Co., Cincinnati, O., has been redesigned, as shown in the engraving.

The general design of this radial drill is well known. The spindle is driven from a horizontal shaft which passes through the swinging column, where it is connected by gearing with the vertical drive-shaft. This construction gives much more direct drive than usual. Another distinctive feature of the machine is the placing of the power-elevating mechanism on the arm instead of at the top of the column. The screw is thus a stationary one acted on by a revolving nut.

In the new design, the particular point of interest is a new spindle drive mechanism. *A*, in Fig. 2, is the horizontal driving shaft, passing through the column as described. This shaft has keyed to it a pinion *B*, driving bevel gears *C* and *D* in opposite directions. These latter revolve loosely on the shaft, and are provided with internal seats against which friction rings may be expanded, so that either of them can be connected with shaft *F*. This double friction clutch is operated by lever *N* through collar *E*. By this means the spindle is quickly reversed in either direction. Spur gear *G* is solid with shaft *F*, and spur gear *I* is keyed to it. These mesh with gears *H* and *J* respectively, which run loose on sleeve *L*. Sliding jaw clutch *K*, controlled by lever *O*, may be operated to engage either one of these with the shaft. This corresponds to the usual back gear provision, giving eight changes of speed with the cone pulley drive, or twelve with the speed box.

An important point in the drive thus described is the fact that the friction clutches for reversing operate between the high-speed shafts *A* and *F*—that is to say, the back gears are placed between the

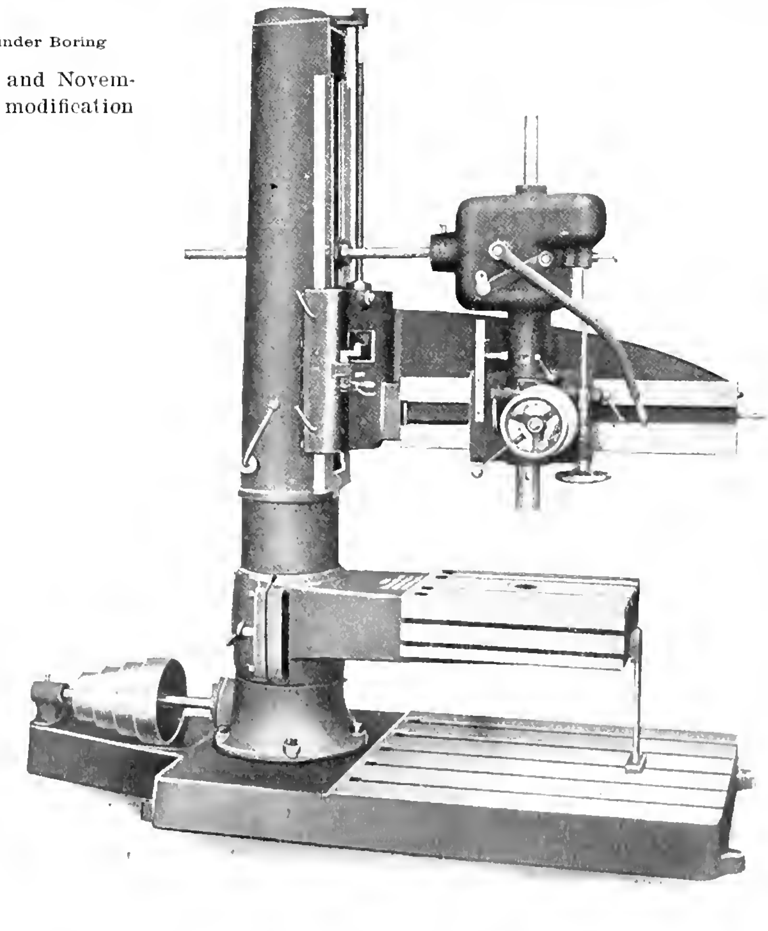

Fig. 1. Gang Radial Drilling and Tapping Machine

clutches and the spindle. By this means they are relieved of the excessive strain that would be thrown on them in such work as heavy tapping which requires the reversal of the

spindle while the tap is lodged in the work. The friction clutch operates without shock or jar.

Another important improvement is the depth gage and automatic stop. The gage is shown at *R*, and the adjustable tripping dog and pointer at *S*. The point of novelty lies in the fact that the graduated scale, instead of being on the spindle and moving with it, is attached in a stationary position on the head. The adjustable dog and pointer is clamped

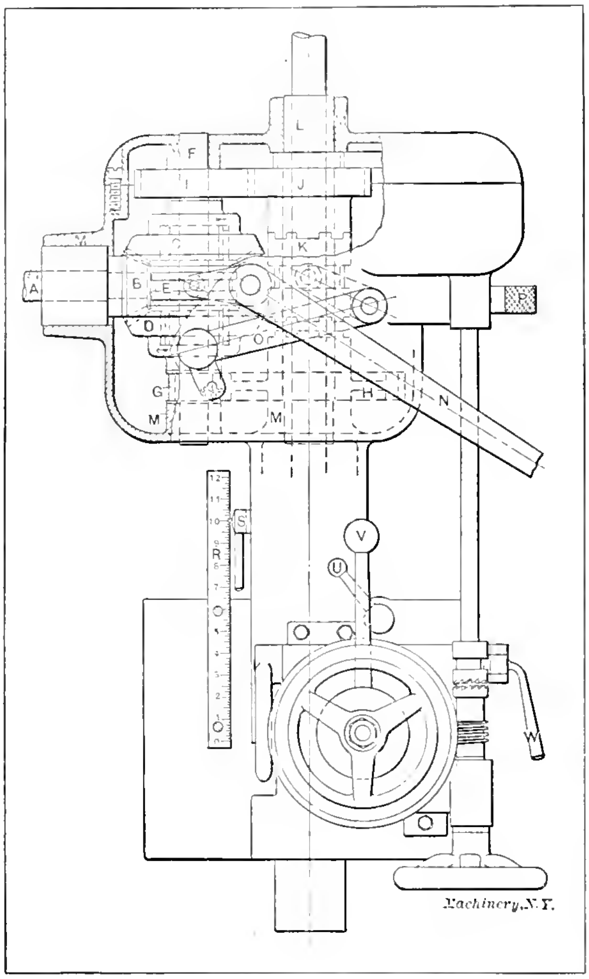

Fig. 2. The Improved Spindle Drive of the Gang Drill

in any required position by a bolt seated in a T-slot in the spindle sleeve. Thus arranged, with the zero point at the lower end of the graduated scale and in a fixed position, all the operator has to do in preparing to drill or counterbore a hole to a given depth is to bring the tool down onto the surface of the work, set the pointer on dog *S* opposite the graduations on the scale corresponding to the required depth, tighten the pointer and start the feed. When the pointer gets to zero, the feed will be knocked out automatically, and the spindle can travel no further. All depths are read from zero.

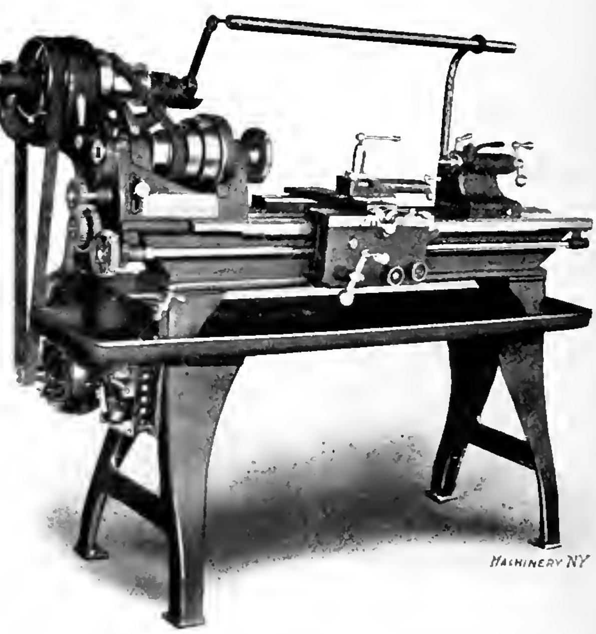
Four rates of feed are provided on this machine—0.008, 0.011, 0.014 and 0.017 inch per revolution of the spindle. The changes are made by turning knurled knob *P*. The feed is taken from a positive connection with gear *J*, through the change mechanism and a worm and worm-gear connection for the rack-pinion. The worm-gear drives the rack-pinion through a friction clutch, operated by quick return lever *V*. Lever *W* operates the positive clutch shown, which can be disengaged when it is desired to use a hand worm feed.

The head is firmly gibbed on the radial arm, and may be adjusted in and out by rack and pinion actuated by a handwheel. It is locked in position by clamp screw and lever *U*. It will be noted that, in accordance with their usual practice, the builders have enclosed all the gearing, thereby protecting both the operator and the mechanism from injury. This construction also minimizes the number of bolted-on bearings, and gives a pleasing appearance of neatness and simplicity to the design.

This machine will be furnished with a square, round, plain swiveling, worm swiveling, round tilting, square box or square tilting table. The square box form of table is shown in the illustration.

SENECA FALLS MOTOR DRIVE FOR "STAR" LATHES

The Seneca Falls Mfg. Co., 330 Water St., Seneca Falls, N. Y., has recently brought out a new type of motor drive for its 9- and 11-inch "Star" lathes. This new arrangement is shown in the accompanying illustration. The advantage of this type of motor drive over other methods employed is in its adaptability to the varying conditions imposed by the users of small engine lathes, as they ask for motors for all kinds of electric current. For this reason the drive has been designed so as to use any kind of constant or variable speed motor. Preferably, it should be non-reversible, and with a speed of 1,000 to 2,000 revolutions per minute. This drive may be easily attached to a lathe. A pulley on the motor of the proper size transmits the power by belt to a countershaft pulley that runs constantly in one direction. A belt is also used to transmit motion from the countershaft to the lathe spindle. Means are provided for quickly tightening these belts so that they can be kept at the proper tension until worn out, without shortening them. Experience has proved that this method of driving small lathes has advantages over rigid gearing and chain belt drives, as the use of belts will often prevent damage to both motor and lathe. Starting, stopping, and reversing the rotation of the lathe spindle is controlled by a shifting bar placed horizontally above the lathe within easy reach of the operator. When this bar is in the central postion, the lathe is stationary. By shifting it to the left, a forward motion is imparted to the lathe spindle, while shifting it to the right gives a reverse movement.



Small Lathe equipped with the New Seneca Falls Motor Drive

The driving mechanism consists of friction clutches and gears for reversing the motion, which are encased and run in a bath of oil. This mechanism is simple in its construction and it is not liable to damage or disarrangement. The bearings are thoroughly lubricated by oil rings.

LELAND SENSITIVE MULTI-SPINDLE DRILL

The accompanying half-tone illustrations show a front and rear view of a four-spindle sensitive drill press built by W. H. Leland & Co., Worcester, Mass. This machine is known as the Leland "sensible" sensitive drill press, and in its design several new and interesting features have been introduced. Chief among these features are the arrangement for obtaining proper belt tension, the variable lever ratchet feed for the spindle, the arrangement of positive spindle stops, and the general design of the frame and the table, which makes it possible to obtain the maximum of strength without giving the machine a clumsy or unattractive appearance. The ma-

chine, however, is very heavy in comparison with the general type of these machines, it being about 250 pounds heavier than some other machines of its class. This additional metal has been distributed with care, so as to put it in such places where it will render the machine more efficient.

As will be seen in Fig. 2, the machine is provided with loose and fast pulley drive for the main driving shaft in the rear. The loose pulley is made smaller than the tight, to relieve the tension on the belt when the machine is not running. On the main driving shaft are placed the four-step cone pulleys from which the power is transmitted to the upper horizontal driving shafts and from there in the usual manner to the vertical spindles. The arrangement for obtaining the proper belt tension on the vertical belts between the cone pulleys as well as on the horizontal belts from the pulleys which drive the vertical spindles, is of especial interest. As shown in Fig. 2 the frame, or, as it has been commonly called, the "goose-neck," of the individual drills, is of a triangular construction, that is, it is provided with two braces in the back so placed that the belt tension from the two belts will largely strain these braces as compression members, thus insuring the maximum strength.

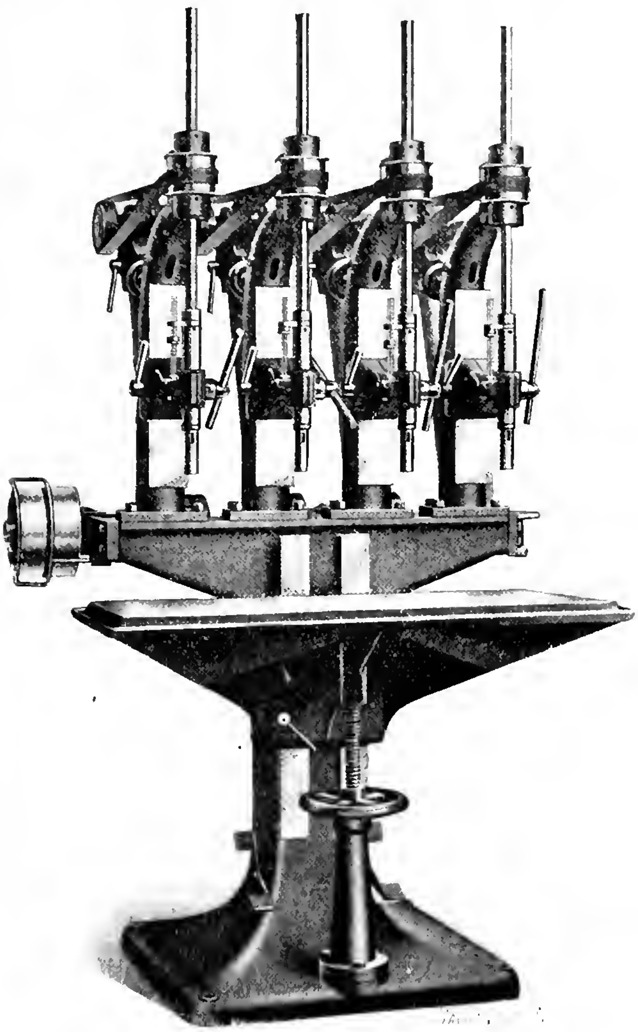


Fig. 1. Sensitive Four-spindle Drill, built by W. H. Leland & Co., Worcester, Mass.

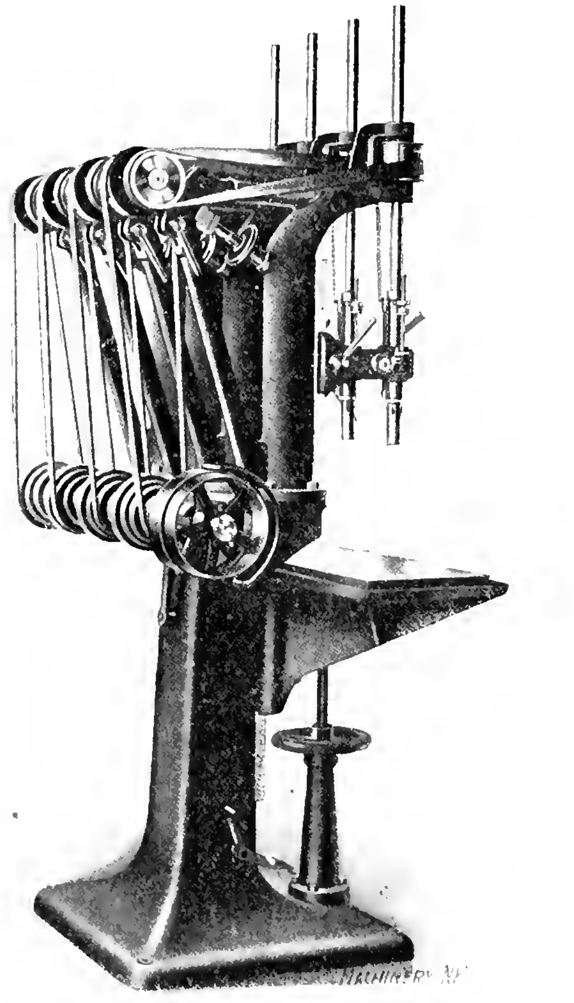

Fig. 2. Rear View of Leland Sensitive Drill, showing Driving Arrangement

At the back where these two braces join, the frame is provided with a slot, the sides of which may be brought together or tightened by means of the handle shown in Fig. 2, immediately below the pulley transmitting power to the vertical spindle. The bearings for the upper cone pulleys and the pulley driving the spindle are held in this slot, and are supported by a screw which enters into an elongated nut provided with a hand-wheel, as shown, between the two braces. The end of the elongated nut rests in a socket in the back of the main column of the frame or goose-neck. When the binding handle mentioned is loosened and the hand-wheel operated, the screw is moved either out or in, according to the direction of rotation of the wheel, and as the bearings for the cone and driving pulleys are directly connected with the screw, they will consequently move outward or inward, as the case may be. Owing to the fact that the thrust on the screw is taken in a direction such that the axis of the screw bisects the angle between the vertical and horizontal belt pulls, the tension on both of the belts will adjust itself automatically so that it will be of the same amount in each, this being possible on account of the socket joint in the main column which takes the thrust. When the bearings have taken their proper location, the bracket carrying them is clamped in position in the slot in the back of the frame, by means of the handle already referred to. This means for tightening the belts is both convenient and efficient. It is quickly operated and it equalizes the tension on both belts automatically. When small holes are drilled and less belt tension is required, the belts may be slackened. When heavier drilling is to be done, it is but a moment's work to again get heavier tension on the belts.

The main driving shaft is provided with a bearing in the center, as well as at each end, in order to maintain perfect alignment; and at the top of the spindle, a bearing is provided at each end of the spindle pulley. It will be seen in Fig. 1 that apparently the pulley on the vertical spindle is wider than necessary. As a matter of fact, this pulley is actually a drum, and the extra width is required on account of the swinging action of the driving pulley when adjusted for belt tension. The width of the belts used is $1\frac{1}{4}$ inch, but the spindle pulley is more than twice the width of the belt. This permits the belt to assume a normal position on the pulley when the shaft in the back is moved either up or down, as required.

The machine is built in two styles, one having all ball-bearings, while the other is provided with bearings with inserted bushings, these latter being made of Parsons white brass. All the bearings on the machine when provided with inserted

bushings are ring-oiled with the exception of the vertical bearings, which are equipped with felt storage for the oil. The bushing bearings are superior in many respects to the usual plain babbitted bearings. When ball-bearings are used, the belts; of course, run in oil and the bearings are dust-proof.

The base of the machine is of a box-shaped section and the top of the base onto which the individual drill frames are bolted is also made of a box section, which maintains the truth of the surface onto which the frames are bolted, a feature which is highly important if accuracy is expected. The table of the machine is heavily ribbed on the under side in a manner very similar to that of a surface plate; this is indicated both in Figs. 1 and 2. This method of ribbing is very necessary on a machine of this type, where accurate work is to be performed. Often the tables of sensitive drill presses are not strong enough to carry the heavy weight of the work with its drill jig, when placed on one corner of the table, without springing to some extent, and in such cases it is, of course, impossible to drill a hole that is at right angles to the base surface of the work. The table is raised and lowered by an elevating screw which is stationary and engages with a revolving nut hand-wheel, the thrust being taken by a ball-bearing. It is not necessary to cut a hole in the floor in order to get the extreme range of the vertical movement of the table. A groove is provided around the edge of the table for oil or other drilling compound.

It will be seen in Fig. 1 that a foot-treadle is provided on both sides of the machine, so that the shipper may be operated by the foot from either side, according to the position of the operator. A locking arrangement consisting of a latch which holds the shipper positively in position when once operated, is provided. This locking arrangement, however, does not prevent the shipper from returning to its original position when the foot-treadle is again pressed, but it locks it in the position to which it has been brought by the last operation of the shipper treadle.

The sliding head is held at any desired position on the face of the column by a binder on the side of the head. An interesting feature in the design of the head is the ratchet feed employed. The feed is by a lever, as usual, which is of sufficient diameter and length to allow of heavy feeds for large drills. By means of a slight twist of the handle, the ratchet pawl is brought out of engagement with any one groove in the ratchet collar, and brought into engagement with the next groove, the engagement being positive as long as there is no twisting action on the handle. This design is very simple, but handy and efficient. The lever can be moved quickly from a short to a long leverage, and can be locked, if required, in any position, but the tension on the spring employed in the ratchet feed device provides enough pressure to ordinarily hold it in any position. The lever is knurled on the end sufficiently to get a good grip.

On the side of the spindle a positive stop arrangement is provided. This device is made in two styles. The regular style consists of a screw provided with two nuts, one of which acts as a check nut binding the other on the screw on which they are both mounted. The nuts abut against a projection of the head when the spindle is brought down. This stop is positive and can be adjusted for very fine differences in measurements when required. It is set, of course, by means of a scale or standard measuring blocks. The special type of stop consists of a micrometer stop arrangement which makes it possible to take actual measurements directly, without the use of a scale. The screw on which the stop nuts are mounted has, in this case, been milled away nearly to its center, and on the flat surface thus provided a scale is graduated, on one side of the center line in tenths, and on the other side in fourths, of an inch. A graduated micrometer collar is then provided on the screw, by means of which it is possible to take any measurements varying by thousandths of an inch. The micrometer screw is adjustable in its end bearings, so that it can be brought up or down as required, in order that readings for different depths of drilled holes may be made to start at zero. The thread of the micrometer screw is a ratchet thread being made like a square thread on one side, and with an angle on the other. As the square side of the thread takes the thrust, this makes a very strong, positive and durable stop.

The machine is furnished with from one to four spindles, as required, and it will drive to their full capacity, high-speed drills up to 29/32 inch in diameter, these drill sizes regularly having a No. 2 Morse taper shank, the spindle being provided with a No. 2 Morse taper socket.

The general dimensions of the machine are as follows: The distance from the face of the column to the center of the spindles is 7 inches and the distance between the spindles 9 inches. The maximum distance from the lower spindle end to the table is 24 inches, and it is possible to bring the spindle clear down to the table. The vertical adjustment of the spindle head is 11 inches, and that of the table 12 inches; the vertical feed of the spindle is 5 inches. The diameter of the spindle pulley is 4 inches. The working surface of the table for the 4-spindle machine is 11 x 41 inches, the outside of the table being 14 x 44 inches. The tables of the one-, two- and three-spindle machines are, of course, proportionally smaller. The diameter of the main driving pulley is 8 inches and its face 2½ inches for the four-spindle machine. The floor space required for the same machine is 33 x 48 inches and the weight is 1,230 pounds.

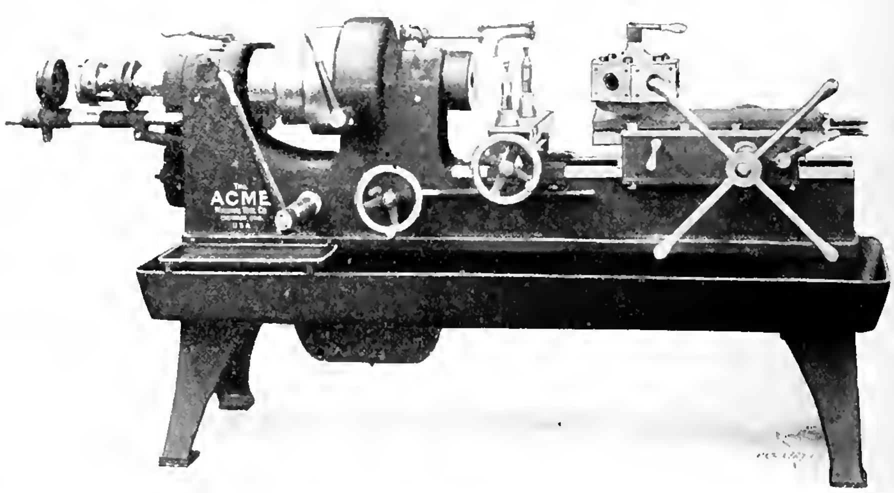

Fig. 1. The Acme Turret Lathe

THE ACME TURRET LATHE

The turret lathe or screw machine herewith illustrated and described is the product of a new firm, the Acme Machine Tool Co., of Cincinnati, O. The machine gives evidence on the first inspection of having been designed to meet the demand for a high grade, powerful tool, for use with high-speed steel. This is evidenced, for instance, by the fact that the head-stock is cast solid with the bed, and by the provision of a wide-faced, three-step cone with a friction clutch back-gear drive. The clutches are so arranged that the spindle can be stopped by throwing the operating lever to the middle position. The deep chip pan should also be noted. This will hold a liberal quantity of chips and oil, making it unnecessary to be constantly cleaning it out when taking rapid reduction cuts on steel.

The spindle runs in ring oiling babbitted bearings of ample size. The end thrust is taken at the front bearing, thus avoiding danger of binding or loosening from the unequal expansion of the steel spindle and the cast iron bed. The automatic chuck is forged solid on the end of the spindle, reducing the overhang, and supporting the collet firmly at its extreme outer end. A master collet is furnished with each machine, together with one set of bushings for stock of the largest capacity of the spindle. The chuck and stock-

feeding lever is placed within easy reach of the operator. Special attention has, in fact, been given to the location of all the hand wheels, levers, etc., to permit easy manipulation without requiring the operator to shift his position.

Interesting details of the turret slide mechanism are shown in Figs. 3 and 4. The turret *A* is hexagonal in form and is provided with tapped holes for attaching tools to the face, in addition to the regular holes with the binder bushings. A hole of the same diameter as those in the turret is bored through the turret stem *B*, thus allowing long work to be turned with short stiff tools. The tool clearance over the top of the slide is made extra large to permit the use of large dies and turret tools, while the slide itself is made wide to give rigidity to the turret and tools. This will be seen in Fig. 4.

Taper gibs *C* and *C*, also shown in Fig. 4, adjust the slide horizontally, while the slide bed has interposed between it and the top of the bed, the taper shim *D*, which by means of screws *E*, *E*, can be adjusted forward or back so as to raise or lower the turret. These two adjustments, working in combination, serve to preserve the alignment of the turret holes with the spindle. An interesting point in the construction of the taper shim *D* will be noticed in Fig. 3. The points of screws *E* bear on inclined surfaces, so that when the turret slide bed is raised from the bed of the machine, shim *D* goes with it, being held without danger of dropping loose.

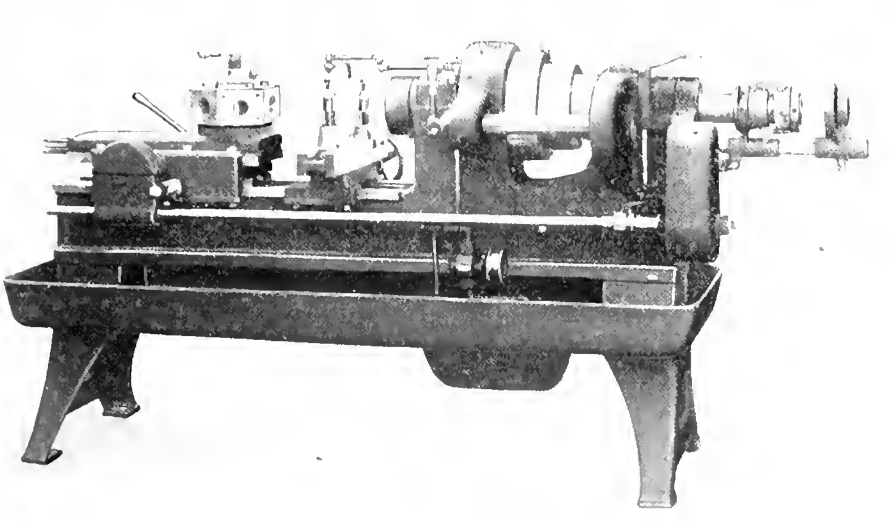

Fig. 2. Rear View of Machine, showing Feed Mechanism

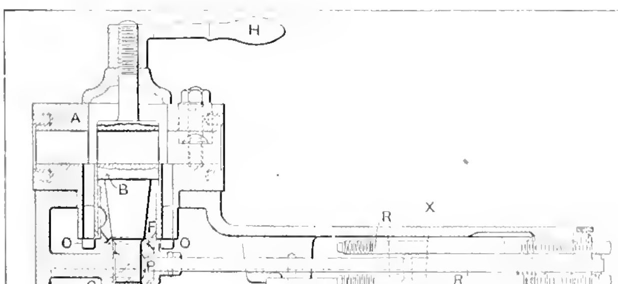

Fig. 3. Longitudinal Sections, showing Turret Indexing and Feed Mechanisms

The neck of the turret contains a bronze sleeve *F*, which is keyed to it, and thus revolves with it. This is bored taper to form a seat for the binding bolt *B*. By adjusting nut *G*, the turret may be held to its seat with any desired degree of freedom, irrespective of the action of the regular clamp handle.

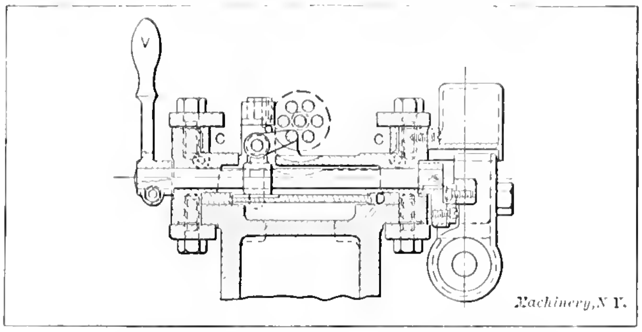

Fig. 4. The Feed and Automatic Stop Motions

The turret revolving mechanism is shown most plainly in the lower view of Fig. 3. As the turret slide nears the limit of its backward movement, the roll on the end of lock bolt lever *J* runs up the incline of tumbler *K*, thus withdrawing the turret lock bolt *L* against the pressure of spring *M*. When *L* has been withdrawn, pawl *N* engages one of six hardened pins *O* driven into the neck of the turret (see upper view) and thus revolves the latter. At the conclusion of the indexing at the extreme end of the stroke, the roller at the end of *J* runs off the back side of tumbler *K*, locking the turret in position again. As the slide comes forward for its next cut, the tumbler *K* tips down out of the way of *J*, and pawl *N* snaps in back of the next pin *O*, both being thus in position to index again on the next return movement.

Details of the turret feed mechanism are shown in both Figs. 3 and 4. An independent stop is provided for each face of the turret. Bushing *F*, already mentioned, has bevel gear teeth cut on it meshing with a corresponding bevel gear *P*, which, by means of the shaft to which it is pinned, revolves the stop cylinder *Q*. This latter carries a series of six stop screws *R*, which are thus brought successively into position in line with the stop screw abutment *S*. The striking of the stop screw against this abutment first throws out the automatic feed (if it is engaged), and then brings up against a positive stop immediately afterwards. This permits using the automatic feed in turning up to a shoulder, which may then be finished by hand, allowing the cut to run out until the face has been smoothed up. The abutment *S* is pinned to a rod *T*, carrying a collar engaging the trip *U*, by means of which the power feed is thrown out. Lever *V* is used for throwing the feed out or in by hand. Also pinned to *T* is the handle *W*, which permits abutment *S* to be swung around out of the way of the stop screws, so as to feed beyond the positive stop, should occasion so require.

The power feed is driven positively from the spindle by gearing enclosed in the case shown at the right of Fig. 2. This gearing provides four changes of feed, controlled by a handle extending over the rear head-stock bearing. This power feed may be attached to the machine after it is purchased, if desired by the user, without additional machining.

The cross-slide is provided with a large graduated dial and positive stops. It has a hand longitudinal adjustment by means of the hand-wheel, bevel gears and screw shown on the front of the bed. This screw runs in a bronze nut screwed to the flat gib of the cross-slide, and is protected from chips and dirt by means of steel tubing. Power feed will be supplied for this cut-off if desired.

A double taper friction countershaft of improved design is

supplied. The construction of the clutch is shown in Fig. 5. The shaft A_1 has keyed to it the driving sleeve B_1. Interlocking with projections on this sleeve, but free to slide on the shaft, is a friction clutch C_1. Bearing sleeve D_1 is a sliding fit in the hub of pulley E_1 and revolves on driving sleeve B_1. It is provided with a large oil chamber holding enough lubricant to run a month or more without refilling. When thimble J_1 is pressed toward the left, levers K_1, of which one only is shown, operate to engage the friction surfaces of E_1 and C_1 in a perfectly obvious manner. Ample adjustment for wear is provided by loosening screw H_1 and turning nut F_1 to bring

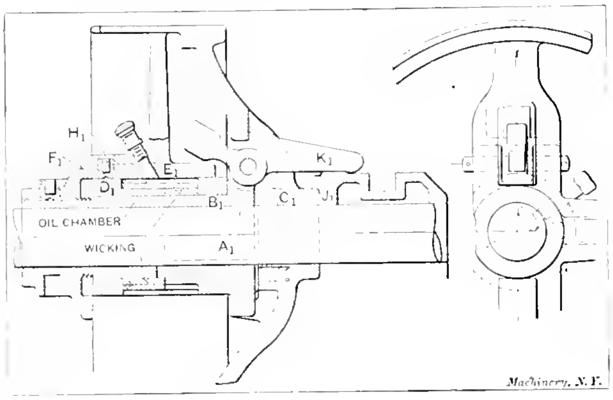

Fig. 5. Detail of Countershaft Clutch Construction

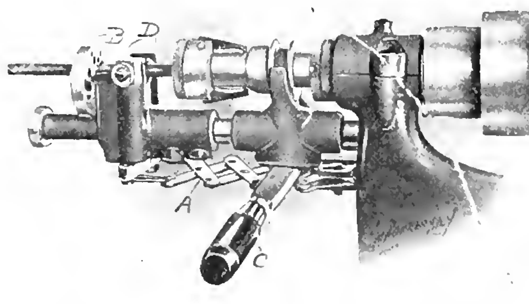
the pulley into closer engagement with the cone surface of C_1. This construction will be appreciated by mechanics who have had to dismantle the counter-shaft and face of the hub of the pulley, in order to get more adjustment.

The machine illustrated is provided with chuck and stock feed, and power feed for the turret slide. It may be purchased without these attachments, however, either of which may be added at a later time without requiring any further machine work on the lathe. The same is true of a power feed to the cut-off slide, which will also be provided for work which requires it.

WELLS IMPROVED WIRE FEED

The accompanying illustration shows an improvement which has been introduced on the hand screw machine made by the F. E. Wells & Son Co., Greenfield, Mass. The advantage of this wire feed is that a single lever movement takes care of all operations and movements of the various parts necessary, including the opening of the chuck, the feeding of the stock forward, and the closing of the chuck. It is not necessary

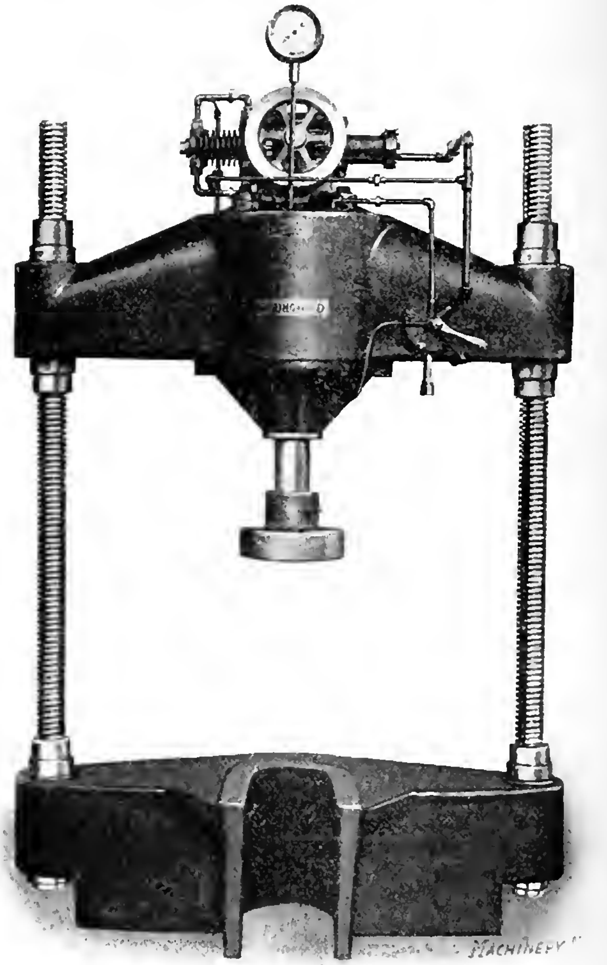


Improved Wire Feed Mechanism, made by the F. E. Wells & Son Co., Greenfield, Mass.

to fasten a dog, collar, or other device to the stock, as is the case with the ordinary type of wire feed. The operation of the device is briefly as follows: When the lever C is pulled forward, the two fingers D, which are provided with cam surfaces on their inner faces, are given a slight turn so that they grip the stock between them. By means of the pantograph, or "Jacob's ladder" arrangement shown at A, the bracket holding the fingers D is made to move through a distance very much greater than that of the movement of the lever C, so that a considerable length of stock may be fed in by a comparatively short movement of the feed lever. When the lever C is moved back after the stock has been pulled forward, the fingers are again opened and are ready to take a new hold on the stock as soon as the handle C is again operated forward. At the same time that the fingers are released and moved back, the bracket immediately above the handle C, which is provided with a yoke engaging with the chuck closing collar, is moved backward, and the chuck is closed, so that thus all the operations of feeding the stock forward and the opening and closing of the chuck are accomplished by a slight movement of a single lever, without any additional manipulation. The disk shown at B is a guide for the stock and can be adjusted for different diameters.

SPRINGFIELD PNEUMATIC PRESS

The illustration shows an ingenious press for shop use made by the Springfield Machine Tool Co., 631 Southern Ave., Springfield, O. It is intended for general shop use in the insertion and removal of heavy arbors, and in making the press fits met



Pnaumatic Press with Automatic Intensifier

with in machine building. It is an improved design of the machine shown in the department of New Machinery and Tools of the August, 1908, number of MACHINERY.

This machine operates by air pressure, either direct or intensified, as will be described. It consists primarily of two heavy frame castings, upper and lower, held together by the strong screws shown on each side. The construction of the lower base permits a large wheel up to 38½ inches in diameter to be placed between the screws. The opening permits the work to be pushed into place instead of being lifted off as would often be necessary if a circular opening only were provided. The two upright screws support the upper frame on the nuts shown. These are adjustable so that the upper frame can be lowered or raised to agree with the height of work being operated upon.

As stated, the press is operated pneumatically. The piston is 15 inches in diameter with a stroke of 8 inches. With an initial pressure of 80 pounds this gives a pressure on the work of 7 tons when direct air pressure is being used. For work

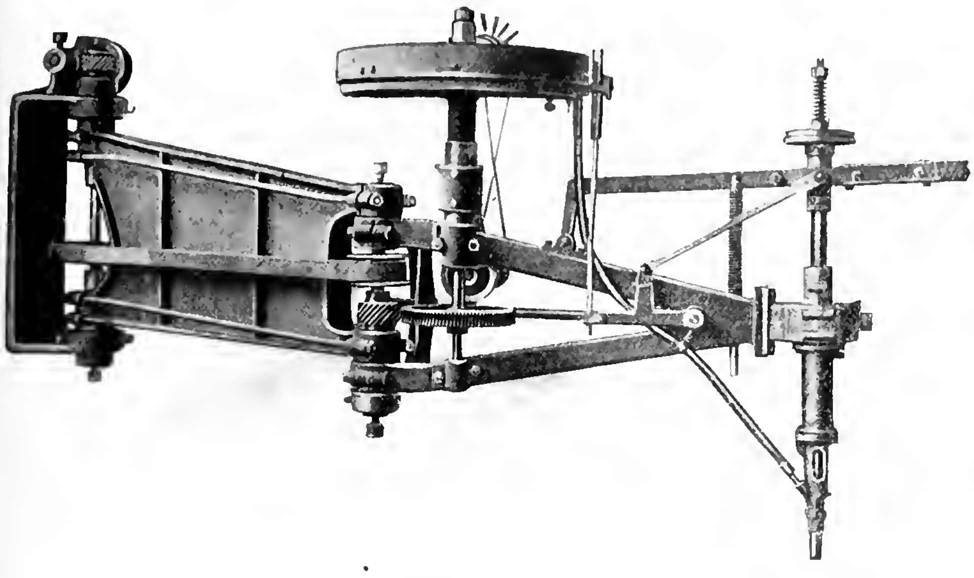
requiring a greater effort, the automatic pump mechanism, shown mounted on the top of the upper frame, is used. This is, in effect, a compressed air engine driving an air compressor capable of giving a maximum pressure of 225 pounds against the 15-inch piston, giving a pressure on the work of about 20 tons.

All the movements of the press are controlled by the valve shown at the right-hand side of the upper frame. In one position of this handle, the piston is raised, and in the next position the initial air pressure is admitted above the cylinder. Should this not be sufficient to drive the work together, the handle is moved to the third position, which automatically starts the pump, gradually increasing the pressure to the desired point. A gage is furnished so that the operator may know at all times what pressure is being applied to the work.

The distance between the upright screws is 38½ inches. The maximum distance of the plunger at its topmost position to the bottom of the base is 42 inches. The machine requires a floor space of 24 by 48 inches.

REYNOLDS RADIAL SCREW DRIVING MACHINE

In the January, 1909, issue of MACHINERY an automatic screw driving machine built by the Reynolds Machinery Co., Moline, Ill., was illustrated and described. The accompanying illustration shows another machine built by this company, which is the latest addition to the line of screw driving machines manufactured by the firm. This machine covers a range of work for which the regular stationary type shown with the previous description is not available, and bears the same relation to the regular or upright type as a radial drilling machine does to an upright drill press. The illustration shows the machine, which consists merely of an arm which can be mounted in any convenient manner, for example, on a post or on the wall of the building in which the machine is used. The working parts of the machine are mounted on the arm which is provided with a joint at about one-half of the distance of the spindle from the wall. The arm is of such proportions that the screw-driving spindle can be brought to a maximum distance of 7 feet from the post, and owing to the jointed construction, the arm may be swung around so that the spindle can be placed in any position within the circumference of a 14-foot diameter circle, except for a small area close to the post.



Radial Automatic Screw Driving Machine, built by Reynolds Machinery Co., Moline, Ill.

The spindle of the machine is spring counterbalanced so that it is automatically raised as soon as the operating lever is released. In operation, the screws are simply thrown into the pan or hopper shown at the top in the illustration. The work is then placed in such a position that the spindle end can reach the place where it is desired to drive the screw. The operator holds the feed lever in in one hand and places the other on the head of the machine so as to be able to swing it quickly into the desired position. He then depresses the lever as soon as the spindle comes in the desired position, thereby starting the screw. The spindle runs at about 800 revolutions per minute, so that the screws are driven in place practically instantly. The size of the machine shown in the half-tone is capable of driving screws up to No. 20, 4 inches long. The magazine, the friction-driven spindle, chuck, hopper, etc., are of the same design as that successfully used in the stationary type of machine previously described.

The machine is built to deliver, if necessary, 3 horse-power to the spindle, thus providing ample power for the largest screw within its capacity. It may be driven either from the line-shaft, counter-shaft, or by individual motor.

NEWTON CYLINDER BORING MACHINE

A new design of cylinder boring machine, which has been adopted as a standard by its builder, the Newton Machine Tool Works, Inc., Philadelphia, Pa., is shown in the accompanying engravings. This machine, as is evident after an examination of the illustrations, is exceptionally massive. The spindle is 8 inches in diameter and its bearings, both in the driving head and outer support, are amply large to insure rigidity and a minimum of wear. The particular machine

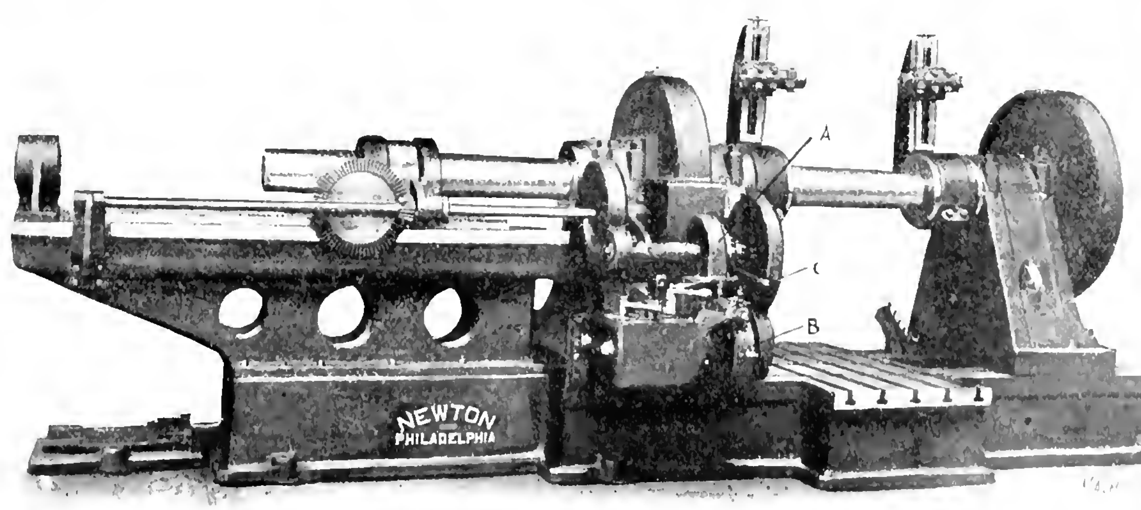


Fig. 1. Front View of the Latest Design of Newton Cylinder Boring Machine

illustrated is intended to be driven by a variable speed motor which will be belted to the single driving pulley shown at the rear of the machine in Fig. 2. From the shaft on which this pulley is mounted, the motion is transmitted by spur gears to a driving worm meshing with a large worm-wheel which is mounted on a sleeve that revolves in bearings at each end of the head. This sleeve, which is 33 inches in length, transmits the motion to the boring-bar. The driving worm is of hardened steel, while the worm-wheel is of cast iron with an outer ring of bronze. The worm is provided with roll thrust bearings, and it has a triple thread of 6-inch lead. The bearing sleeve in the outboard head for supporting the end of the bar, is of large diameter and has a length of about 20 inches. The feed motion for the bar is transmitted from the end of the driving shaft to the worm-wheel B, which is mounted on the feed box shaft. From this shaft, through the different combinations of gears, nine changes of feed are obtained. A feed yoke which may be gripped to the bar at any point, and which is driven by pinions on either side of it meshing with racks mounted upon a supporting bed, serves to transmit the motion to the bar. This bed, as will be seen, is unusually rigid. For the fast traverse of the bar the worm shaft is connected with an idler male friction gear at A. The hand-lever C operates a friction clutch, controlling the fast traverse of the spindle and also the tooth clutch that engages the feed. With this design of drive and feed it is possible to obtain great variations in the spindle speed, although the present machine is arranged for from 3 to 9 revolutions per minute of the spindle, and for feeds ranging from 0.062 inch to 0.647 inch per revolution of the spindle. The length of the feed is 72 inches, and the distance from the center of the spindle to the top of the work table is 37½ inches. The facing arms are mounted on extensions of the spindle sleeves, permitting adjustments of the spindle without interfering with the arms. If desired, these arms can remain stationary while the spindle rotates. They are furnished with swiveling tool-holders which are mounted on a slide having a reversing power feed. This machine is furnished, when desired, with a counterbalance, as shown, to equalize the weight of the facing arms and to insure a steady even motion of the spindle when boring and facing at the same time. The machine has a capacity for boring cylinders up to 40 inches in diameter, and it will bore and face cylinders up to 50 inches in length. When motor-driven, the machine requires a 15-horse-power motor which should have, preferably, a 3 to 1 speed variation.

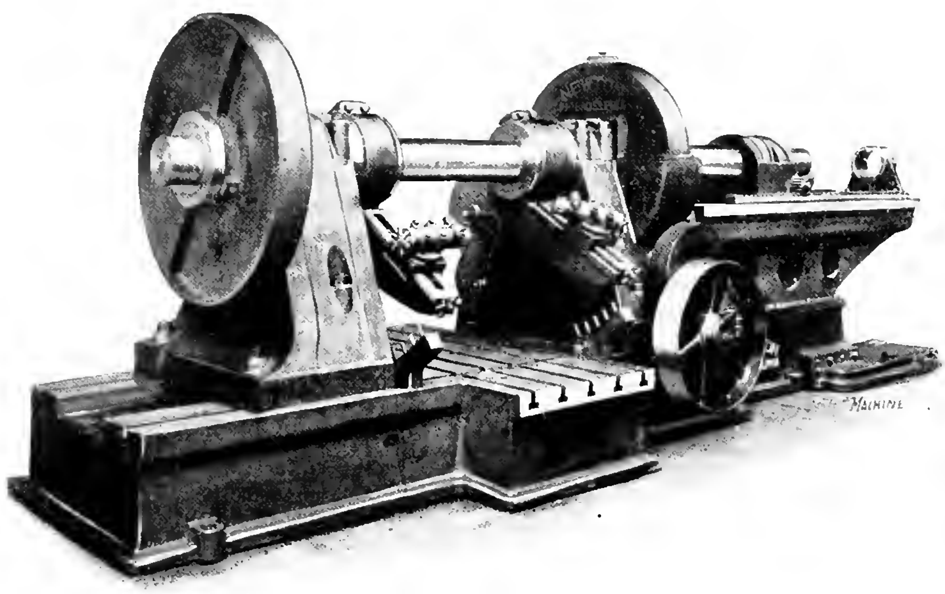

Fig. 2. Rear View of the Newton Cylinder Boring Machine

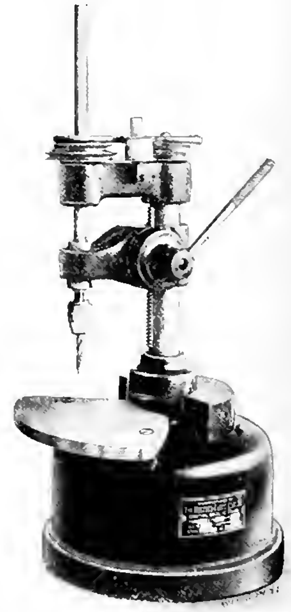
HOLTZER-CABOT UNIVERSAL DRILL

The accompanying illustration shows a small drill made by the Holtzer-Cabot Electric Co., 621 Albany St., Boston, Mass. This machine is intended for use in garages, machine and repair shops, and in manufacturing plants where light metal work is handled, as well as in all other places where there is a considerable amount of light drill press work. The arrangement of the drill is rather ingenious and novel. As shown in the illustration, the drill is mounted directly on the motor casing, the main driving shaft passing up through the inside of the column, and transmitting the power by means of a round belt on a three-step grooved pulley, a small idler being provided to furnish the required contact of the belt with the pulley, this being necessary on account of the short center distance between the two grooved pulleys. The chuck will take drills up to 13/64 inch diameter. The tool is equipped with a ¼ horse-power motor and is arranged to drill at speeds varying from 800 to 2,700 revolutions per minute. Motors are supplied for any class of electric current supply.



A Small Drill Press of Novel Design

* * *

NEW MACHINERY AND TOOLS NOTES

Combined Punch and Shear: Covington Machine Co., Covington, Va. This is a punch and shear of the type in which the two machines are set back to back, with a common driving mechanism. The novelty of the design lies in the provision of sliding gears for giving a choice of either of two different speeds, depending on the service demanded.

Handy Die Stock: Handy Mfg. Co., Bridgeport, Conn. This die-stock is intended to cut a wide range of sizes with one set of dies, and without requiring the use of special tools for adjustment. It is at the present made in four sizes—the smaller size with single and the larger with double end chasers, to give different pitches for different diameters of pipe.

Speed Indicator with Timing Attachment: Karl Weiss, 30 Woodlawn Terrace, Waterbury, Conn. This is a combination of watch movement and speed indicator, which automatically throws the worm gear out of mesh with the worm at the expiration of any desired time, up to three minutes. Its use makes the watch unnecessary when timing shafts and other rotating parts.

Hand Press: Standard Machinery Co., Providence, R. I. This machine is of the vertical slide type, with a cast iron frame mounted on a table with legs. The slide is cast in one piece and has attached to it a machine steel rack, operated by a pinion mounted on the lever shaft. It is adapted to fine work requiring more sensitive action than is obtainable with a hand-wheel or foot-treadle.

Centrifugal Hot Air Polishing and Drying Machine: Tolhurst Machine Works, Troy, N. Y. This machine is intended for cleaning small metal articles after electro-plating. It has been fonnd that when such work is rotated at high speed in a centrifugal drier and subjected to a blast of hot air for 10 minutes or so, a high polish results. While the action is somewhat obscure, it is said to give unusually good results.

Draftsmen's Square and Protractor: D. J. Kelsey, New Haven, Conn. This protractor is similar in design to the maker's celluloid protractor, but is made of sheet steel. The edges of the tool are turned down to secure stiffness and to

prevent the contact of broad bearing surfaces of metal with the paper, and the consequent rubbing of dirt into the drawing. The swinging arm is graduated in 32nds of an inch. A vernier reading to 10 minutes is provided.

Double Spindle Polishing and Buffing Lathe: Osborn Mfg. Co., Cleveland, O. This tool comprises two separate buffing and polishing spindles, mounted in a single frame, of light but very rigid construction. The shape of the front legs is such as to permit two men to work easily on the same machine without interfering with each other. The spindle drives are separate, so that the stopping of one spindle does not interfere with the other, while the advantages of the double machine in the matter of space economy are retained.

Adjustable Drill Jig: G. R. Carlson, 367 Ellicott St., Buffalo, N. Y. This tool has a work-table 5 inches square, mounted on slides having screw adjustments in both horizontal directions, read by micrometer dials graduated to thousandths of an inch. A drill bushing is supported by a vertically-adjustable overhanging arm. The work-table is provided with slots for holding parallels or stops for locating the work. The device weighs about 15 pounds, and should be useful in work made in too small quantities to make a special jig profitable.

Twenty-inch Drill: Aurora Tool Works, Aurora, Ind. This machine is an improvement over previous designs, the principal improvement consisting in increasing the strength and weight of the machine. It is built either plain or with back gears. The maximum distance between the spindle and the table at the base is 31 inches, and between the spindle and the regular drill table, 20 inches. The table has a traverse of 20 inches and the spindle a traverse of 7 inches. The machine requires one horse-power for its drive. The floor space occupied is 36 by 18 inches.

Calibrating Apparatus for High Pressure Gages: Watson-Stillman Co., 192 Fulton St., New York City. This apparatus is designed for calibrating master gages or for comparing other gages with a master gage. In the first case the pressure is applied directly by weights acting on a piston in a carefully designed and fitted cylinder. Provision is made for eliminating friction effects and for controlling the pressure within fine limits, permitting accurate work in testing. In the second case the two gages are connected with a cylinder in which the pressure is produced by a hand-operated screw action.

Turbine Dynamometer: Herschell-Spillman Co., N. Tonawanda, N. Y. This is an absorption dynamometer in which the resistance is furnished by a turbine pump construction, discharging in a closed circuit through a by-pass. The by-pass may be throttled more or less to change the load imposed by the action of the blades on the water. The introduction of a small supply of fresh water serves to regulate the temperature and keep it below the boiling point. It is particularly adapted to automobile engine testing and will be furnished with a frame to fit the same testing stand in which the engines are mounted.

Adjustable Bolt and Clamping Device: Red Wing Adjustable Bolt Co., Red Wing, Minn. This adjustable bolt is intended for various temporary uses, but particularly for securing work to the tables of machine tools. It can be quickly shifted to vary the length, and is therefore of advantage in cases where it would otherwise be necessary to have a large assortment of different lengths of bolts for clamping. The bolts are provided with ratchet-shaped stops, on any one of which a clamp may be secured. Two bolts comprise a set, and by means of these and a U-clamp, work of a great variety may be clamped down.

Bi-centric Master-keyed Padlock: Yale & Towne Mfg. Co., 9 Murray St., New York City. This is a new design of padlock of the highest quality, embodying the makers "Bi-centric" system of master-keying. Separate plugs are provided for the master key and the operating key. When thus made, the locks may be arranged in any number of sets, each set controlled by a master key and all controlled by a grand master key. No two padlocks have keys alike, and the original simplicity and security of the pin-tumbler mechanism is not impaired. The locks can also be arranged as for safe deposit system, so that the use of two keys is required to operate the lock.

Ronson Universal Wrench: Cryder & Co., Park Ave. and 63rd St., New York City. This wrench, when closed is only 6 inches in length and weighs but 8 ounces, though it provides 9 wrenches in one, ranging in size from 3/16 to 13/16 inch. It consists in general of a set of four wrenches, held together by a screw and wing nut in the center. The wrenches are slotted so that any one of the four wrenches may be projected outside of the others, when it is to be used. When one of the wrenches is pulled out for use, the others form a handle, giving considerable leverage. The screw passing through the slot in the wrenches has a square body, making it impossible for the members to turn.

Stop Mechanism for Lathe Cross-slide and Carriage Movements: Lodge & Shipley Machine Tool Co., Cincinnati, O. In the July and August, 1909, numbers of Machinery, department of New Machinery and Tools, we described two special forms of Lodge & Shipley lathes, in which an improved stop mechanism was incorporated as one of the principal features. The builders are now prepared to furnish their regular patent head lathes in the smaller sizes with this stop mechanism, giving such lathes many of the advantages of the turret machine in the matter of the duplication of diameters and shoulder lengths. With the use of these stops, a single tool may be used for turning or boring duplicate work of considerable complication.

Automatic Tapping Chuck: Pawtucket Tool Co., Inc., Pawtucket, R. I. Two styles of automatic tapping chucks, known as styles A and B Thompson chucks, have been brought out by this company. The style A chuck is intended for use in radial drills and the style B more especially for upright drills; the latter style contains its own reversing mechanism, while the other is employed on machines on which such mechanism is already incorporated. There are no projecting parts on these chucks. The advantages claimed for them are that they are simple in construction and require no tightening and loosening. Holes can be tapped clear to the bottom, and the breakage of taps is practically eliminated. The chuck stops automatically and instantaneously at the bottom of the hole.

Riveting Machine: Charles Greiner Co., New Haven, Conn. The principal feature of this machine is its high speed; the machine will strike from 1,000 to 6,000 blows per minute when the treadle is depressed. The principal working element of the machine is a spring cushion hammer which works in a gun metal cylinder and which is actuated by the engagement of a roll at its upper end, with cam-like projections on the end of a flange which revolves on a horizontal plane and is driven by a friction clutch. In combination with the great number of blows per minute the hammer spins at a high rate of speed and causes the head of the rivet to be evenly spread. The elastic blow prevents injury to fine work and allows working of rivets at different heights without altering the adjustment.

Horizontal Boring, Drilling and Milling Machine: Fosdick Machine Tool Co., Cincinnati, O. This machine, known as the style A, is a new design capable of performing all the operations of drilling, milling, tapping, boring, facing, etc., on light and heavy work, within the dimensional limits of the machine. It is of the type in which the spindle is mounted on a head, vertically adjustable on the face of a column, which is itself horizontally adjustable on the base of the machine. A particular feature of the design is the rugged construction of the slide mechanism for operating the boring bar feed. Special attention has also been given to placing the spindle-driving gears close to the work, so as to reduce to a minimum the torsional stress in the spindle. Power feed and quick-return movements are applied to the movement of the column on the base, and to the movement of the head on the column. Eight changes of positive feed are provided for these movements, as well as for the end motion of the spindle. There are sixteen spindle speeds, ranging from 4 to 216 revolutions per minute. The machine is built in two sizes. The No. 1 machine has a table 42 by 72 inches area, and the No. 2, 42 by 120 inches. An outboard support for the boring bar is provided, adjustable horizontally and vertically. The machine will also be furnished, if desired, with a constant or variable speed motor drive. All the gears are of steel and the bearings are all bronze bushed. Careful attention has been given to workmanship and design in all details throughout the machine.

* * *

VANADIUM FORGING DIES

The severity of the service imposed on riveters and forging dies, boiler punches and other tools in similar uses often makes the upkeep abnormally expensive even when the best carbon steel is used. It is in such trying situations that certain alloy steels have shown marked superiority—a superiority so great in fact as to be in some instances very noteworthy. For example, in a ship-building yard on certain severe work, pneumatic hammer riveting dies made of the best carbon steel obtainable and treated in approved manner lasted only about ten hours each. The vibrations crystallized the shanks of the dies, the result being breakage at the juncture of the shank and the die proper. When these carbon steel riveter dies were replaced by vanadium steel dies, their life was greatly extended, fourteen months' service being reported by one concern using this alloy for its pneumatic riveter dies. An article on the characteristics of vanadium steel referring to its marked superiority for severe service was published in the engineering edition of Machinery, October, 1907.

The accompanying illustration shows a pair of forging dies made of mild type H vanadium steel supplied by the American Vanadium Co., Frick Building, Pittsburg, Pa., which are worthy of attention in this connection. In this case the bes-

carbon steel dies lasted only about two days when worked to the limit of capacity. The vanadium steel dies substituted have been in service for four months, and are still in good shape. The ratio of gain in endurance is already 60 to 1, and the prospect is that it will be much greater. Type H vanadium steel analyzes: carbon, 0.75; chromium, 0.90; vanadium (contained), 0.25; sulphur and phosphorus, very low. The amount of vanadium contained is small, being only about 1/400 of the total. It is evident, as has been before remarked, that vanadium has a very subtle and marked physic effect to make so great a change in characteristics of steel when administered in such small quantities. It seems to make a great improvement by its presence alone aside from its chemical combina-

Vanadium Forging Dies

tion. Vanadium acts as a deoxidizer, and counteracts the effect of fatigue and induced crystallization, the prime cause of failure of riveter dies, forging dies, and other dies and punches subjected to severe and often repeated shocks.

It is interesting to note that recent practice in making vanadium alloys tends toward the use of even smaller quantities of vanadium, particularly in iron castings. Where the practice several years ago ran about 0.25 per cent it is now found advisable to reduce the vanadium content to 0.12 or 0.10 per cent. Sometimes even smaller percentages are used with marked increase of tensile strength and elasticity.

* * *

In the account of MACHINERY'S seventh annual outing in the November number it was stated that the Sandy Hook R. R. is the only railroad owned by the United States Government. This statement is an error. The Panama R. R. is also owned by the government; it was purchased with the Panama Canal.

* * *

PERSONALS

R. H. Victory, formerly of the Lowell Machine Shops, Lowell, Mass., is now assistant superintendent with the Eastern Bolt & Nut Co., Providence, R. I.

David Millington is now traveling in Europe introducing a new line of full and one-half automatic screw machines lately brought out by Ludwig Loewe & Co., Berlin, Germany.

Charles Flannigan has been made superintendent of the Fox Machine Co., Grand Rapids, Mich., succeeding Matthew Lund, who has been placed on the road as salesman for the company.

John W. Doyle, for fifty-two years an employe of the George W. Prentiss Wire Co., Holyoke, Mass., and for many years foreman of the fine wire department, has resigned on account of ill health.

Guy H. Gibbs, who has been with the Westinghouse Electric & Mfg. Co. for the past eight years, four of which have been with that company's Cincinnati office, is now with the Western Electric Co. at Cincinnati.

T. Commerford Martin, for many years editor of the *Electrical World*, has retired to become permanent secretary of the National Electric Light Association. Mr. Martin is writing the biography of Thomas A. Edison.

C. A. Koehler, for the past three years foreman of the wood pattern department of the Chapman Valve Mfg. Co., Springfield, Mass., has resigned to become foreman of the wood pattern work of the Stevens-Duryea Co., Chicopee Falls, Mass.

Henry L. Barton, for several years works manager of the Westinghouse Machine Co., East Pittsburg, Pa., has left that company, and with others has formed a new company known as the Metal Products Co. which will manufacture automobile parts in Detroit, Mich.

Charles E. Meech, secretary of Wilmarth & Morman Co., Grand Rapids, Mich., who has been in charge of the company's Alaska-Yukon-Pacific exposition in Seattle, Wash., is now making an extended business trip in the interests of the company along the Pacific coast.

Holden I. Crane, for the past six years connected with the operating department of the Cincinnati Milling Machine Co., Cincinnati, Ohio, and Percy S. Crane, a well-known Cincinnati business man, have formed the Crane Machine Tool Co., and have taken over the sensitive drill business of the Knecht Bros. Co.

Francis Walker has been employed sixty-four years without a break in the Fairbanks Co.'s scale factory, St. Johnsbury, Vt., and for forty-nine years has been at the head of its foundry department. Col. Walker, as he is known in his home town, was eighty-four years old October 27, and, despite his age, he is at his post every day directing the work of 160 men.

A. P. Warner, vice-president of the Warner Instrument Co., Beloit, Wis., whose purchase of a Herring-Curtiss aeroplane was mentioned in the August number, has made a few successful trials on the Morgan farm near Beloit. The first flight was made November 2, when a height of about fifty feet was attained. Mr. Warner has an improved form of aeroplane in mind, and if his plans are successful it is possible that he will manufacture aeroplanes for sale.

* * *

OBITUARIES

Frank J. Ludington, an inventor of cigarette-making machinery, died at Waterbury October 2, aged sixty-three years.

Richard Watson Gilder, editor of the *Century* and a well-known author and poet, died suddenly of heart disease in New York, November 18, aged sixty-five.

George W. Hoffman, manufacturer of the U. S. metal polish, and other specialties, died at his home in Indianapolis, Ind., October 22, after a short illness. The business will be continued by his widow.

Joseph B. Bancroft, president of the Draper Co., Oakdale, Mass., manufacturers of cotton mill machinery, died at his home in Oakdale, October 25, aged eighty-eight. He succeeded Gen. William F. Draper as head of the Draper Co., two years ago.

Tatem Parsons, the first engineer of the locomotive *John Bull*, died at Camden, N. J., November 5, aged ninety years. He was the first engineer to handle the throttle. The famous locomotive is now in the National Museum at Washington, D. C.

Lemuel Coburn, president of the Coburn Trolley Track Co., Holyoke, Mass., died at his home in Holyoke, October 26, aged seventy-nine years. Mr. Coburn was the inventor of the Coburn trolley apparatus and of many other devices, among which was a successful rag cutter for paper mills. This rag-cutting machine first brought Mr. Coburn prominently before the mechanical world.

John Moffitt, inventor of the threshing machine, died recently in Denver, aged eighty-four years. Moffitt constructed his first threshing machine on his father's farm near Canton, Ohio, in 1851, to do away with the old flail method of threshing grain. It proved to be so great an advance that it brought him international fame. The new machine was exhibited at the world's fair in London in 1851 where it attracted the attention of royalty itself. Mr. Moffitt built and sold his thresher for several years and later became interested in the rubber business in Boston. Still later he went to California and engaged in mining, and developed a cheap and expeditious method of smelting; also improved mining machinery.

Edward D. Entwhistle, who in his youth was a fireman and engineer of George Stephenson's locomotive *Rocket*, died at his home in Des Moines, Iowa, November 1, in his ninety-fifth year. He was only sixteen when employed by Stephenson as fireman of the *Rocket* on its epoch-making trial trip from Manchester to Liverpool in 1831. After a few trips Stephenson turned the care of the locomotive over to Entwhistle, who made two trips daily over the first railroad for nearly three years. Mr. Entwhistle came to the United States, and in 1856 settled in Des Moines. He was first employed in the United States as engineer on the steamer *Troy* running on the Hudson River, and later was engineer of one of the lake steamers for several years. In Des Moines he was in charge of the engines of various large mills. He had a clear memory of his trial trip with Stephenson, and the enthusiasm of the crowds who witnessed it. He lived in Des Moines for fifty-three years.

Robert M. Van Arsdale, publisher of the *American Engineer and Railroad Journal*, died suddenly of apoplexy at his home in New York, November 23, aged sixty-one years. Mr. Van Arsdale was connected with trade journalism from his twenty-fifth year when he became associated with a high tariff paper in Chicago. In 1875 he joined the staff of the *Railroad Gazette* as advertising solicitor, and remained with that journal until he purchased the *National Car Builder* and began its publication in 1880, with James Gillet editor. In 1896 Mr. Van Arsdale purchased the *American Engineer and Railroad Journal* from M. N. Forney, who remained its editor for one year, when the two papers were combined under the name of *American Engineer, Car Builder and Railroad Journal.* Two

years later the name was changed to the present title, *American Engineer and Railroad Journal*, G. M. Basford then being the editor, who was succeeded by R. V. Wright, the present editor, in 1905. Mr. Van Arsdale had a wide acquaintance among railway mechanical officials and manufacturers of railway supplies, and was a man highly esteemed by his friends and acquaintances. He is survived by his widow. The burial was in Chicago.

* * *

COMING EVENTS

December 1-3.—Annual convention of the National Society for the Promotion of Industrial Education. An exhibition of school work from all over the United States will be one of the features. J. C. Monaghan, secretary, 20 West 44th St., New York.

December 6.—New York meeting of the American Society of Refrigerating Engineers. Secretary W. H. Ross, 154 Nassau St., N. Y.

December 7-10.—Thirtieth annual meeting of the American Society of Mechanical Engineers in the Engineering Societies Building, 29 West 39th St., New York. The professional papers assigned to the meeting are as follows: Tests on a Venturi Meter for Boiler Feed, Charles M. Allen; The Pitot Tube as a Steam Meter, George F. Gebhardt; Efficiency Tests of Steam Nozzles, F. H. Sibley and T. S. Kemble; An Electric Gas Meter, C. C. Thomas; Tan Bark as a Boiler Fuel, David M. Myers; Cooling Towers for Steam and Gas Power Plants, J. R. Bibbins; Some Studies in Rolling Mill Engines, W. P. Caine; An Experience with Leaky Vertical Fire Tube Boilers and the Best Form of Longitudinal Joint for Boilers, F. W. Dean; Testing Suction Gas Producers with a Koerting Ejector, C. M. Garland and A. P. Kratz; Bituminous Gas Producer, J. R. Bibbins; The Bucyrus Locomotive Pile Driver, Walter Ferris; Line Shaft Efficiency, Mechanical and Economic, Henry Hess; Pump Valves and Valve Areas and a Report on Cast Iron Test Bars, A. F. Nagle. The social entertainment will be in charge of the members residing in and around New York, under the direction of a local committee, of which Mr. William D. Hoxie is chairman. A number of excursions are planned to points of interest, and a lecture for members and guests on agricultural machinery will be given in the evening of one of the meeting days.

December 8-10.—Annual meeting of the American Society of Chemical Engineers, Philadelphia, Pa. J. C. Olsen, secretary, Polytechnic Institute, Brooklyn, N. Y.

January 1-8.—Tenth international exhibit of automobiles and automobile appliances, Grand Central Palace, New York, under the auspices of the American Motor Car Manufacturing Association. R. E. Olds, chairman, 505 Fifth Ave., New York.

January 8-15.—Association of Licensed Automobile Manufacturers' tenth annual exhibition of automobiles and automobile appliances, Madison Square Garden, New York. M. L. Downs, secretary, 7 East 42d St., New York.

January 18-20.—Annual meeting of the American Society of Heating and Ventilating Engineers. W. M. Mackay, secretary, P. O. Box 1818, New York.

January 19-20.—Annual meeting of American Society of Civil Engineers, New York. Charles W. Hunt, secretary, 220 West 57th St., New York.

June 1-August 31, 1910.—American Exposition in Berlin, under illustrious auspices, to stimulate trade relations between Germany and America. This will be the first all-American exposition ever held in a foreign country and will be of interest to all Europe as well as America. It will be held during three of the best months of the year for an exposition, being at the full tide of the foreign travel when people will be attracted in large numbers. Max Vieweger, American Manager, 50 Church St., New York.

SOCIETIES AND COLLEGES

Teachers' College, Columbia University, New York, has planned a series of night courses by which young men who have first-rate technical ability in the wood-working and machinist's trades can prepare themselves for the profession of teaching in industrial schools. This course is being offered at night in the school in industrial arts, and covers mathematics, drafting, design, wood-working, machine shop work, industrial history and methods of teaching industrial arts. A three years' course of night work will enable an expert mechanic, otherwise qualified, to gain a diploma as teacher of industrial arts.

Technical Publicity Association, New York, held its second fall meeting Thursday evening, November 11, at the National Arts Club, 14 Gramercy Park. The subject of the evening's discussion was the merits of special issues of technical and trade papers. The argument for the affirmative was opened by James H. McGraw, president of the McGraw Publishing Co. The question was debated pro and con with enthusiasm. The vote on the question was in the negative, it being the opinion of the majority that there is no valid reason for the publication of special numbers to celebrate birthday anniversaries, etc.

Technical Publicity Association, of New York, held its first monthly meeting for 1909-10 Thursday evening, October 14, at its headquarters, 14 Gramercy Park. Mr. Charles S. Redfield, advertising manager of the Yale & Towne Mfg. Co., was toastmaster. George H. French, head of the advertising and sales department, delivered an address on the principles of advertising, of much general interest to advertisers and publicity managers. Howard M. Post, advertising manager of the Western Electric Co., told of plans for a systematic study of the direct results of trade paper advertising. The burden of Mr. French's talk was the psychology and psychological aspect of advertising copy.

British Association of Engineers, 17 Victoria St., Westminster, S.W., has instituted an employment register for the use of engineers seeking employment, the principal features of which are: No fee of any kind will be charged, the cost of the management being defrayed by the association with a view to the ultimate benefit of the profession; qualified engineers of all grades may have their names recorded, though in making the selection, preference, naturally, will be given to members of the society; only a few names of probable suitable candidates will be submitted for each vacancy, so as to facilitate the employer's choice; and effort will be made to get personal knowledge of the candidates with full details of their qualifications, etc. A. S. C. Ackerman is the secretary.

NEW BOOKS AND PAMPHLETS

Fuel Tests with Illinois Coal. By L. P. Breckenridge and Paul Diserens. 55 pages, 6 x 9 inches. Published by the Illinois Engineering Experiment Station, Urbana, Ill.

Utilization of Fuel in Locomotive Practice. Bulletin No. 402. By W. F. M. Goss. 28 pages, 6 by 9 inches. Published by the Department of Interior, U. S. Geological Survey, Washington, D. C.

Incidental Problems in Gas Producer Tests. Bulletin No. 393. By R. H. Fernald, C. D. Smith, J. K. Clement and H. A. Grine. 29 pages, 6 by 9 inches. Published by the Department of Interior, U. S. Geological Survey, Washington, D. C.

Commercial Deductions from Comparison of Gasoline and Alcohol Tests on Internal Combustion Engines.—Bulletin No. 392. By Robert M. Strong. 38 pages, 6 x 9 inches. Published by the Department of Interior, U. S. Geological Survey, Washington, D. C.

Bulletins of Revenues and Expenses of Steam Roads in the United States for April, May and June, 1909. Published by the Interstate Commerce Commission, Washington, D. C.

These bulletins give the mileage of various railway systems and tables of revenues and expenses of railroad systems operating more than 500 miles of lines.

The Slide Rule. By J. J. Clark. 62 pages, 4¾ x 6¾ inches. Published by the Technical Supply Co., Scranton, Pa. Price 60 cents.

This book on the Mannheim slide rule is a plain, simple, practical description of the instrument and its use. The principles of logarithms are explained and the methods of use of the rule in combined multiplication and division, locating the decimal point, principles of reciprocals, square and square roots, cubes and cube roots, and trigonometrical functions. The treatment of the slide rule is one that will be appreciated by many who have never been able to use it with facility or satisfaction. The description is prepared in the plain, understandable style characteristic of the work of Mr. Clark, who is manager of the textbook department of the International Text Book Co., and dean of the faculty of the International Correspondence Schools. The book is highly recommended to all in need of a practical treatise on the subject.

Handy Man's Workshop and Laboratory. By A. Russell Bond. 467 pages, 5½ x 8 inches, 370 illustrations. Published by Munn & Co., Inc., New York. Price, $2.

This book was compiled largely from contributions published in the *Scientific American*, and valuable suggestions received in response to the opening of the department devoted to the interests of the "handy man." It treats of fitting up a work shop, shop kinks, the soldering of metals, and the preparation of solders and soldering agents, the handy man in the factory, and the handy man's experimental laboratory, and the handy man's electrical laboratory, the handy man about the house, and model flying machines. It will be found of considerable interest and probable value by amateurs and other tinkers who have a penchant for making models, model apparatus and repairing machinery. The book is an appropriate present for boys of mechanical tendencies and inventive ability.

Cyrus Hall McCormick—His Life and Work. By Herbert N. Casson. 264 pages, 5¼ x 8 inches. Published by A. C. McClurg & Co., Chicago, Ill.

In this book Mr. Casson has given an account of the life and activities of McCormick, the inventor of the reaper, in the same interesting style characterizing his books, "The Romance of the Steel" and "The Romance of the Reaper." The effect of the invention of harvesting machinery on the world's industrial activity is tremendous and can scarcely be over-estimated. The reaper made the work of one man as effective in harvesting grain as that of ten laborers before its advent. The harvesting machine has greatly increased the available food supply and is one of the great contributing causes of the advancement made in civilization and material comforts during the past sixty years. The book will be read with profit by all interested in the characteristics of a man who had the genius of the inventor combined with the capability of a remarkable business man.

Mechanical World Electrical Pocket Book for 1910. 271 pages, 4 x 6 inches. Published by Emmott & Co., Ltd., 65 King St., Manchester, England. Price 6 d. net.

This electric pocket book is a companion publication to the well-known Mechanical World Pocket Diary and Year Book. The Electrical Pocket Book is confined to data on electrical matters comprising electrical units, resistance, specific resistance, mechanical and electrical unit equivalents, magnetos, electric bells and bell currents, electric transmission of power, dynamos and motors, methods of distinguishing electrical energy, alternating current systems, alternating current generators, polyphase motors, machine driving by electric motors, horse-power required to drive machinery, starting switches, motor generators, rotary converters, transformers, care and management of dynamos and motors, balancers, boosters, accumulators, conductors, cables, house wiring, circuit breakers, testing circuits, electric measuring instruments, lamps and lighting, electric welding, etc.

Prevention of Industrial Accidents. By Frank E. Law and William Newell. 194 pages, 5¼ x 7¾ inches. Published by the Fidelity and Casualty Co., New York. Price, 25 cents.

The appalling frequency of industrial accidents has aroused general interest in ways and means of accident prevention. Aside from the humanitarian aspect of the matter, the financial loss alone is so great as to demand the attention of manufacturers, business men and all concerned in the prevention of accidents from a purely selfish motive. In 1908 $22,392,072 was paid in premiums for liability insurance, which is an indication of the responsibility carried by the manufacturers and the burden imposed on industry as a whole by industrial accidents. The pamphlet discusses care on the part of employers and employees; safety devices; steam boilers; electrical apparatus; elevators; the factory; wood-working machinery, etc. It is thoroughly practical and will be found of general value by manufacturers and by employees in charge of apparatus likely to cause injury or death by accident.

The Steam Engine. By Charles H. Benjamin. 316 pages, 6 x 9 inches, 198 illustrations and diagrams. Published by the Technical Press, Brattleboro, Vt. Price, $3.

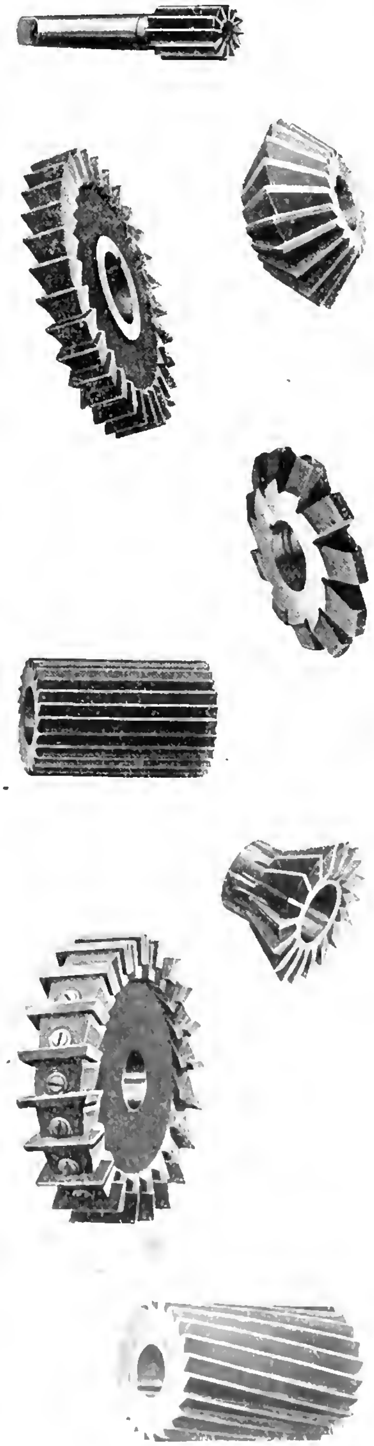
This treatise was prepared with the intention of covering practically the whole list of subjects relating to the steam engine, and is designed primarily for a text-book rather than a work of reference for engineers, although it will serve admirably for the latter purpose. The author explains the elementary principles of engines so that they may be readily understood by students. It pays much attention to practical problems, and questions in economy in operation are referred to the results of recent experiments made under working conditions. The contents of the work by chapters are as follows: Definition of terms, elementary principles, the simple steam engine, thermodynamics of air, thermodynamics of steam, valve and link motion, indicators and indicator diagrams, compound engines, conveyors, fly-wheels, steam in the cylinder, condensers, and heaters, piping and flow of steam, steam engine performance, steam engine design, specifications and costs. It closes with standard tables of weights of water, ammonia table and hyperbolic logarithms. The typographical excellence of the book is notable, the text, illustrations and press work being unexcelled.

Industrial Training; Twenty-Sixth Annual Report of the Bureau of Labor Statistics. 394 pages, 5½ x 8¾ inches. Published by the State Department of Labor, Albany, N. Y.

The report reviews the general conditions as to advancement in the manufacturing industries of New York State; the supply of skilled workers; the training of workers in industrial establishments; apprenticeship systems; attitude of employers and organized labor toward general industrial or preparatory schools; and attitude of organized labor toward trade schools. The summary of investigations is that the need of skilled male labor in the industries of the state is most severe in the manufacture of blown glass, many of the machinery and metal trades, manufacture of boots and shoes, and in certain of the building trades. It was found that the apprenticeship system in such industries as machine and building trades can be made more effective by introducing definite provision for systematic instruction. The need and value of general industrial and preparatory trade schools for boys and girls between fourteen and sixteen years is strongly testified by the report-

Providence, R. I., U. S. A.

B&S CUTTERS



Cutter Quality

is a manufacturer's

Essential Requirement

inasmuch as it influences cutter costs. Furthermore, it is a particularly prominent characteristic of

B. & S. Milling Cutters

and

Gear Cutters

Each cutter is carefully inspected at every stage of its manufacture and the successive lots are of a uniform hardness.

36 Varieties.

7300 Sizes.

A cutter list will be sent free to any address upon request.

of employers in all industries and is agreed to by the labor unions. Practical trade schools seem to be most in need in the machine and buildings trades. An extension of evening schools giving both practical and technical instruction in the trades is demanded by employers in a large proportion of the industries.

HAND BOOK FOR MECHANICS. By Franklin E. Smith. 328 pages, 5 x 7½ inches. Published by D. Van Nostrand Co., New York. Price $1.50 net.

This book is intended for the general instruction of mechanics, particularly those who are weak in arithmetic. It treats of notation, addition, subtraction, multiplication, division, weights and measures, reduction of fractions, addition of fractions, arithmetical signs, subtraction of fractions, multiplication of fractions, division of fractions, decimal fractions, reduction of decimal fractions, addition of decimals, subtraction of decimals, multiplication of decimals, division of decimals, proportion, compound proportion, interest, involution and evolution, cube root. Part II treats of arithmetical signs and characters, and explains the solving of formulas. Part III is on mensuration and gives rules for finding the circumference, diameter and area of circles, area of ellipses, triangles, rhomboids, trapeziums, volume of solids including the sphere, cylinder, pyramid, cone and frustum. Part IV treats of weights, specific gravity, dimensions, measurements and weights of vessels, calculation of contents of tanks, cisterns, etc. Parts V and VI treat of the elements of simple machines, including the lever, pulley, wheel and axle, inclined plane, wedge and screw, and strength of materials. The work is one that can be recommended for the instruction of apprentices, mechanics and others who have not had the advantages of a good common school education, and it will also be found useful by those who desire to renew their knowledge of the things learned in youth and partly forgotten through disuse.

MECHANICAL DRAWING FOR TRADE SCHOOLS. By Charles C. Leeds. 122 pages, 8 x 11 inches. Published by D. Van Nostrand Co., New York. Price, $2 net.

The author, who is assistant to the head of the school for apprentices and journeymen Carnegie Technical Schools, has presented a work on mechanical drawing that is a refreshing contrast to many of the books on the subject that have been published. It has been prepared with the idea of making students in mechanical drawing think and work without merely copying models. It is the outgrowth of his work in the Carnegie Technical Schools where the importance of developing the faculty of imagination and mental picturing an object was forcibly impressed on him. It is a faculty that many students lack, and the need for developing it became very apparent. The book in the beginning treats of the tools and elementary processes used in drawing, comprising pencils, pencil points, drawing board, T-square, triangles, drawing lines, laying off dimensions, use of compass and dividers, drawing circles and arcs tangent to lines, lettering, sketching, inking, etc. The plan of the work is that of displaying the drawing to be made on the right-hand page, giving the instructions for making the drawing on the left-hand page. A large number of practical examples are given, comprising the following: Flanged pin, machine bolt, clamp, sleeve, problems in projection, flanged pulley, 8-inch hand-wheel, lathe face-plate, positive clutch coupling, compression shaft coupling, safety flange coupling, geometrical problems, ellipses, spur gear, conic sections, intersections and developments, bevel gear, 12-inch speed lathe details, comprising the legs, bed, tool-rest, tail-stock and head-stock, examples of tabular data, bench grinding details comprising the frame, commutator bar, commutator ring, armature spider, generator frame, worm gearing, plate cam, periphery cam, conventional signs used in structural work, standard framing, beam connection, etc. The book is one that we can recommend to those who would learn mechanical drawing at home, and to the instructors in trade schools and other institutions requiring a good practical work on the subject.

ELEMENTS OF MACHINE DESIGN—PART I. By W. Cawthorne Unwin. 531 pages, 5½ by 8½ inches. 387 illustrations and diagrams. Published by Longmans, Green & Co., London and New York. Price $2.50.

This well-known textbook on machine design was first published in 1877, and it since has been revised three times. In the revision of 1890 the chapters relating to steam engine details were published separately as Part II. Part I deals with general principles, strength of materials, rivets, bolts and other fastenings; journals and shafting; couplings; pedestals; transmission of power by gearing, belting, ropes and chains. In the present revision the work has been almost entirely rewritten, and the page size has been changed from 4½ by 6¾ to 5½ by 8½ inches. In the foreword the author writes of the great task of originally writing the book, and of the still greater task of keeping it abreast of the times, as follows: "If originally the author had fully realized the multiplicity and complexity of the problems which arise in designing machinery, the present treatise would probably not have been written. If he had now for the first time the task of writing it, he would no doubt take the view that for an adequate scientific treatment of the subject a much larger treatise would be necessary. . . . 'There are now so many aids to the study of the application of scientific principles to all branches of engineering practice and so much of engineering experience has been made accessible, that the difficulty of dealing with the subject at the time this book was written will hardly be recognized now. . . . This treatise was intended to occupy a distinct field between works on applied science and empirical books of rules and collections of examples of machine details." The practical nature of Unwin's work has been generally recognized, and the machine designer using it will find that the present edition upholds the plan of the former editions and extends and improves it. One new chapter on keys and cotters has been added besides the general additions and changes in all other chapters. The index his been somewhat extended, but much room is yet left for improvement.

CATALOGUES AND CIRCULARS

GISHOLT MACHINE CO., Madison, Wis. Leaflet illustrating and listing standard boring and facing tools for Gisholt lathes.

WASHBURN & GRANGER, 120 Liberty St., New York. Catalogue B of Dean dumping, shaking, and stationary boiler grates.

CUTLER-HAMMER MFG. CO., Milwaukee, Wis. Copy of revised navy specifications covering electric motors and controlling devices.

HYDRO MFG. CO., Pittsburg, Pa. Circular of "Hydro" recording and velocity gage for measuring the rate of flow of gases in pipe lines or ducts.

SCHUTTE & KOERTING CO., Philadelphia, Pa. Circulars of Koerting deep-well water jet pump and water jet eductors for mines, tunnels, etc.

E. C. ATKINS & CO., INC., Indianapolis, Ind. Circular illustrating and describing Atkins AAA car mover, being an improved form of pinch-bar.

COLLINS WIRELESS TELEPHONE CO., 54-56 Clinton St., Newark, N. J. Catalogue of wireless telephone sets for experimental, lecture, office and field purposes.

PEERLESS ELECTRIC CO., Warren, O. Booklet illustrating the use of Peerless motors on paper box machinery, blowers, pumps, envelope mailing machines, etc.

FOSDICK MACHINE TOOL CO., Cincinnati, Ohio. Circulars of Nos. 1 and 2 Fosdick horizontal boring, drilling and milling machines of the elevating head type.

WALTON CO., Hartford, Conn. Circular of Walton extractor of broken taps. This extractor is made in 16 sizes, suitable for taps ¼ to 1¼-inch diameter.

PIKE MFG. CO., Pike, N. H. Mailing card advertising Pike's "Little Four" sharpening set, reversible oil stone, "Koenig" razor hone and "Pykarvo" knife sharpeners.

EMERSON ELECTRIC & MFG. CO., St. Louis, Mo. Bulletin No. 3309 replacing bulletin No. 3307 of electric forge blowers, direct connected for direct and alternating currents.

CRESCENT LAMP CO., 516-518 West Monroe St., Chicago, Ill. Circular of incandescent lamp guards, including the "Loxon," which is a guard that prevents theft as well as breakage.

NORTH BROS. MFG. CO., American St. and Lehigh Ave., Philadelphia, Pa. Circular illustrating and describing the "Yankee" breast drill with right- and left-hand ratchet movement.

AMERICAN BLOWER CO., Detroit, Mich. Sectional catalogue No. 250 of A B C blowers for cupolas, forges, melting and heating furnaces, forced draft, pneumatic tube systems, etc.

S. E. HORTON MACHINE CO., Windsor Locks, Conn. Price list of four-jaw independent reversible jaw chucks, made in seven sizes, covering the usual ratings of 8-inch to 26-inch sizes inclusive.

HARRISON SAFETY BOILER WORKS, Philadelphia, Pa. Treatise on Cochrane feed water heaters and the profitable utilization of exhaust steam in condensing and non-condensing steam power plants.

F. W. DEVOE & C. T. RAYNOLDS CO., New York and Chicago. Catalogue of artists' and drawing materials, comprising colors, India inks, pencils, rubbers, pantographs, drawing instruments, T-squares, protractors, etc.

CELFOR TOOL CO., Buchanan, Mich. and 207 Railway Exchange, Chicago, Ill. Catalogue No. 10 of Celfor tools, reamers and three-lip drills, Rich flat drills, Celfor-Rich and quick-change chucks, reamer sockets, and grinding machinery.

SCHUMACHER & BOYE, Cincinnati, Ohio. Mailing folder illustrating S. & B. instantaneous change gear engine lathes, built in 18-inch, 20-inch, 24-inch, 26-inch, 30-inch, 36-inch, and 48-inch sizes. Details of construction, including double-plate apron and head-stock, are also shown.

CAMERON ENGINEERING CO., 154-156 Berriman St., Brooklyn, N. Y. Circular on overhead tramways, trolleys, switches, cranes, and scales for overhead handling and weighing; a pulley block crane mounted on four truck wheels, made in five sizes, and having a capacity from ½ to 3 tons.

STROMBERG ELECTRIC MFG. CO., 108-128 North Jefferson St., Chicago, Ill. Descriptive circular of new wall type electric chronograph for registering the time of entrance and exit of employees, the time of starting and completion of jobs and other purposes where a time registering device is essential.

UNION STEAM PUMP CO., Battle Creek, Mich. Catalogue B of Union air compressors, comprising a complete line of various types and sizes in ordinary use for operating pneumatic tools, coal cutters, pumps, sand blast work, and for other purposes, in foundries, machine shops and manufacturing plants.

HARRISON SAFETY BOILER WORKS, Philadelphia, Pa. Pamphlet describing Cochrane steam stacks and cut-out valve heater and receiver, and its application in connection with commercial systems of exhaust steam heating. The diagrams illustrating the installations of service are printed in colors.

CARBORUNDUM CO., Niagara Falls, N. Y. Vol. VII of the "Revised American Statesman Series" on Benjamin Franklin, by F. W. Haskell, president of the Carborundum Co. The biography treats of the activities of B. Franklin in a brief but startling way, and we have no doubt that all readers of MACHINERY fortunate enough to receive one of these unique booklets will be much edified by the story.

GEORGE WESTINGHOUSE, Pittsburg, Pa. Pamphlet describing the Melville-Macalpine speed reducing gear for marine turbines; the 6,000 horse-power hydraulic absorption dynamometer used for testing the reducing gear at the works of the Westinghouse Machine Co., East Pittsburg, Pa., and report of tests of the reducing gear; also report of efficiency of high-speed steam turbines.

CLEVELAND PUNCH & SHEAR WORKS CO., Cleveland, O. Catalogue and stock list No. 3 of machines and small tools for the fabrication of iron and steel, comprising standard punches, coupling nuts, button-head rivet snaps (chrome-nickel alloy steel), twist drills, chisels, backing out punches, shear blades, punching machines, shears, I-beam punch, angle shears, bending rolls, rotary planers, wall radial drills, etc.

WESTINGHOUSE ELECTRIC & MFG. CO., Pittsburg, Pa. Circular No. 1181 of portable direct current ammeters and voltmeters. The characteristics of these instruments are accuracy and durability, though they are neither bulky nor heavy. They are operated on the D'Arsonval principle with a permanent magnet and moving coil. The magnetic structure is so arranged that the moving element can easily be taken out for repairs.

MAX VIEWEGER, 50 Church St., New York. Prospectus of the American Exposition to be held in Berlin, June, July and August, 1910, with diagram of floor space in exposition buildings Nos. 1 and 2. The prospectus gives the name of the American and German committees, which include such distinguished citizens as J. Pierpont Morgan, David R. Francis, John Wanamaker, Dr. George F. Kunz, Emil L. Boas, Dr. Nicholas Murray Butler, William G. McAdoo, C. A. Moore, etc.

NATIONAL-ACME MFG. CO., Cleveland, O. Circular illustrating the Acme automatic screw machine and samples of its work, also some interesting statistics. The company has a product department wherein 10,000,000 pounds of iron, steel and brass stock are annually cut into 100,000,000 parts. 3,000,000 screws and parts are carried in the New York store, 77 White St., 3,000,000 parts in the Chicago store, 56 West Washington St., and 15,000,000 in the Cleveland factory.

ARMSTRONG BROS. TOOL CO., 113 North Francisco Ave., Chicago, Ill. Catalogue and price list of Armstrong tool-holders, for turning, reaming, boring, slotting, drilling, cutting-off metals; and other machine shop specialties comprising lathe tool sets and cabinets, grinding holders, Armstrong cutting-off and grinding machines, drill and reamer holders, lathe tool-post, lathe dog, bolt driver, quick-action drill vise, planer jack, universal ratchet drill, automatic drill drift, C-clamps, etc.

NATIONAL TUBE CO., Frick Building, Pittsburg, Pa. Catalogue H-1909 of material manufactured by the Kewanee Works of the company, embracing wrought pipe for steam, gas, water and air, cast and malleable iron and brass fittings, brass and iron body valves and cocks, drive well points and well supplies. The catalogue is attractively arranged and well printed; some of the illustrations are partly in color to distinguish brass from iron. It should be in the files of all concerns using pipes, valves, cocks, flanges, and other supplies mentioned.

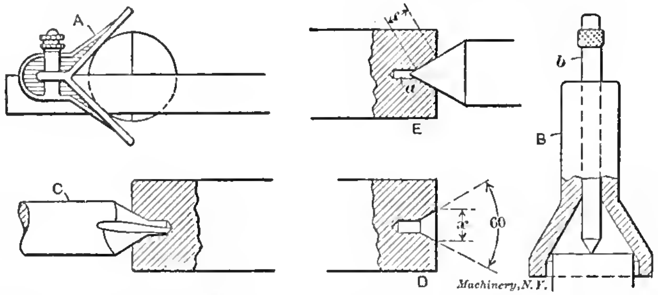
BUCKEYE ENGINE CO., Salem, Ohio. Catalogue of Buckeye electric blue-printing machines with testimonials of many users. The catalogue is unique in that the upper and lower edges of each page imitate the characteristics of blue-prints, being in blue with white lines. The Buckeye Engine Co. was one of the first American concerns to use blue-prints and it has consistently promoted their use for many years.

Supplement to MACHINERY, January, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Centering"

SHOP OPERATION SHEET NO. 121

Franklin D. Jones — MACHINERY, January, 1910



Making a Lathe Arbor—Centering

1. Select a piece of tool steel of a good grade, and cut off, in a hack-saw, a length suitable for the arbor to be made. This length will depend upon the diameter of the arbor, and it is equal to 9 times the diameter for sizes from ½ inch to 1 inch; 8 times, for sizes from 1 inch to 1½ inch, and 7 times for diameters between 1½ and 2 inches.

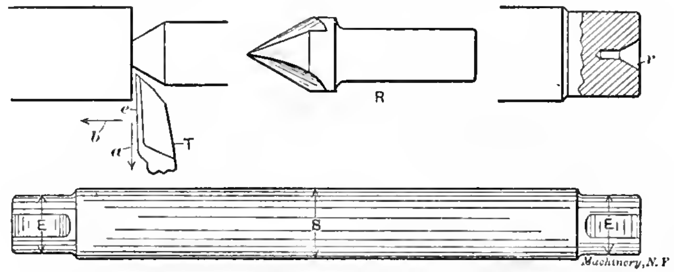
2. With a center square *A* draw two lines at right angles to each other across each end of the stock as shown, and at the intersection of these lines make a center-punch mark. If a cup or bell center-punch *B* is available, the center may be located without first drawing the lines by placing the conical part over the end of the work as shown and striking the end of punch *b*. If accurate results are expected, this punch should only be used on work which is round and square on the end. Furthermore, it should always be held in alignment with the piece being centered.

3. A combination center drill and reamer *C* is next caught in a drill chuck inserted in the spindle, or in a regular chuck of small size, and set perfectly true. A center is then drilled and reamed into one end of the work, while the other is supported by the dead center, which should be inserted in the previously made punch mark and be set in the position for straight turning. The piece may be kept from revolving while it is being reamed by attaching a dog to it close to the tail-stock end, and then adjusting the cross-slide until the dog is in contact with it. A little lard oil or other lubricant should be used when reaming. The included angle of the taper of the center, is 60 degrees (as at *D*) this being the angle to which lathe centers are ground. The size of the largest part *x* of the center, should be made equal to one-half the diameter of the arbor for sizes up to 1 inch. For larger sizes up to 5 inches in diameter dimension *x* should be made equal to (diameter — 1) ÷ 8 + 0.5. A section through a correctly formed center as it appears when in contact with a lathe center, is shown at *E*. The small hole *a*, besides being a reservoir for lubricant, provides clearance for the point of the lathe center, which should not come in contact with the mandrel, so that the latter may have a good bearing throughout the conical part *c*.

NOTE.—When a regular centering machine is available, it is not necessary to locate a center in the end of the work, as the latter is properly located with reference to the drill by the universal chuck with which the centering machine is provided.

SHOP OPERATION SHEET NO. 122

Franklin D. Jones — MACHINERY, January, 1910



Making a Lathe Arbor—Turning

1. After the stock has been accurately centered, it should be carefully placed between the lathe centers. At times work is spoiled because the driving dog bears on the bottom of the driving slot in the face-plate with the result that the live center is in contact with only one side of the center in the work. Then again, chips or dirt in the centers, or the lack of oil, often results in inaccuracies which well-fitting lathe and work centers were intended to overcome.

2. The first operation performed on a cylindrical part which is being turned between the centers, is to square the ends; that is, face them so that they are flat and at right angles to the work. This is done with what is known as a right-side tool, the cutting end of which is shown at *T*. The stock should have been cut off to nearly the correct length, so that it will not be necessary to remove much metal from the ends. Usually the tool is not set so that the straight cutting edge *e* is at right angles with the axis of the work, but at a slight angle as shown. The point is then brought into contact with the work close to the center, after which the tool is fed out in the direction of the arrow *a* by the cross slide. A smooth finishing cut may be obtained by slightly rounding the tool point.

NOTE.—If the end of the work does not need to be exactly flat, the tool may be set approximately at right angles with the work axis, and then be fed in the direction of the arrow *b*, thus removing a chip equal to the width of one side. Obviously, this method is confined to comparatively small diameters.

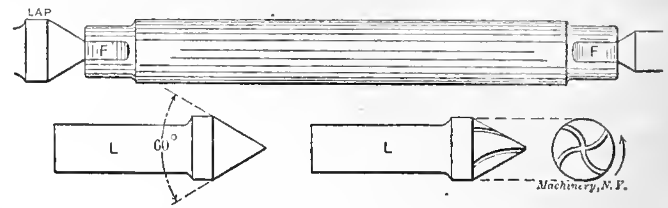
3. The arbor is first rough turned, after which it should be annealed to relieve it of any internal strains which may have been set up. The ends *E* are then finished and polished, and the body *B* is turned to size with a suitable allowance for grinding. This allowance will depend on the size and style of arbor, some being distorted in hardening more than others. An allowance of from 0.012 to 0.015 inch should be sufficient.

4. The centers are next rounded at *r* by holding one end of the arbor in a true-running chuck, while the other is supported by a steady-rest, and using a hand graver. If the corner *r* is left sharp it is easily bruised.

5. Grip a 60-degree center reamer *R* in the chuck and set it perfectly true. Then, with the spindle locked and the arbor mounted between the reamer and dead center, ream each center by hand, turning the work slowly.

SHOP OPERATION SHEET NO. 123

Franklin D. Jones — MACHINERY, January, 1910



Making a Lathe Arbor—Finishing

1. The flats *F* on the ends, against which the set-screw of the driving dog is to bear, are next milled. The arbor is then ready to be hardened. This is done so that the accuracy of the centers is not easily impaired, and to give a hard surface to the arbor and make it more rigid.

2. When a piece of steel is hardened, it is usually distorted or sprung out of shape more or less; for this reason the centers in each end of the hardened arbor should be lapped true so that their axes exactly coincide. A lap *L* made of brass or copper will give excellent results. The conical ends should be finished to the same taper as the lathe center, or to an included angle of 60 degrees. All scale and dirt should be removed from the centers before lapping is begun.

3. Grip the lap in the chuck of a speed lathe (preferably) and set it perfectly true. If the tail spindle is not provided with a lever feed, remove the spindle cap so that the spindle may be easily moved back and forth. Place a little medium grade emery and oil in one center hole and with the other resting against the tail-center push the work gently against the lap which should be revolving at a high speed. Almost as soon as the lap and work are in contact, they should be separated, the work turned part way around, and again moved against the lap. After this operation is repeated a number of times, the work should be turned end for end. In this way the two centers are finally ground true and in alignment with each other. A new and perfectly true lap should be used for finishing the centers and a fine grade of emery used. As the abrasive toward the mouth of the center moves more rapidly than that farther in, and as centrifugal force tends to move it to the largest part of the hole, the lap will cut faster at this point. Because of this tendency, centers which are to be hardened and lapped are sometimes reamed to an angle (say 59 or 59½ degrees) of somewhat less than 60 degrees. Spiral grooves are sometimes cut into conical laps, which serve to carry the abrasive and oil back toward the point. In order that these grooves may be effective, they should curve toward the direction of rotation, as shown in the end view.

4. The arbor is next ground to the required size. A description of this operation will be found on sheet No. 96. After rough grinding, it is good practice to allow the work to "season" before taking the final cut.

NOTE.—The steel used for making arbors should not have too high a carbon content, as such steel is more liable to crack or spring out of shape when it is being hardened. A steel for arbors of medium size, having one per cent of carbon, will give good results.

The fraction giving the altitude of the rectangle is found at top of the columns, the base in the left-hand column, and the area in the body of the table.

The areas of intermediate rectangles varying by $\frac{1}{64}$ can be found by interpolation as the following examples show:

One side given in 64 ths.
$$\frac{3}{32}\times\frac{5}{64} = (\text{next smaller area} + \text{next larger area}) \div 2$$
$$\text{next smaller area} = \frac{3}{32}\times\frac{1}{16} = 0.005859$$
$$+\ \text{next larger area} = \frac{3}{32}\times\frac{3}{32} = \underline{0.008789}$$

THE DESIGN OF AUTOMOBILE SPRINGS*

EGBERT R. MORRISON†

Egbert R. Morrison‡

It is doubtful if scientific calculations ever entered into the design of the original forms of such springs as are used under ordinary road carriages. Satisfactory as they are, they are not engineering results, but accepted standards born long ago of the cut-and-try methods of the blacksmith shop. Their manufacture belongs to such arts as are taught by father to son, or acquired through years of experience, during which have been gathered the "tricks of the trade." The manufacturer of this class of springs does not attempt to arrive at results by mathematics. He has learned as a part of his trade that certain styles of carriages should have certain springs.

Sufficient time did not exist during the development of railroad cars for a gradual development of definite types of springs for various types of cars. It devolved, therefore, upon the engineer to design these springs; but as soon as the spring maker found that the 70,000, 80,000, and 100,000-pound capacity car each had its own peculiar set of springs, and that any car could be fitted with springs according to its capacity, he adopted the engineer's designs as another class of standards. Railroad cars, while resting on springs whose dimensions were originally scientifically estimated, are now, therefore, suspended largely upon springs belonging to a few fixed classes.

With the advent of the automobile, came a carriage traveling fast over uneven country roads, meeting severe usage in inexperienced hands, and demanding the extreme of comfort and safety. The question of springs and spring suspension thus becomes of primary importance, so that in these carriages each particular design requires a specially designed suspension. Automobile springs are fundamentally cantilevers, the same as all leaf springs. This class of springs more readily lends itself to an easy vibration, as well as to a better general design of the machine. It is possible to carry a load on a narrow-leafed elliptic leaf spring where there would not be room for a helical spring. Also, the addition of a leaf to an elliptic leaf spring adds to its capacity without changing its deflection, while the addition of a coil to a helical spring does not change its capacity but adds to its deflection.

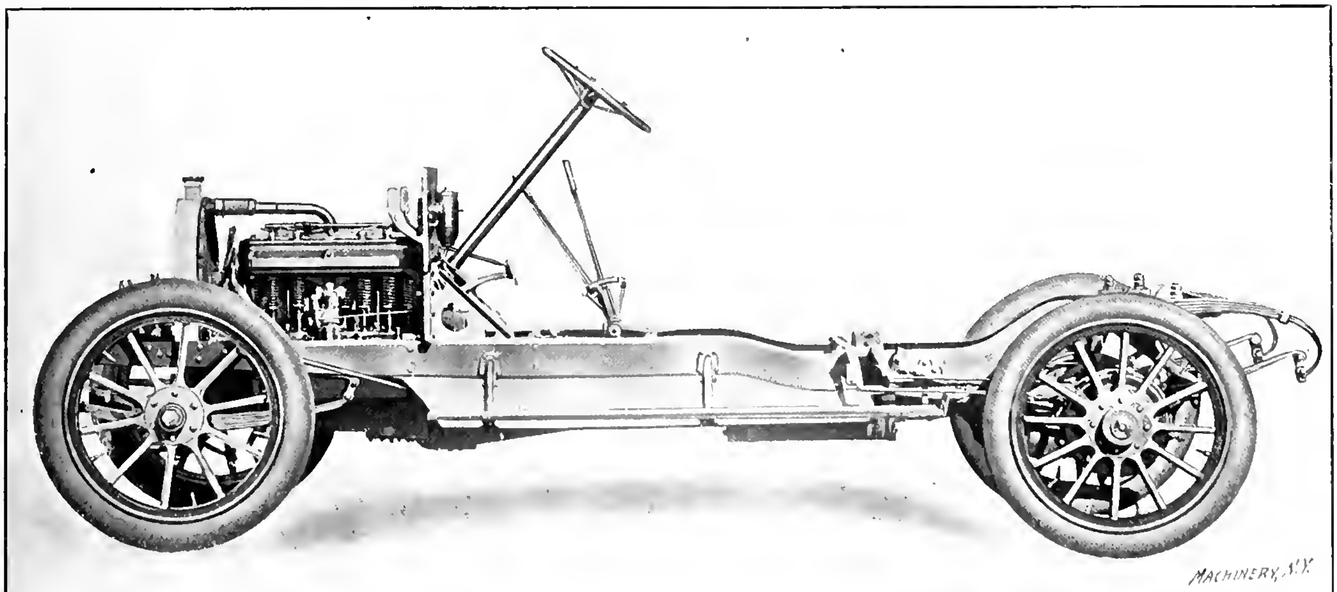

Fig. 1. Chassis of an F. B. Stearns Motor Car, showing Three-quarter Elliptic Spring Suspension in Rear and Semi-elliptic Springs in Front

Any leaf spring, tightly banded around the middle, should be considered as composed of two cantilevers of length l, where l is one-half the distance from center to center of the end bearings less one-half the width of the band. The length of each cantilever is then expressed (see Fig. 2):

$$l = \frac{c - w}{2}$$

To consider a spring a simple beam of length c, is to overlook the effect of the band. It is easily demonstrated that variations in the width of the band cause corresponding variations in the strength and deflection of the spring. The elliptic spring, graduated throughout, with but *one* leaf in each section extending from end bearing to end bearing, is fundamentally a cantilever of *uniform strength;* and the formulas applicable are based on the fundamental formulas of that type of cantilever. An elliptic spring with *all* leaves in each section extending from end bearing to end bearing is, on the other hand, a cantilever *of uniform section*, and the formulas for this type of cantilever are then applicable.

* The following information relating to various classes of springs and kindred subjects has previously been published in MACHINERY: What a Machine Designer should Know about Springs, May, 1898, July, 1898, August, 1898; Rig for Winding Springs, January, 1901; A Device for Winding Springs, May, 1902; A Device for Winding Small Springs, July, 1902; Hardening Coil Springs, July, 1902; Winding Small Springs, October, 1902; Experience in Making Small Coil Springs, June, 1904; To Increase the Working Length of Coil Springs, August, 1906, November, 1906; Securing Uniformity in Phosphor-Bronze Springs, September, 1907, engineering edition; Tools for Winding Springs in an Engine Lathe, December, 1907; The Design of Springs for Gas Engine Valves, May, 1908, engineering edition; Helical Springs, January, 1909, engineering edition; Winding Springs with Initial Tension, February, 1909; Winding Springs, April, 1909. † Address: Sharon, Penn.

‡ Egbert R. Morrison was born in Sharon, Pa., in 1881. He was educated in Westminster College, New Wilmington, Pa., and the Case School of Applied Science, Cleveland, Ohio. He has worked for the Standard Engineering Co., Ellwood City, Pa., Union Spring & Manufacturing Co., New Kensington, Pa., and Sharon Boiler Works, Sharon, Pa., in the capacity of draftsman, estimating engineer, and assistant general manager. He is the author of Morrison's Spring Tables, and a member of the firm of Morrison & Martin, patent engineers.

The springs used in automobile practice are frequently combinations of these two forms, inasmuch as a considerable portion of the leaves extend the full length from bearing to bearing. It follows that neither of the above formulas will apply, but that the applicable formulas may be derived by combining the fundamental formulas for the two types of cantilevers. The load capacity of a cantilever is not affected by its form, for in either case:

$$P = \frac{S\,b\,h^2}{6\,l}$$

in which P = load,
S = allowable stress,
b = width of beam,
h = thickness of beam,
l = length of cantilever.

In other words, the load capacity is equal for like conditions, such as stress, size of beam, and length of span.

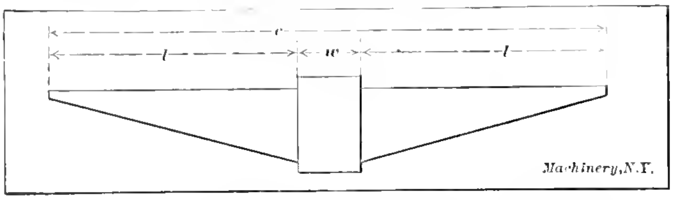

Fig. 2. Diagrammatical Sketch of Graduated Spring, giving Length Notation used in Formulas

A great difference exists, however, in the deflections under the same load, one being fifty per cent more than the other:

$$f = \frac{4\,P\,l^3}{E\,b\,h^3},\ \text{for uniform section cantilevers,}$$

$$f = \frac{6\,P\,l^3}{E\,b\,h^3},\ \text{for uniform strength cantilevers,*}$$

in which f = deflection, and E = modulus of elasticity.

When such a difference as this exists, it is rather remarkable that many engineers calculate the properties of an elliptic spring no matter what the cantilever conditions, as though all elliptic springs were subject to the same rules and formulas; but, as a matter of fact, the proportion of back leaves, or the leaves on the longer side of the spring which commonly extends the full length, ranges from 5 to 50 per cent of the total number of leaves. It is not unusual to see attempts made through actual tests of the springs themselves to find the proper constant with which to modify the uniform strength equations so as to render them applicable to springs composed of uniform section cantilevers in combination with uniform strength cantilevers. The desired modifier, however, is a variable quantity, depending upon the relative size of the fundamental spring elements.

Lack of due consideration of this combination of different cantilevers accounts also for the different and conflicting formulas which various authorities advance. Thus Goodman, in "Mechanics Applied to Engineering"; Reuleaux, in his "Constructeur"; and "Des Ingenieurs Taschenbuch" (Hütte), give formulas all of which reduce to uniform strength cantilevers. Molesworth and the Automotor Pocket Book base their formulas on uniform section cantilevers. Henderson, who assumed all semi-elliptic springs to contain one-fourth full length leaves, and made an approximation of the result, was the first to recognize the influence of the combination of cantilevers.

Deduction of General Formulas

For further consideration we will adopt the following notation, discussing only the semi-elliptic spring:

P = total load on spring,
P_1 = portion of load on one end of spring,
P' = portion of load on one end of full-length leaves, or on uniform section cantilever,
P'' = portion of load on one end of graduated leaves, or on uniform strength cantilever,
n = total number of leaves,
n' = number of full-length leaves,
n'' = number of graduated leaves,
$r = \frac{n'}{n}$,
S = maximum fiber stress in spring,
S' = maximum fiber stress in full-length leaves,
S'' = maximum fiber stress in graduated leaves,
f = total deflection of banded leaves,
f' = total deflection of full-length leaves if unbanded,
f'' = total deflection of graduated leaves if unbanded,
b = width of leaves,
h = thickness of leaves,
l = length of cantilever,
L = net length of spring, i. e., actual distance between end bearings, less width of band,
x = proper initial space between fundamental cantilevers before banding.

It is but reasonable to assume that the maximum fiber strain should be the same in both fundamental parts, or

$$S' = S''.$$

But

$$S' = \frac{6\,P'\,l}{n'\,b\,h^2},$$

$$S'' = \frac{6\,P''\,l}{n''\,b\,h^2}.$$

Hence

$$\frac{P'}{P''} = \frac{n'}{n''}.$$

In a well-designed spring there should be, at full load, a division of the work proportional to the respective number of leaves in the two fundamental parts. The fundamental formulas of the two cantilevers have shown, however, that such proportional loads would produce different deflections in their respective carriers. This difference in deflection would cause a separation of the two portions of the spring were they initially together and unbanded. Were they initially together and banded the result would be internal stress under load which would mean that a division of the load proportional to the respective number of leaves in the two fundamental parts could not exist.

It is evident that by placing a space between the two fundamental parts when unloaded and unbanded, equal to the difference between the two deflections, there will result no space between the two fundamental parts at full load; and hence if banded in this position there will be no internal stress, so that the load on each part will be proportional to the number of leaves in that part. If then the load be removed, it follows that the band alone holds the two portions together and that there must exist a resulting stress upon the band and leaves.

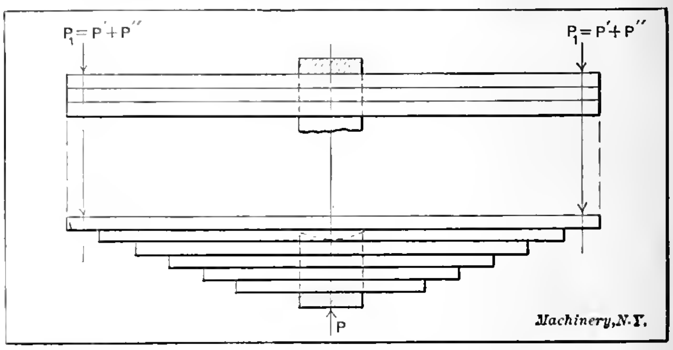

Fig. 3. Showing Division of Spring into Cantilevers of Uniform Section (Upper Portion) and Cantilevers of Uniform Strength (Lower Portion). One of the Full Length Leaves should always be considered as a Part of the Graduated Leaves

Now

$$f' = \frac{4\,P'\,l^3}{E\,n'\,b\,h^3} \tag{1}$$

and

$$f'' = \frac{6\,P''\,l^3}{E\,n''\,b\,h^3} \tag{2}$$

But, as shown,

$$\frac{P'}{P''} = \frac{n'}{n''},$$

* The formula given is that for a cantilever of uniform strength where the height h is uniform, but the width of the section of the cantilever decreases towards the outer end; b is the width at the support.—Editor.

or

$$P' = \frac{n' P''}{n''}.$$

Hence $f' = \dfrac{4 P'' l^3}{E n'' b h^3}$, as derived by substituting in (1).

Hence,

$$f'' - f' = \frac{2 P'' l^3}{E n'' b h^3}.$$

Also, since

$$\frac{P'}{n'} = \frac{P''}{n''} = \frac{P_1}{n} = \frac{P}{2n},$$

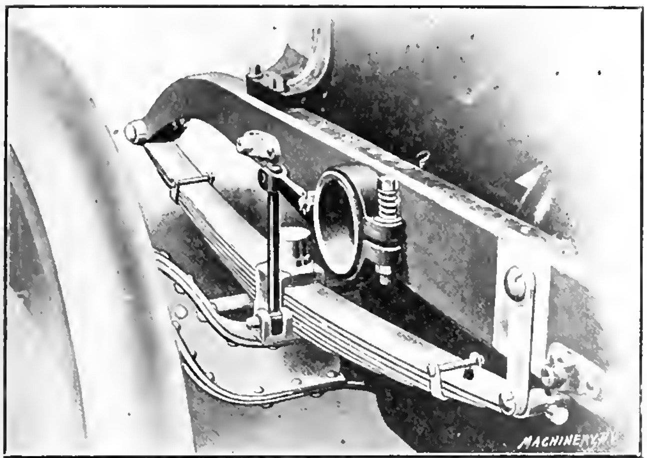

Fig. 4. Front Spring Arrangement of the 1910 Model Winton Six-cylinder Car

we have

$$f'' - f' = \frac{P l^3}{E n b h^3}.$$

Also since

$$l = \frac{L}{2},$$

$$f'' - f' = \frac{P L^3}{8 E n b h^3},$$

or

$$x = \frac{P L^3}{8 E n b h^3}.$$

This last expression is then a general expression of the proper initial distance between the two fundamental portions

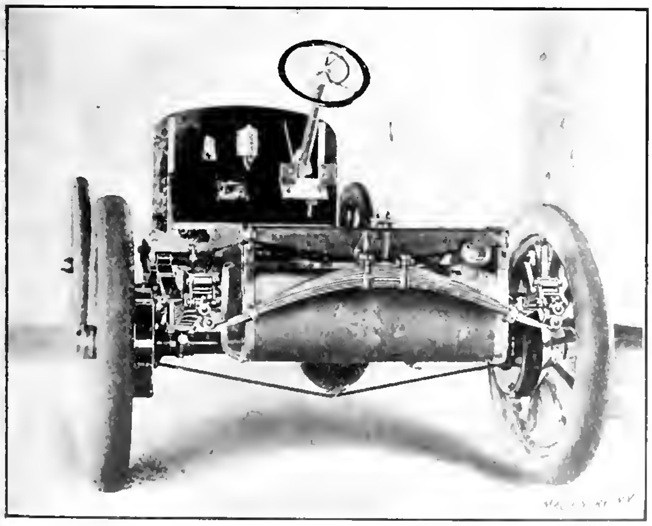

Fig. 5. Spring Support of the Lozier Motor Co.'s "Light Six" Car

before banding, expressed in terms of total load on spring, total number of leaves in spring, and net span of spring. To find the actual working deflection of the entire spring it is only necessary now to ascertain how much either portion is deflected by the process of banding. For this purpose let us adopt the following notation:

P_x = force exerted by band,

f_x' = deflection of full-length leaves caused by band,

f_x'' = deflection of graduated leaves caused by band.

Then,

$$f_x' = \frac{2 P_x l^3}{E n' b h^3} \text{ and } f_x'' = \frac{3 P_x l^3}{E n'' b h^3}.$$

Hence

$$\frac{P_x l_3}{E b h^3} = \frac{f_x' n'}{2} = \frac{f_x'' n''}{3}$$

or

$$f_x' = \frac{2}{3}\left[\frac{(1 - r)}{r}\right] f_x''$$

But

$$f_x' + f_x'' = \frac{P l^3}{E n b h^3}$$

Hence

$$f_x'' + \frac{2}{3}\left[\frac{1 - r}{r}\right] f_x'' = \frac{P l^3}{E n b h^3}.$$

$$f_x'' = \left[\frac{3r}{2 + r}\right] \frac{P l^3}{E n b h^3}$$

But

$$f_x'' = \frac{3 P_x l^3}{E n'' b h^3}$$

Hence

$$\frac{3 P_x l^3}{E n'' b h^3} = \left[\frac{3 r}{2 + r}\right] \frac{P l^3}{E n b h^3}$$

or

$$\frac{3 P_x l^3}{E (1 - r) n b h^3} = \left[\frac{3 r}{2 + r}\right] \frac{P l^3}{E n b h^3}$$

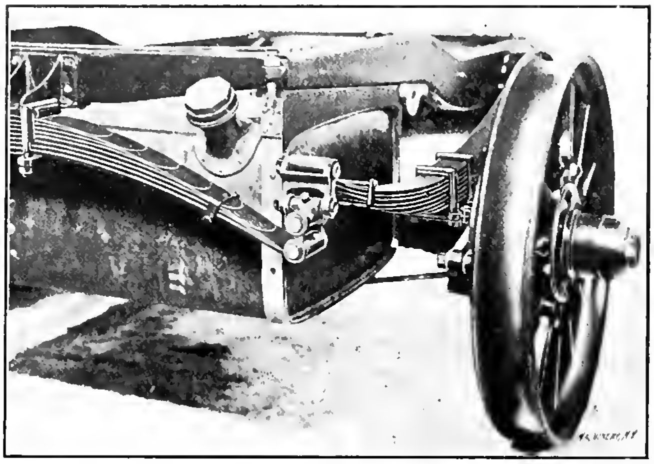

Fig. 6. Arrangement of Semi-elliptic Springs on the Lozier Motor Co.'s Four-cylinder Model

or

$$P_x = \left[\frac{r (1 - r)}{2 + r}\right] P$$

The expression inside the bracket in the above equation becomes zero for either extreme value of r, as would be expected, the extreme values of r being unity and zero. The formula gives the force exerted by the band, *i. e.*, the load upon the band.

The total deflection of the graduated leaves, as already developed, is,

$$f'' = \frac{3 P l^3}{E n b h^3}.$$

The deflection of the graduated leaves, caused by the band, is

$$f_x'' = \left[\frac{3 r}{2 + r}\right] \frac{P l^3}{E n b h^3}$$

The difference is, therefore, the deflection left to the graduated leaves after banding, or the general formula sought for the deflection of such a spring:

$$f'' - f_x'' = \left\{3 - \left[\frac{3 r}{2 + r}\right]\right\} \frac{P l^3}{E n b h^3}$$

or,

$$f = \left[\frac{6}{2 + r}\right] \frac{P l^3}{E n b h^3}$$

or, since $l = \dfrac{L}{2}$

and

$$P = 2\,P_1 = 2\left[\frac{S\,n\,b\,h^2}{6\,l}\right]$$

$$f = \left[\frac{6}{2+r}\right]\left[\frac{2\,S\,n\,b\,h^2}{3\,L}\right]\frac{L^3}{8\,E\,n\,b\,h^3}$$

Hence

$$f = \frac{1}{2\,(2+r)} \times \frac{S\,L^2}{E\,h}.$$

This last expression is then a general formula for the deflection of all semi-elliptic springs. If all the leaves are graduated, $r = 0$, and

$$f = 1/4 \cdot \frac{S\,L^2}{E\,h}.$$

If all the leaves are full length, $r = 1$, and

$$f = 1/6 \times \frac{S\,L^2}{E\,h}.$$

As was to be expected, the spring composed of all graduated leaves has a deflection, according to the above general formula, 50 per cent above that of a spring composed of all full-length leaves. For values of r above zero, the deflection will be found to decrease until r equals unity.

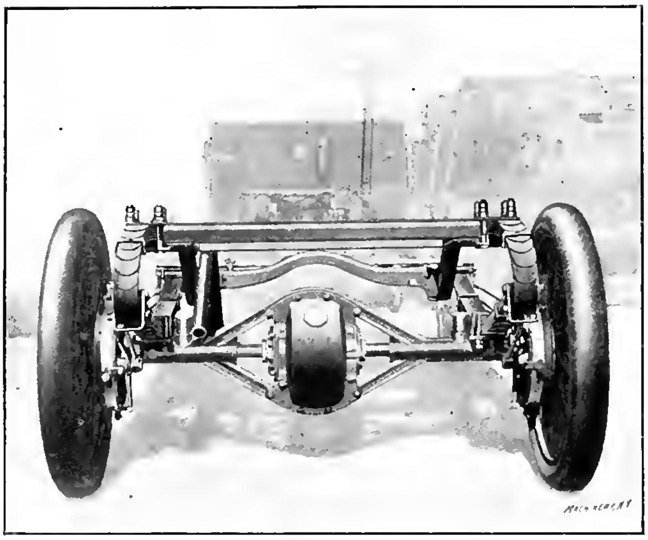

Fig. 7. Three-quarter Elliptic Spring Suspension on the F. B. Stearns Co.'s 15-30 H. P. Car

General Remarks

The general formulas given above were first deduced by the writer in the early part of 1905, at which time they were placed before Prof. C. H. Benjamin, then of the Case School of Applied Science, with a view of making extended experiments for the preparation of a thesis. It was the intention to have springs built with initial space as deduced, and compare the actual deflections of such springs with the estimated deflections. Although these experiments were not carried out, they are mentioned because it is believed that when such experiments are made, they will prove valuable. The deduction of the formulas is here published for the first time. This deduction was made in connection with certain springs which were giving very poor service, although designed by the same formulas as other elliptic springs. It was the writer's conclusion that had the springs been built with the proper initial space between the fundamental parts, these springs would not have broken, and that the omission of this space caused an over-stress in the full-length leaves, and an under-stress in the graduated leaves, which caused the over-strained leaves to break, throwing an overload upon the previously under-stressed leaves which also broke when the stress was excessive. This conclusion seems to explain why springs of this type are frequently found with only the long leaves broken; the remaining leaves, all being of one type, divide the resultant overload evenly so that the over-stress is not so excessive. Perhaps the strongest indication of the correctness of the deduction lies in the well-known fact that the percentage of breakage is always much greater with semi-elliptic springs (of the combination type, usually) than with full elliptic springs. Also, it is generally found upon unbanding these springs that no initial space exists.

Comparison of deflections estimated from the above formulas, with actual deflections has in some cases been quite satisfactory, while in other cases the actual deflections have appeared closer to those estimated by uniform strength formulas. In such cases where the writer has been able to make comparisons, however, the springs had been *made to specified deflections which evidently were estimated by the uniform strength formulas.* Experienced spring makers know that it is quite possible by putting a "pull" in the springs to vary the deflection and load. This trade term, "pull," is itself nothing more nor less than the introduction of an initial space between the leaves before banding.

Suspension of Automobiles

In road carriages, except in the heavier wagons, it is usual to find but two springs, one over each axle placed across the width of the carriage. In automobiles, one finds almost invariably at least the rear suspended upon two springs running lengthwise of the car, while, as is shown in the accompanying illustrations, it is the tendency to use the same suspension in the front. Such an arrangement takes up the forward and side lunges in a manner impossible with simple transverse springs. The further use of links and shackles, and of scroll ends, adds to the comfort, allowing the car to swing upon the springs rather than to be thrown upon them. In quite a few models, the two rear springs are attached in front to the frame and in the rear to a platform spring, which is itself attached to the center of the rear cross member of the frame. The three-quarter elliptic spring lends itself to both comfort and convenience of arrangement, and is rapidly coming into general use in this country, our manufacturers having apparently adopted it from foreign cars.

Steel Used in Automobile Springs

Automobile springs call for a high grade of steel, the ordinary spring steel lacking in strength and elasticity. Various grades of high carbon, silicon, manganese, nickel, chromium, and vanadium steels are used. Often such alloys are used as silico-manganese, chrome-nickel, and chrome-vanadium, the stiffening elements seeming to rank in the order given. Data as to the physical properties of such steels cannot well be given, as such properties must depend upon the proportions in the particular alloy used. Certain alloys of the vanadium group having an elastic limit of from 180,000 to 225,000 pounds per square inch, and tensile strength from 190,000 to 250,000 pounds, appear to be the most ideal steels yet produced.

Calculations of Springs

The calculation of spring properties by formulas is long and tedious. The writer appends, therefore, a table based on a modulus of elasticity of 25,400,000 and a fiber stress under maximum safe load of 80,000 pounds per square inch. Calculations of springs made of materials having other physical properties are made by simple proportion. This table is to be used only when all leaves are fully graduated.

SEMI-ELLIPTIC SPRING TABLE

Giving safe load and deflection for 1 inch wide leaves, 1 inch net length. Used only when all leaves are fully graduated

Thickness of Leaf	P_u	f_u	Steel	P_u	f_u
$\frac{1}{32}$	52.08	0.02519	$\frac{9}{32}$	4218.75	0.00280
$\frac{1}{16}$	208.33	0.01260	$\frac{5}{16}$	5208.33	0.00252
$\frac{3}{32}$	468.75	0.00840	$\frac{11}{32}$	6302.08	0.00229
$\frac{1}{8}$	833.33	0.00630	$\frac{3}{8}$	7500.00	0.00210
$\frac{5}{32}$	1302.08	0.00504	$\frac{13}{32}$	8802.08	0.00194
$\frac{3}{16}$	1875.00	0.00420	$\frac{7}{16}$	10208.33	0.00180
$\frac{7}{32}$	2552.08	0.00360	$\frac{15}{32}$	11718.75	0.00168
$\frac{1}{4}$	3333.33	0.00315	$\frac{1}{2}$	13333.33	0.00157

The safe load on one leaf one inch wide is found by dividing the constant given under P_u by the net length. The corresponding deflection is found by multiplying the constant given under f_u by the square of the net length.

Example: What is the safe load on a semi-elliptic full graduated spring of five leaves if of one-quarter by two inch steel; length between end bearings, thirty-six inches; band or seat, three inches?

Net length $= 36 - 3 = 33$ inches.

Load on one leaf one inch wide $= \dfrac{3333.33}{33} = 101.01$ pounds.

Load on one leaf two inches wide $= 2 \times 101.01 = 202.02$ pounds.

Load on five two-inch leaves $= 5 \times 202.02 = 1010.10$ pounds.

Corresponding deflection is:

$$0.00315 \times (33)^2 = 3.43 \text{ inches.}$$

Formulas can easily be deduced making it possible to use the accompanying table for other classes of elliptic springs than those of the semi-elliptic type with all leaves fully graduated.

The formulas for the semi-elliptic spring with all leaves graduated are:

$$P = \frac{2\,S\,n\,b\,h^2}{3\,L} \text{ and } f = \frac{S\,L^2}{4\,E\,h}.$$

To find the values of P_u given in the table, insert $S = 80,000$, $n = 1$, $b = 1$, $h =$ the value given in the first column in the table, and $L = 1$. To find the values of f_u, insert in the second formula $S = 80,000$, $L = 1$, $E = 25,400,000$, and $h =$ the value given in the first column in the table.

Now if the values in the table are to be used for other springs, constants can be deduced by which the table values may be multiplied.

For a semi-elliptic spring with a portion of the leaves graduated the load P remains the same as for a spring with all leaves graduated. The formula for the deflection, however, is:

$$f = \frac{1}{2\,(2 + r)} \times \frac{S\,L^2}{E\,h}.$$

The values in the table, therefore, must be multiplied by $\dfrac{2}{(2 + r)} \times L^2$ to find the deflection for any given combination full leaf and graduated spring of effective length L.

For a full elliptic spring with all leaves graduated, P still remains the same as for a semi-elliptic spring, but f doubles its value, or:

$$f = \frac{S\,L^2}{2\,E\,h}.$$

The values in the table, therefore, in this case must be multiplied by $2\,L^2$.

For the full elliptic spring with part of the leaves only graduated, the load P remains the same as before, but the deflection is twice that of a semi-elliptic spring:

$$f = \frac{1}{2\,(2 + r)} \times \frac{2\,S\,L^2}{E\,h} = \frac{S\,L^2}{(2 + r)\,E\,h}.$$

In this case, then, the values for the deflection in the table are to be multiplied by $\dfrac{4}{2 + r} \times L^2$.

The flexibility of a spring is the amount of deflection as compared to the load. This may be expressed as so many inches deflection per hundred pounds, or y.

Example:—Assume a full-elliptic, fully graduated spring, where

$S = 80,000$,
$E = 25,400,000$,
$b = 1\frac{3}{4}$ inch,
$n = 4$,
$h = \frac{1}{4}$ inch,
$L = 30$ inches.

Then the safe load equals:

$$P = 4 \times 1\tfrac{3}{4} \times \frac{3333.33}{30} = 778 \text{ pounds.}$$

And the deflection equals:

$$f = 30^2 \times 2 \times 0.00315 = 5.67 \text{ inches.}$$

Then,

$$y = \frac{5.67}{778} \times 100 = 0.73 \text{ inch.}$$

On the other hand, assume that the thickness and number of leaves is unknown. Then we have:

$P = 778$ pounds,
$S = 80,000$,
$E = 25,400,000$,
$b = 1\frac{3}{4}$ inch,
$L = 30$ inches,
$y = 0.73$ inch.

Then

$$f = \frac{778}{100} \times 0.73 = 5.67 \text{ inches.}$$

But $f = 2\,f_u L^2$, where f_u is the constant for deflection in the accompanying table:

Hence,

$$f_u = \frac{f}{2\,L^2} = \frac{5.67}{1,800} = 0.00315.$$

The thickness of steel in the table which corresponds to this value of f_u is one-fourth inch.

The number of leaves is found by using P_u, thus.

Load on one leaf, one inch wide is:

$$\frac{3333.333}{30} = 111.11 \text{ pounds.}$$

Load on one leaf one and three-quarter wide is:

$$111.11 \times 1\tfrac{3}{4} = 194.25.$$

Number of leaves is then,

$$\frac{778}{194.25} = 4.$$

The present calculation makes no allowance for the leaves of a spring varying in thickness. Where such springs are used, the deflection of the different leaves will not be uniform. Hence, in such springs also a suitable initial "pull" should exist, and such springs should be estimated by a general formula based upon a combination of different cantilevers, thus making allowance for different depths of cantilevers. It is much better to use springs composed of but one thickness of leaves, as the combination of different thicknesses adds a complexity scarcely necessary.

Results obtained from fully graduated full elliptic springs would seem to show that the action of the friction between the leaves is not great enough to seriously affect the bending action, in that the formulas give results agreeing very closely with actual conditions.

* * *

ELECTRIC VS. STEAM LOCOMOTIVES

Almost at the same time as the experiments carried on for several years past on the Swedish state railways have led the railway administration in that country to install electric traction on one of the state railways for both passenger and freight traffic, it is decided by the Swiss railway administration to return to the use of steam locomotives on one railway line after two years trial with electric locomotives. The main reason for this appears to be that electric operation proved more costly than expected, the excess of cost of electric operation over that of steam operation being about $1,000 a year per mile of road electrically operated. The results obtained by the Swiss railway administration are significant, inasmuch as Switzerland is especially adapted for electric operation of the country's railways. The abundant water power available makes it possible to generate electric current as cheaply as conceivable. Coal, on the other hand, is costly in Switzerland, due to the fact that all coal must be imported. The results of the experimental operation in Switzerland indicate that electric traction will be profitable only on the lines having very heavy grades or dense traffic. If this is the case in a country where water power can be obtained in abundance and where coal is costly, it indicates that the existence of the steam locomotive is placed on a very firm foundation in countries where water power is comparatively scarce and coal abundant, as, for instance, in the United States.

CUTTING SQUARE HOLES ON A KEYSEATING MACHINE

ETHAN VIALL*

The making of square holes of any considerable length in tough metal is always something of a problem, especially if the holes are to be of uniform size within very narrow limits. As a general rule, such holes would be made by running a number of broaches through a drilled hole, but a method is in use at the shop of Blood Brothers Machine Co., Kalamazoo, Mich., where holes 1¼ inch square and 4 inches long are made in a very tough grade of steel by first drilling a hole the same diameter as the side of the square wanted, cutting out the corners on a Mitts & Merrill keyseater and then finishing the hole by forcing a short sizing-broach down through it.

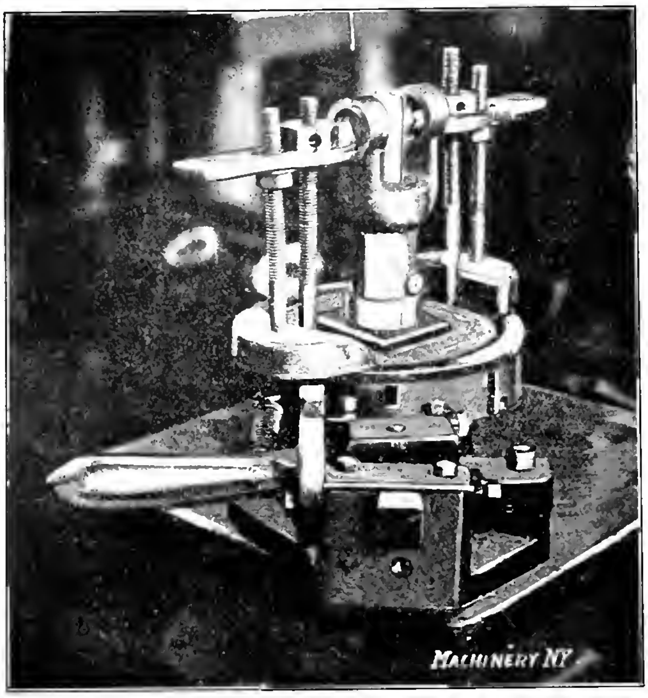

Fig. 1. Indexing Fixture used on Keyseating Machine while Squaring Holes

The part in which this square hole is made is the hub of a fork for a universal joint, manufactured by the firm mentioned. After the fork is drilled it is placed on a keyseater fitted with the indexing fixture shown in Fig. 1, and one corner of the hole cut out. The fixture is then indexed a quarter turn, the next corner cut, and so on until the hole is squared within a few thousandths of the size wanted. The work is then placed in a small hydraulic press and a sizing broach run through as mentioned before.

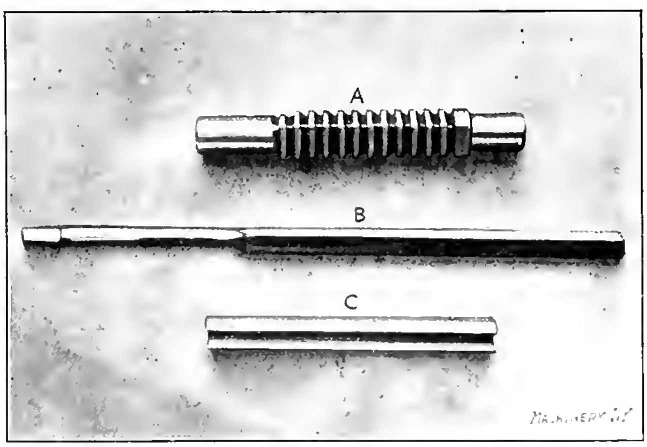

Fig. 2. Broach, Cutter and Cutter Guide used in making Square Holes

The cutter used to cut out the corners is shown at *B*, Fig. 2, the cutter guide at *C* and the broach at *A*. In Fig. 3 are shown samples of the work, after it has been drilled as at *A*, cut out as at *B*, and broached as at *C*.

In cutting out the hole, enough of the round is left to act as a guide for the pilot on the broach. Those who have ever used a broach of this type know of its tendency to crowd over to one side when it is not started perfectly straight. By having a pilot-guide, this tendency is largely overcome and the hole is started and kept straight with little difficulty.

Some will no doubt think that the keyseater method of rough squaring the holes is slower than draw-broaching, but all things being considered, the use of a keyseater is, in a case like this, probably cheaper owing to the amount and toughness of the metal to be removed. At least two and perhaps three draw-broaches would have to be used, and the actual time would be about the same, while the cost of the broaches would be very largely in excess of cutters. By the method just described, from twelve to fifteen holes are finished per hour, a liberal supply of soapwater being used while cutting.

The push-broaches used for this job are about fourteen inches in length with a 2½- or 3-inch pilot and a 2-inch shank. Beginning with the first tooth, the size increases 0.001 inch for each one up to the last or sizing tooth. This is left twice as wide across the top as the others as shown at *A*, Fig. 2. The other teeth are ¼ inch wide with a ¼-inch flute, and the face or outside is ground perfectly straight and parallel with the center line of the tool, giving absolutely no clearance. The cutting edge, however, is hooked under just enough to cause it to cut a nice curling chip, all sharpening, of course, being done on the cutting edge and not on the outside, as that would change the size. By giving the teeth no outside clearance, the tendency to "creep" in case the metal were a little softer on one side, is minimized, and with the aid of the pilot a perfectly straight hole is made.

Beside cheapness, another advantage claimed for this method, is that there is no tearing of the metal, perfectly smooth holes being obtained. Of course, full-sized square holes could be made without the use of a broach, but more time would undoubtedly be taken in getting as accurate results.

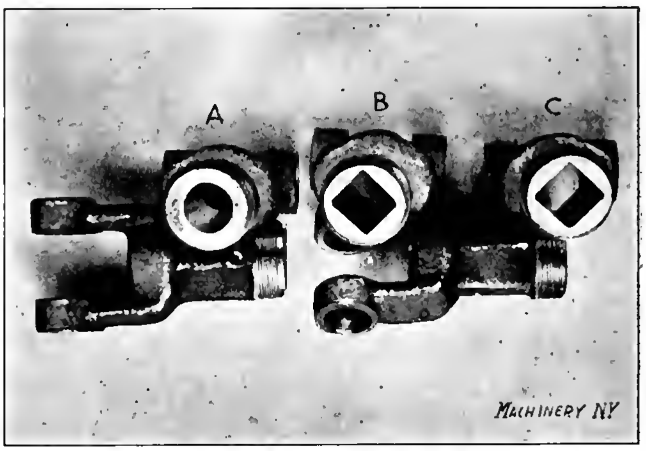

Fig. 3. Universal Joint Forks, showing Drilled, Machined, and Broached Holes

The keyseater may also be used to cut triangular, hexagon, octagon or almost any other shaped holes by simply grinding a cutter to the proper outline, and if any quantity were wanted, an indexing fixture similar to the one shown could be easily made.

* * *

The Norwegian Parliament has just passed a measure of great industrial importance, relating to the future exploitation of the country's water power. This act recognizes distinctly the rights of the whole nation to the country's national resources in the form of available water power. Concessions for use may be given for a term of from 60 to 80 years, but at the end of the concession the water fall, with regulating works connected therewith, and the sites and rights required for the exploitation of the water power and for the power station, become the property of the state with full ownership and without compensation; this latter provision gives to the state a compensation for the privilege conferred upon the private exploiting company during the period of the concession. Water falls of a capacity of less than 1,000 horse-power are excepted from the rulings of this act.

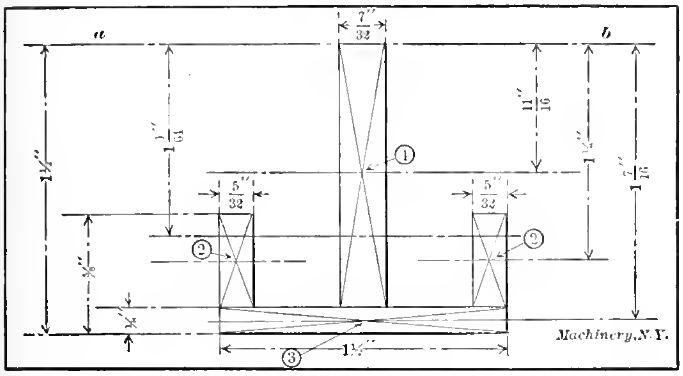
* Associate Editor of MACHINERY.

TO CALCULATE THE DEFLECTION OF A SPECIAL STEEL SECTION*

MARTIN JOACHIMSON†

The problem presented in the following, although taken from actual practice, has been selected as a specimen for calculations relating to special steel sections, because it involves all the calculations which ordinarily occur in such cases. When sections are built up of plates and angles, the areas, center of gravity and moment of inertia of the parts can be found in the hand-books published by the various steel companies; this of course simplifies the calculations.

The problem in the present case is as follows: How much will the proposed section, shown in the accompanying engraving, deflect under a total load of 400 pounds, if this load be



Section of Built-up Beam, used as Example for the Calculation of Moment of Inertia and Deflection

uniformly distributed over the total distance between the supports, which is 6 feet? The formula for the deflection of the beam is:

$$D = \frac{5\,Wl^3}{384\,EI}$$

in which D = deflection in inches,

W = total load = 400 pounds + weight of beam,

l = length between supports in inches = 72 inches,

E = modulus of elasticity for steel = 29,000,000,

I = moment of inertia of section.

This formula was given in MACHINERY's Data Sheet No. 48, September, 1905.

The weight of the beam and the moment of inertia of the section must now be obtained before the deflection can be calculated. The general formula for the moment of inertia with respect to any given axis is:

$$I = \Sigma\,(ad^2 + i)$$

in which a = area of each part making up the complete section,

d = distance from the center of gravity of each part to the axis with respect to which the moment of inertia is required,

i = moment of inertia of each part.

The Greek letter Σ (sigma) indicates that the sum of the moments of inertia of each part with respect to the axis required gives the total moment of inertia.

The position of the neutral axis must be determined before we can determine the moment of inertia with respect to this axis. The neutral axis of the whole section passes through the center of gravity of the section. The location of the center of gravity is determined with respect to the line ab by the formula:

$$\text{distance of center of gravity from line } ab = \frac{\Sigma\,(ad)}{A}$$

in which a = area of each part making up the complete section,

d = distance from the center of gravity of each part to line ab,

A = total area of section.

indicates in this case, as above, that the sum of the areas of the various parts multiplied by the distance of the center of gravity of each part to the line ab, is required. The use of this formula will be understood from the following simple calculation:

First find the total area of the section. The different rectangles in the section of the sample beam are called (1), (2), (3) and (4), respectively.. The areas of the sections are then as follows:

$$\text{Area (1)} = \frac{7}{32} \times 1\tfrac{3}{8} = 0.300781$$

$$\text{Area (2)} = \frac{5}{32} \times \tfrac{1}{2} = 0.078125$$

$$\text{Area (2)} = \frac{5}{32} \times \tfrac{1}{2} = 0.078125$$

$$\text{Area (3)} = \frac{1}{8} \times 1\tfrac{1}{2} = 0.1875$$

The areas are found from the tables in the accompanying Data Sheet Supplement; in the case where 7/32 is to be multiplied by 1⅜, of course, 7/32 is multiplied by 1, and then by ⅜, and these two products are added. Now to find the weight of the section per foot, multiply the sum of the areas obtained by the factor 3.4 for steel, as a steel bar weighs 3.4 pounds per foot when the section is one inch square. Then the weight per foot equals:

$$0.64453 \times 3.4 = 2.19 \text{ pounds,}$$

and the weight of the whole beam 6 feet long equals:

$$2.19 \times 6 = 13.14 \text{ pounds.}$$

Now to find the distance of the center of gravity of the section from the line ab, multiply the area of each section by the distance of its center of gravity from the line ab, thus:

area	× distance	= moment
0.30078	× 11/16	= 0.20678
0.07812	× 1⅛	= 0.08788
0.07812	× 1⅛	= 0.08788
0.1875	× 1 7/16	= 0.26952
0.64452		0.65206

Now adding the four moments obtained gives us 0.65206 as shown, which equals the quantity $\Sigma\,(ad)$. Dividing this sum by the total area, which equals 0.64452 gives us the distance of the center of gravity of the whole section from the line ab:

$$\frac{0.65206}{0.64452} = \frac{65}{64} = 1\ 1/64 \text{ inch, very nearly.}$$

We are now ready to find the moment of inertia of the section. The moment of inertia of a rectangular section is found by the formula:

$$I = \frac{bh^3}{12}$$

in which h equals the height of the rectangle and b the width or breadth, the height meaning the dimension which is at right angles to the neutral axis. This formula is found in any engineering hand-book. The individual moments of inertia of each rectangular section are now found with respect to their own neutral axis, as below:

$$\frac{\frac{7}{32} \times (1\tfrac{3}{8})^3}{12} = 0.04739$$

$$2 \times \frac{\frac{5}{32} \times (\tfrac{1}{2})^3}{12} = 0.00325$$

$$\frac{1\tfrac{1}{2} \times (\tfrac{1}{8})^3}{12} = 0.00024$$

Having now found the moment of inertia of each section we find the quantity $ad^2 + i$ for each of the sections with relation to the neutral axis of the section. The sum of these various quantities gives us the total moment of inertia, I.

a	d	d^2	i	$ad^2 + i$
0.30078	21/64	0.1077	0.04739	0.07976
0.15625	7/64	0.01196	0.00325	0.00512

* With Data Sheet Supplement.

† Address: 518 West 156th St., New York City.

a	d	d^2	i	$ad^2 + i$
0.1875	$\frac{27}{64}$	0.1780	0.00024	0.03361
				$I = 0.11849$

We can now find the deflection by inserting our values in the original formula for the deflection, W being 413.14 pounds and $I = 0.1185$.

$$D = \frac{5 \times 413.14 \times 72^3}{384 \times 29{,}000{,}000 \times 0.1185} = 0.5847 \text{ inch.}$$

This deflection, of course, would be too much for practical purposes.

* * *

BOILERS AND CHIMNEYS*†

A. WIND‡

The writer read with great interest the article entitled "Simple Method of Stack Design," published in the August, 1909, issue of MACHINERY. The expression "horse-power" of a boiler, used in this article, is an expression that is not customary in England. The term horse-power for a boiler seems to me very vague, because the boiler when used for two different types of engines would give a very great difference in the amount of power that may be obtained from it. A boiler, for instance, may be able to evaporate say 6,000 pounds of water per hour at 120 pounds working pressure. Assuming twenty pounds of steam for every horse-power, this boiler would be a 300 horse-power boiler; but if the boiler were supplying steam to an engine exhausting into the air and working under unfavorable conditions, 35 pounds of steam per horse-power might be required. In this case the boiler would be of only 170 horse-power. Again, a boiler may not be used for raising steam for engine driving, but it may be used for boiling purposes, as in paper mills, creosoting plants or celluloid works; then the term horse-power would convey an altogether wrong idea.

I find, therefore, that it is better to follow the custom used in England and on the Continent, of speaking of boilers as being built to evaporate so many pounds of water per hour under ordinary circumstances. At the works where the writer is employed this method of designating boilers applies as well to water tube, Lancashire, Cornish and multi-tubular boilers. Of course, it must be understood that a boiler being built to evaporate 6,000 pounds of water per hour when fired with good coal by hand, would be able to evaporate 8,000 pounds of water per hour, or thereabouts, when fired with a mechanical stoker and fed with pre-heated feed water.

[Our correspondent apparently has an erroneous idea as regards the meaning of a boiler horse-power, as this expression is used in the United States. The Centennial standard boiler horse-power adopted by the American Society of Mechanical Engineers in 1884, is defined as an evaporation of 30 pounds of water into dry steam under a pressure of 70 pounds per square inch above atmosphere from feed water at a temperature of 100 degrees F., or the evaporation of 34½ pounds of water from feed water at a temperature of 212 degrees F. into steam of the same temperature. This standard is equal to 33,305 B. T. U. per hour.—EDITOR.]

As regards the size of chimneys, the writer would say that the draft that is necessary for hand firing will almost without exception be sufficient when firing the boiler with an ordinary mechanical stoker. In the accompanying Data Sheet Supplement heights and diameters of chimneys for different kinds of boilers are given. This table is based upon the grate area of the boiler, assuming the burning of from 20 to 25 pounds of coal per square foot of grate per hour. The size of the grate in many instances will vary very little with the length of the boiler. In the works where the writer is employed the same grate is put into a Lancashire boiler 25 feet long as in one 30 feet long. This applies also to Cornish and multi-tubular boilers. When two or more boilers are worked together it is not necessary to calculate the size of the chimney for the total combined grate area of all the boilers, as it is very seldom that all the boilers are fired in all furnaces at exactly the same time. Therefore, a greater number of boilers permits of a comparatively smaller size of chimney. The table in the accompanying Data Sheet Supplement gives the diameters of boilers, grate areas and the diameters and heights of chimneys for any number of boilers from one to five, in the case of the Cornish type, one to fifteen in the case of the Lancashire type, and one to ten in the case of the multi-tubular boilers. In each case the height of the chimney is taken to be 20 times its diameter.

Where forced draft or induced draft plants are installed, the size of chimneys can, of course, be considerably reduced. Each given size of chimney would prove sufficient for 33 per cent greater capacity than shown in the table, when such draft is employed. To determine the size of the chimney for six boilers with induced draft, for example, select the chimney given in the table corresponding to four boilers.

The sizes of chimneys given in this table correspond to the ordinary practice in England and on the European continent. It may, of course, differ slightly from that customary in the United States, but the writer thinks that, nevertheless, this table may be of interest to steam engineers in America.

RECIPROCITY

W. L. CHENEY*

"I will put in one of your machines if you will put in one of mine"; how often we hear this expression!

It is all rot, and time it was so understood. The only legitimate reason for buying a machine is that the buyer will be better off for having bought it. The interest of the buyer of a machine is in what the machine will earn for him; therefore he should buy the one which is best for his purpose, and it follows that a man who buys a machine which is *not* best for his purpose, simply because the other fellow will buy one of *his* machines, is worse than silly, because his profit is soon eaten up by the increased cost of what the inferior machine produces, and after that it is all loss. This is so simple a proposition that it is axiomatic, and there is, therefore, no use arguing with a man who cannot see it at first glance when it is brought to his attention.

The same principle applies to different *grades* of machines of approximately similar design. Either one machine *is* better designed and made, will do more and better work, and is in the repair shop less than another, or it is *not;* if it *is*, why buy the other because of a few dollars saving in first cost, and go on losing profits ever after?

The mistake is often made of assuming that the interest of the seller of a machine is only in the profit which the sale brings; but the seller has a further interest and *this is identical with the interest of the buyer*, because the profit on the sale of a machine ends with the sale, and no concern can live on the profit from *one* sale. The man who habitually sells machines which are not best for the user's purposes has a hard row to hoe. Nothing helps sales like the "good word" from the satisfied user. So, what can be said that is strong enough against the folly of two men who make "exchanges" and "trade deals" for no other reason than their blind worship of the fetish of "reciprocity?"

* * *

Attention is called in the *Electrotechnische Zeitschrift* to the fact that the static charge of the cover-glass of electrical instruments is the source of many errors in electrical observations. The longer the pointer, the nearer it is to the glass, the feebler the directive force of the instrument, and the drier the atmosphere, the greater will be the error in the reading. In a dry warm room instruments have been known to indicate wrong as much as twenty per cent when touched with the dry hand. By drawing a piece of soft leather across the glass of a galvanometer, deflections up to five per cent may be produced. The deflections are not lasting, of course, but it may be as much as an hour before the pointer will again indicate correctly. Errors are produced, for instance, when cleaning the glass by wiping off the dust. As a preventative for the difficulty, it is stated that breathing upon the glass will eliminate the static charge.

MACHINING CYLINDERS AND PISTONS FOR AUTOMOBILE ENGINES*

HAROLD WHITING SLAUSON†

Less than ten years ago, an automobile race held in France was won by a certain car propelled by a two-cylinder gasoline motor developing four horse-power. Today, duplicates of this motor, so far as number of cylinders, bore and stroke are concerned, are made by the thousand in one of the large French factories; but these motors now develop *twelve* horse-power—an increase of 200 per cent! This is indeed a striking illustration of the improvements in design and the rapid strides in shop and manufacturing methods made in the automobile industry during the past decade and it serves to show why the modern motor car renders such vastly better service than did its ancestor of ten or twelve years ago.

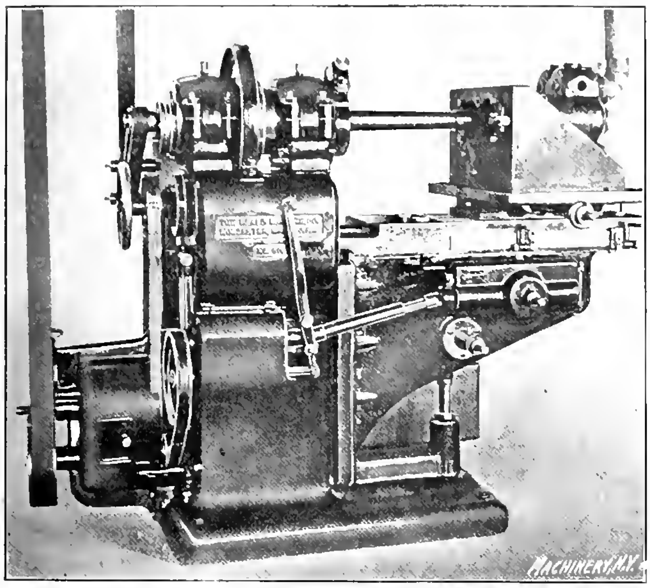

Fig. 1. Heald Grinder used in Premier Factory, showing Exhaust Attachment for Drawing off the Iron and Emery Dust

Much of this increased efficiency has doubtless been due to improved shop methods and tools whereby a far better fit of pistons and rings in the cylinder has been made possible. Good compression and the ability of the piston rings to prevent the escape of gas during the comparatively short time that the so-called explosion lasts is of such vital importance to the internal combustion motor that it is doubtful if the square pistons of the time of Watt would have served the purpose for any prime mover in which the source of energy is located in the cylinder itself. Owing to the higher temperature and pressure generally found in the internal combustion motor cylinder, the rings must be tighter and the piston looser than is the case with the steam engine, while the higher speed of the former power plant necessitates the minutest attention to details of workmanship and material to prevent undue wear of the moving parts. This higher speed also requires a more perfect balance of piston, connecting-rod and crank-shaft, and it is the practice in one of the leading American automobile factories to allow a margin of but ¼ ounce between the weight of any two pistons in any of the motors turned out.

There may be said to be almost as great a variety of methods in use for the preparation of the cylinder and piston of a modern automobile engine as there are makes of cars on the market. There are a number of different ways for performing the operations of boring, grinding and reaming cylinders and for grinding, "lapping" and "running in" pistons and rings, and nearly every possible combination of the processes for treating these two principal parts of a motor will be found in the numerous automobile factories of this country. One factory may bore the cylinders and grind both cylinders and pistons; another may treat the former in the same manner, but prefer to "lap in" the pistons; a third may ream the cylinders and both grind and "run in" the pistons; while still another may perform all four operations. When to these are added the drilling and tapping of holes in the casting, the facing off of the base, valve seats and the like, and the reaming of the pockets, it is small wonder that every cylinder on one of the well-known makes of cars has received nine different operations at the hands of as many different artisans before it is ready for its installation as a part of the completed motor.

In many of the shops special machine tools have been designed for the purpose of performing but a single operation on a number of cylinders at once. On the other hand, however, excellent work is performed in those factories in which attachments have been improvised for use on regular tools and machines such as will be found in any well-equipped machine shop, and the quality of the output will compare favorably with that of the concerns employing the most modern special equipment. Horizontal boring mills in a variety of forms are used in the majority of factories for giving the rough and finishing cuts to the cylinder castings. In some of the factories which make engines having the cylinders cast in pairs, a double mill is used having two bars which bore both cylinders at once. Several of these are in use in the Peerless factory at Cleveland, and each is equipped with a turret on which the casting is held while the cylinders are being bored. Another pair may be set in place while the operation of boring is in progress on the first set, and when these are completed, the turret is turned and the new casting is in position to be worked.

The rough and finishing cuts in the boring mill were formerly the only machine operations that the interior of the cylinder received, and even today some of the manufacturers do not consider it necessary to grind the walls. When the cylinders are not ground after being bored, it is necessary that the motor shall be run under belt power for a considerable time before the walls are worn sufficiently smooth to permit the engine to operate efficiently under its own power. In lieu of grinding, graphite has been found to produce good results when worked into the cylinder walls by the piston. The small particles of this substance fill every minute pore and hole left in the cylinder walls by the boring tool, and produce an almost perfectly smooth surface. As graphite is unaffected by heat, the high temperatures of the combustion chamber do not injure or alter it and it remains in its place in the cylinder walls for a practically indefinite period.

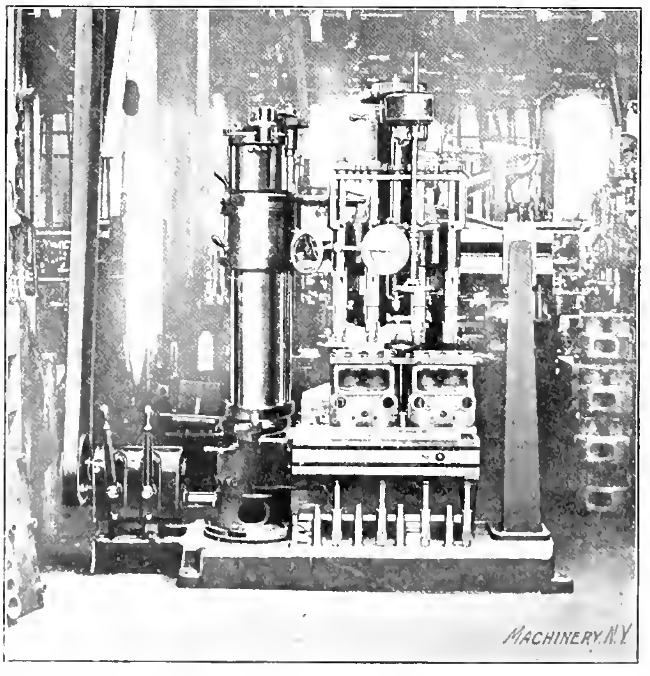

Fig. 2 "American" Radial Drill in Winton Factory, with Four-spindle Attachment for Reaming Automobile Cylinders

All of the motors for the Gaeth automobile, made in Cleveland, are bored on a lathe, and the results speak highly for the methods of treating cylinders employed in this shop. The cylinders are cast in pairs, and when bored, each pair

* For articles previously published on this and kindred subjects, see "The Design and Manufacture of a High Grade Motor Car," "Manufacturing Methods in the Stevens-Duryea Automobile Works," "Automobile Factory Practice," Efficient System for the Rapid Assembly of Motor Cars," "Treatment of Gears for Automobile Motors and Transmissions," October, 1909, and articles there referred to.

† Address: Box 27, Times Square Station, New York.

is held in place on a fixture which is attached to the faceplate of the lathe. This fixture is so arranged that either cylinder may be turned into the proper position for boring without the necessity of removal from the faceplate. When one of the pair is finished, the other cylinder may be swung into position with only a few seconds' delay, and as no readjustment is necessary, it is certain that the two borings in the casting will be absolutely uniform. After the finishing cut of the boring tool has brought the cylinders to within about 0.010 inch of their proper diameter, the same lathe is converted into a grinding machine by the addition of a small electric motor and emery wheel, and the cylinders are then ground to exact size.

The emery wheel is attached to the end of a long spindle, which is in reality an extension of the armature of the motor, and the whole apparatus is clamped rigidly to the tool carriage of the lathe. The motor is run at high speed, while the back gear of the lathe is used to turn the cylinder casting slowly in the opposite direction. The length of the spindle on the motor allows the emery wheel to travel the entire distance of the cylinder walls to be ground, without danger of interference between casting and tool or carriage. Although this method of converting a lathe into a grinder is by no means new to machine shops, it is not common in automobile factory practice.

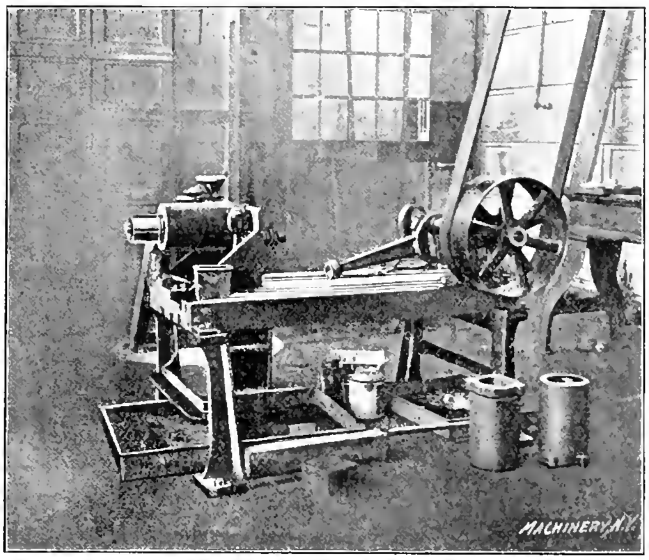

Fig. 3. Piston Lapping Machine in Marmon Factory, showing Connecting-rod Disconnected at Ball-and-socket Joint*

The cylinder of a modern automobile must of necessity be designed with such a small factor of safety in order to bring the whole machine down to the required lightness, that the utmost care must be taken in boring and grinding to prevent any weakening of the walls which might produce disastrous results if the pressure in the combustion chamber should become too great. Although these cylinder castings are constructed of the finest quality of gray iron, too deep a cut or too rapid speed in the boring mill may produce sufficient heat to strain the material unduly, and although all the factories exercise the greatest care in this respect, the methods employed in two of the shops to prevent such an occurrence are worthy of note.

In the factory in which the Marmon car is made, in Indianapolis, the cylinder casting is placed on the boring mill in a special fixture. This fixture contains intake and outlet water pipes with terminals which are attached to the respective plugs of the cooling system of the cylinder. When the boring mill starts its cut on the cylinder wall, water is run through the fixture and the jacket of the casting, thus keeping the material at an even temperature throughout the operation. It has been found that, with this method, the boring mill can be run at a higher speed and take a deeper cut with no attendant danger of inducing strains in the cylinder walls.

An entirely different practice is employed at the Premier factory, also located at Indianapolis. This method is a *cure*, whereas that described above is a *prevention*. After the first rough cut has been taken on the boring mill, the cylinder is removed and taken to the heat treating room where it is thoroughly annealed. This process is repeated after the final or finishing cut, and while it is not probable that the metal has received any strains due to the excessive generation of heat in the boring mill, any internal strains that may have been set up will surely be removed by these heat treatments.

After these operations, the cylinder is placed in the fixture on the Heald grinding machine and, as shown in one of the accompanying illustrations, Fig. 1, is connected at its valve openings to an air suction pipe which serves to remove all emery and iron dust formed in the casting. This type of grinder is in use in many of the leading automobile factories. The emery wheel is mounted on the end of a spindle which revolves at high speed on its axis. The bearing of this spindle is set in an adjustable eccentric which serves to give a circular sweep to the emery wheel in the opposite direction to that of its rotation. In other words, the eccentricity of the bearing of the spindle causes the outer point of the periphery of the emery wheel to describe a circle of the same diameter as that to which it is desired to grind the cylinder. An idler pulley, actuated by a cam, moves with the eccentric and serves to keep at the proper tension the belt which drives the spindle. [See MACHINERY, April, 1908.]

Many of the factories making motors having cylinders of small diameter and stroke accomplish the results attained by the finish-boring cut and grinding by means of the single operation of reaming. For this purpose, a large drill press, a lathe or a vertical boring mill with revolving table is used. (See Fig. 2.) It is a simpler operation than any of those already described, requires the use of fewer tools and machines and, in cylinders of small size, produces very satisfactory results.

Opinions seem to differ among many of the automobile manufacturers in regard to the necessity of grinding pistons. To say that, in all the leading factories, all the pistons are ground, would be unfair, for many a car, whose proved reliability and efficiency place it among the leading makes, has been designed and built in a shop in which the piston has gone directly from the lathe to the cylinder. Some makers claim that, inasmuch as the contact of the piston itself with the cylinder walls is not an essential in preventing leakage, it is useless to bestow the extra time and labor of grinding upon it—especially if the emery wheel has left the wall of the cylinder with a hard, glazed surface which would wear the rings to a perfect fit after a few hours' run of the motor under belt power. Others claim that too much attention cannot be bestowed upon these important moving parts of an internal combustion engine, and hence grind both the piston and the rings before installation in the motor.

The piston casting, of course, is turned, bored and the ring grooves cut to size in a lathe. The process following this operation in use in the Gaeth factory is interesting and unique in the extreme and, so far as the writer has been able to ascertain, is employed in this establishment exclusively. After the piston has left the lathe and the rings have been fitted to their grooves by the usual method, a special cement is applied to the rings, which holds them firmly in place. After this cement has hardened, the piston is taken to the lathe, the emery wheel attached and the surface ground down to exact size. The rings have been cemented in place so that their notched ends are closed around the pins in the grooves and, in consequence, they are ground down flush with the surface of the piston at all points on their outer circumference.

When this grinding is completed, only the closest scrutiny will reveal several very fine lines which indicate the sides of the rings. These lines defining the rings cannot be detected by the most sensitive touch, and it is evident that the whole surface is, to all intents and purposes, absolutely smooth. After the rings have been thus fitted, the cement is dissolved, the rings spring out to their normal positions and the piston is ready for installation in its cylinder.

As evidence of the attention given to detail by the leading automobile designers, the dimensions of every piston as it is

* For a more detailed view of the opposite side of this machine and additional information, see the article: Automobile Factory Practice, published elsewhere in this number.

finished in this factory are worthy of note. Instead of being of the same diameter throughout its entire length, the piston is tapered for a distance of one inch down from its upper end. Although this difference in diameter is small, amounting to 0.020 inch for the lower half of this tapered part and an additional 0.007 inch for the upper half, it has been found to be sufficient to allow for the greater expansion which occurs at this end of the piston, caused by its proximity to the combustion chamber and the intense heat generated therein.

A Norton Grinding Co.'s grinding machine is used in the Premier factory for piston grinding, and is typical of the machines used for this purpose in many of the best automobile shops. It is a too familiar sight in most of the best-equipped machine shops to require description.

In the majority of cases, when the piston and rings are not ground, they are "lapped in." This consists in moving the piston and rings up and down in the cylinder, under belt power attached to the flywheel, for several hours, and at the same time introducing an abrasive material between the moving surfaces. At the end of this operation, the rings and all parts of the piston which may have come in contact with the cylinder walls will have been worn smooth and to a practically perfect fit. The motor is then tested on the blocks under its own power with a variable load attached in the form of a dynamometer. When the engine has been thoroughly "tuned up" and all adjustments made, it is ready for installation in the chassis, and finally the completed car, with the exception of the stock body, is taken out for a severe and thorough road test. This road test generally covers a couple of hundred miles at the least, and when this is completed, it is almost certain that the rings will have been worn to as perfect a fit as though they had been ground.

At the Marmon factory, a special machine, Fig. 3, is used for lapping in the piston rings, which, while simple, is very effective. An iron casting is bored and ground to the exact size of the cylinder diameter and is mounted on a fixture at one end of a short bed. Directly opposite the opening in this casting and mounted on a shaft with axis at right angles to the stroke of the cylinder, is an eccentric and connecting-rod. The free end of this connecting-rod terminates in a ball-and-socket joint which can be attached to the connecting-rod of the piston to be lapped. The shaft on which the eccentric is mounted is driven by belt power and a reciprocating motion is thus communicated to the piston in the casting. The ball-and-socket joint allows the piston to be rotated by hand during its travel in the casting, thus bringing all parts of its surface in contact with every point on the cylinder walls. A hole is drilled in the upper side of the cylinder casting and a funnel attached through which may be fed the abrasive mixture—generally composed of finely powdered emery and oil. The fixture in which this casting is mounted will accommodate a pair of the motor cylinders, in which the pistons may be lapped, but it is simpler and more convenient, as a rule, to use this iron block ground exactly to the proper bore.

It is manifestly impossible in an article of this length to describe all of the variations of methods for the treatment of gas engine cylinders and pistons in use in the numerous automobile factories in this country. The practices dealt with in the foregoing paragraphs, however, represent the methods used in many of the leading factories. The impression gained from a recent inspection of the majority of the leading factories brings the writer to the conclusion that shop practices are becoming more uniform and that, as the industry has advanced, the number of different methods for producing the best work with the attendant expenditure of a minimum amount of time and labor has greatly decreased.

* * *

The large stern frame for the new White Star liner *Olympic* was lately transported from Darlington to Belfast. It weighs 70 tons and measures 68 feet by 22 feet. The traffic on the North-Eastern Railway had to be stopped while the frame was transported by the railroad from Darlington to West Hartlepool, owing to the fact that the width of the frame prevented cars from passing on the adjoining tracks.

AUTOMOBILE FACTORY PRACTICE*

NORDYKE & MARMON CO., INDIANAPOLIS, IND.

ETHAN VIALL†

The Nordyke & Marmon Co. has manufactured flour and cereal mill machinery for nearly sixty years, and in this business is well known the world over. In 1905 the company placed an air-cooled motor car on the market and continued this type of car until 1908. A change was then made to the production of water-cooled motor cars and since then rapid strides have been made in the matter of enlarged and improved manufacturing facilities. At present the company is manufacturing one chassis, known as the "Marmon Thirty-two" (now in its second season), and the parts have reached a standardization that is almost perfect.

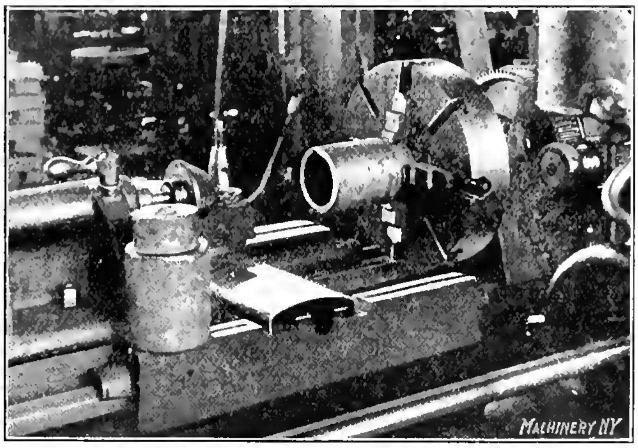

Fig. 1. First Operation on Pistons: Breaking the Inside Edge, Roughing Outside and Cutting Off Chucking Plug

While the shop equipment is not as extensive as in some other automobile factories, it is large and very complete, including modern tools of the best makes. The tool, jig and fixture equipment is unusually good, showing on every hand evidence of considerable skill and ingenuity. Profiting by the mistakes of others, the company has been enabled to cut out a lot of expensive experimenting, so that its car and its shop practice compare very favorably with those of firms who have been building automobiles for a longer period. The general superintendent follows the plan of calling the various

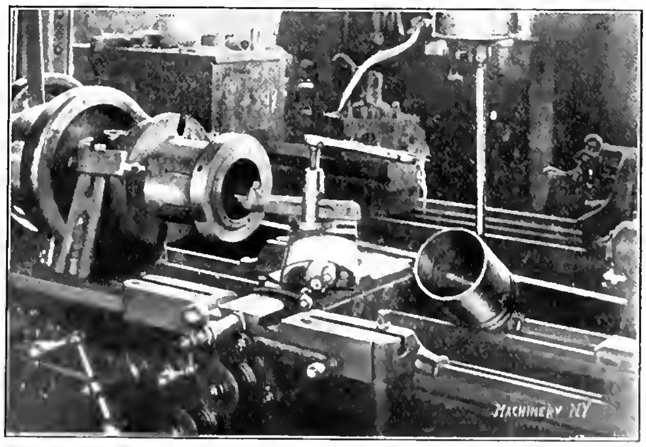

Fig. 2. Second and Third Operations: Boring Inside, Truing Edge, Facing and Centering End

foremen together whenever a new tool or machine is being designed and allowing each one to take a "whack at it," discussing the good or bad points until by the time they are ready to make it, the rough, impractical spots have all been taken off. So as a rule, the tool or machine, when made, works just as desired, without any great change or alteration being necessary, for if there are flaws anywhere, a half dozen or more keen, bright, mechanical foremen are pretty apt to detect them long before they leave the designer's hands for the toolroom. Then, too, the general foreman had been in the automobile business with one of the oldest and largest

* See "Manufacturing Automobile Equalizing Gears" in the December, 1909, issue of MACHINERY, and article there referred to.

† Associate Editor of MACHINERY

concerns in the world from its inception, until he took his present position, and, in consequence, he knows how good tools should be used and how parts should be handled to the best advantage.

A rather unusual, though good plan of the foreman, is to have jigs and fixtures made, when possible, to fit more than one class of machines. For instance, a jig intended for use in a screw machine may also be used in a lathe or a drill-press, or a lathe fixture may be used on a boring mill, or perhaps, in some cases, on a milling machine also. In this way a few machines of one class are not overcrowded while others are idle, because the parts to be machined can easily be placed where most convenient and promptly finished, where otherwise they might be held up for days, as so frequently is the case.

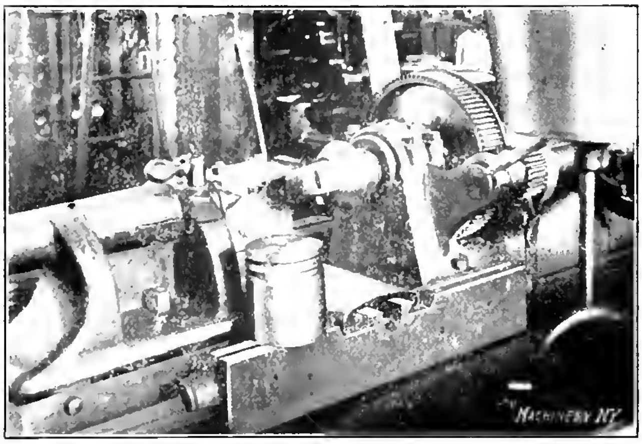

Fig. 3. Fourth Operation: Turning Outside and Cutting Ring Grooves

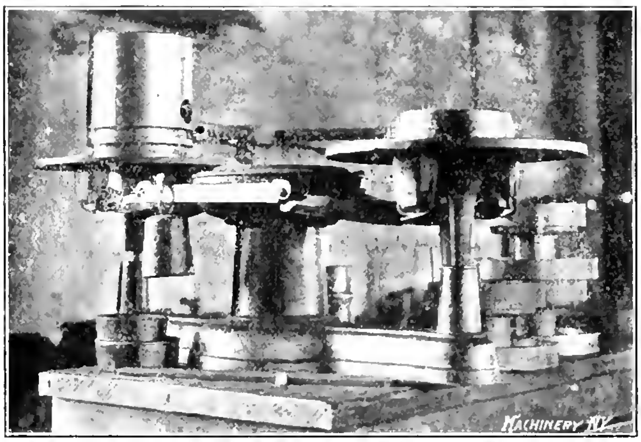

Fig. 4. Scales on which the Pistons are weighed

Everywhere, hand feed is dispensed with if practical, and power feed used. Especially is this noticeable in the drilling operations, and the result is an almost uniform rate of output, which is not true where hand feed is used, as then the rate is highest when the man is fresh and decreases as he tires.

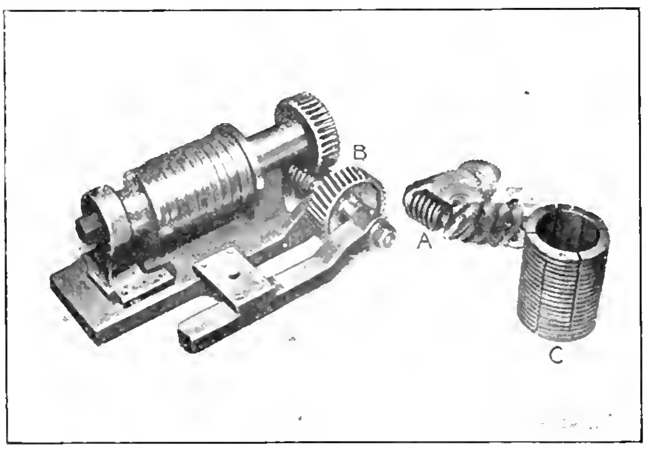

Fig. 5. Milling Fixture and Tools for Cutting off Piston Rings

Piston castings are made with an extension of reduced diameter instead of the usual flange or lugs. They are first placed in a regular lathe chuck as shown in Fig. 1, the inside edge beveled slightly for the large tail center, and the outside rough turned. The casting is then cut off, leaving the extension in the chuck, and placed in the hollow chuck shown in Fig. 2. The inside is then bored out to the wrist-pin bosses; the inside edge trued up; the casting turned end for end; and the closed end surfaced off and centered. The piston is then put into a lathe fitted, as in Fig. 3, with a large center and a floating driver which goes in between the wrist-pin bosses; the grooves are next cut and the outside trued up. From this point on, the piston goes through the processes common to the majority of automobile shops, which have been repeatedly described in these columns. Finally it is brought to a certain weight by testing it on balance scales as in Fig. 4, superfluous metal being removed until it balances.

Piston rings are made by first truing up a cast iron sleeve and then placing this sleeve on an expanding arbor and cutting it into rings with a gang of milling saws. The method is similar to that employed in the Stevens-Duryea shop, as described in the October number, except that here the work is done on a regular instead of a vertical, milling machine, the fixture and parts shown in Fig. 5 being used. In using this fixture, the worm *A* is placed on the arbor with the milling saws and meshes with the gear *B*, causing the expanding arbor to rotate as the cut proceeds. Different expanding sleeves or bushings are provided for the various sizes of piston rings, one of which is shown at *C*. The rings are split straight across by two saws while clamped between the flanges of the fixture shown in Fig. 6. Extra clamping mandrels, like *D*, which fit the table bracket, are used for the various sizes.

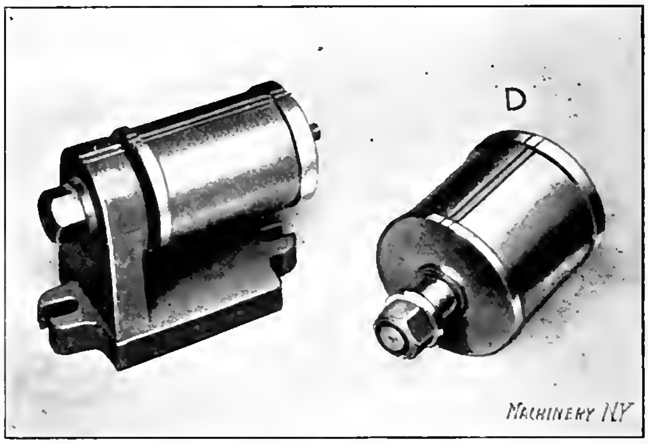

Fig. 6. Milling Fixture for Splitting Piston Rings

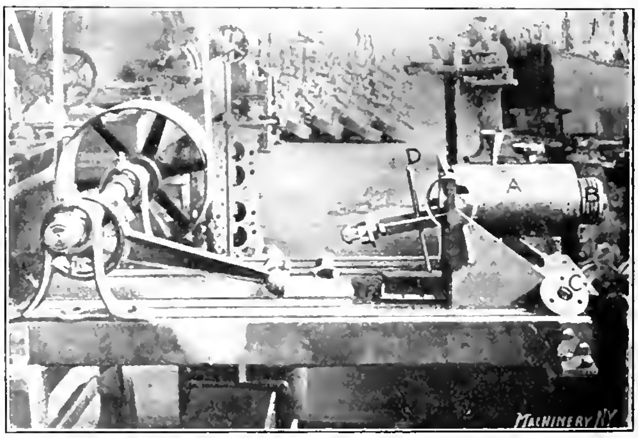

Fig. 7. Piston Ring Lapping Machine

Lapping the Piston Rings

Instead of lapping the piston rings in the engine cylinder in which they are to be used, as is commonly done, the rings are lapped in the machine shown in Fig. 7. The cylinder used is a cast-iron sleeve *A*, which is bored to the exact size of the cylinders, and is easily replaced. The rings are placed on the false piston *B* and held by screwing on the flange *C*, which merely keeps them from coming off the piston and does not clamp them tight enough to prevent their expanding. As the machine moves the piston and its load of rings

back and forth in the cylinder, it is revolved by hand by means of the handle *D*, the connecting-rod joint being made so as to allow the piston to be turned easily. While the operator turns the rings, he feeds emery and oil through the funnels in the top of the cylinder.

Timing the Fly-wheels

Nowhere have I seen a better arrangement for marking the timing points on fly-wheels. Instead of the usual "cut-and-try" method of marking after the fly-wheel is in place, it is here marked before assembling on the shaft. Two of the bolt holes in the center of the fly-wheel are drilled farther apart than the others, in a drill jig, and these serve as guides when placing the wheel on the flange pins of the marking

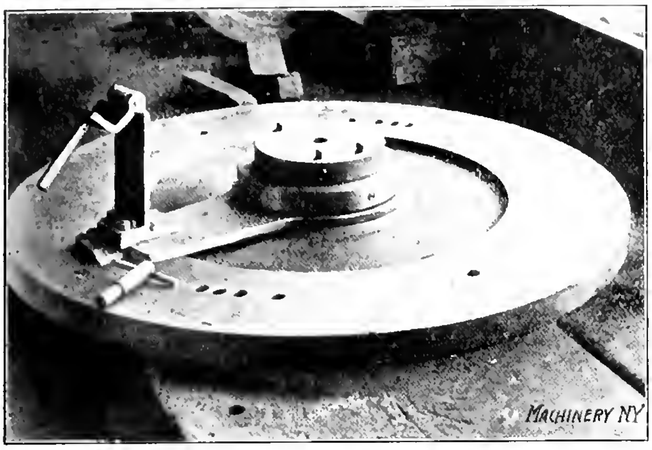

Fig. 8. Fly-wheel Timing Gage

gage shown in Fig. 8, and also make it impossible for the assembler to put it on wrong. The fly-wheel is placed on the gage as shown in Fig. 9 and is, of course, stationary while the arm or marking guide is movable. This arm is set at the various points by a hardened pin passing through its base and fitting into bushed holes in the circular bed of the gage. The respective markings are stamped into the rim of the wheel with steel stamps lettered to indicate: "inlet closed," "exhaust closed," etc.

Balancing Fly-wheels

Fly-wheels are balanced after the fashion of balancing a millstone or a limber cockhead drive by spinning them on the

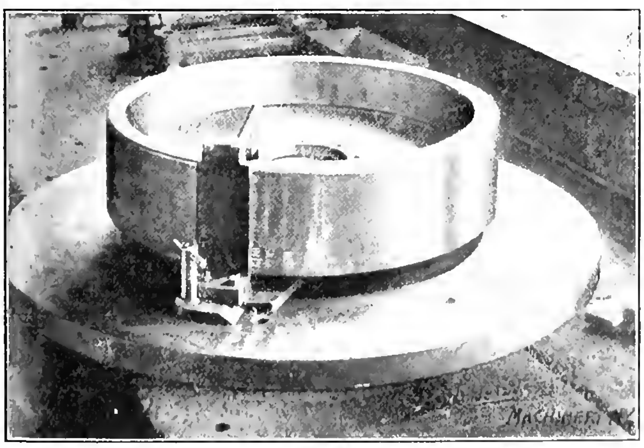

Fig. 9. Timing Gage with Fly-wheel in Position

machine shown in Fig. 10. The rim is marked with chalk and then enough metal drilled out to balance it. An experienced man can tell pretty accurately how much to drill out and where, by the appearance of the marks. Fig. 11 shows how the machine looks with the fly-wheel removed. The flanged center to which the fly-wheel is bolted, is still in place. Fig. 12 shows the machine with this center removed and set up on edge so as to show the bottom of it and the cockeye in the center. The cockhead on which the flanged center rests, and the two drive pins, are also shown. By this arrangement the fly-wheel is given the necessary freedom of movement to enable it to seek its balance while in rapid motion. The wheel is also put in standing balance on the crankshaft.

Rolling Bronze Bushings

The crank ends of connecting-rods are bushed with Parson's white bronze, and the final sizing is done, not by reaming, but by rolling with the tool shown in Fig. 13. The connecting-rod is held in the jig shown, which has a guide bushing

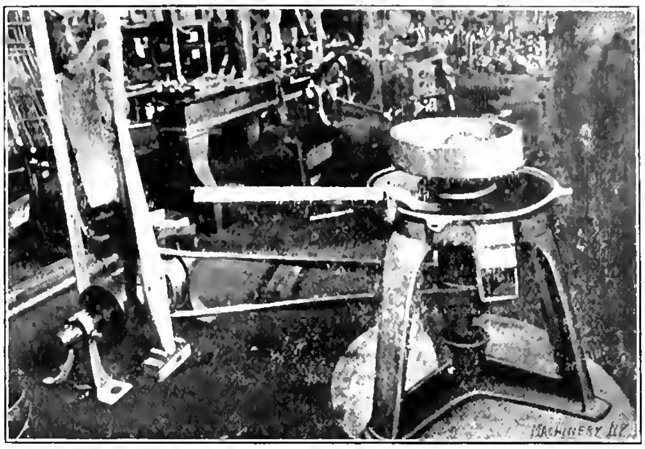

Fig. 10. Fly-wheel Balancing Machine with Wheel in Place

in the bottom for the pilot of the roller tool, at the right. This tool is so made that it may be adjusted for size, to a limited extent. The rollers are highly polished, hardened steel rollers with rounded ends, held in place by a cupped retaining ring at each end and supported by the steel center of the tool body. Not only does this tool give an excellent

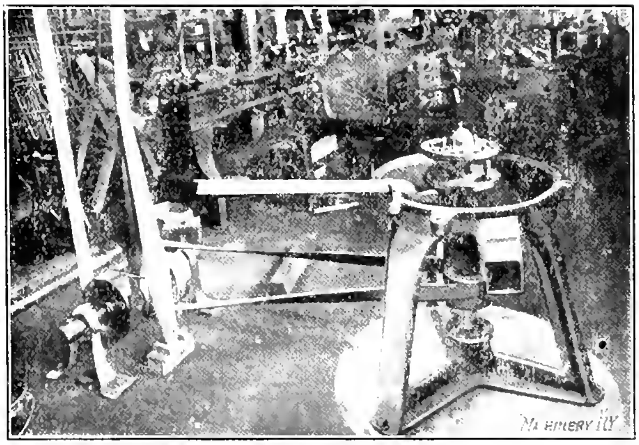

Fig. 11. Balancing Machine with Wheel Removed

finish to the bearing surface, but it also presses the metal firmly into place. Through an oversight, an unbushed connecting-rod was used when photographing, but the connecting-rod shown on the balancing device (Fig. 14), shows the style of bushing used. This device was made for balancing

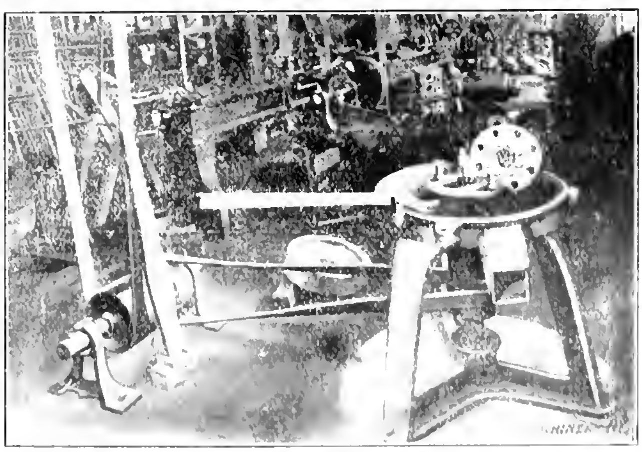

Fig. 12. Balancing Machine with Floating Disk Removed

connecting-rods so that the weight would be properly distributed.

Casting Bronze Ends onto Steel Axles

Phosphor-bronze ends are cast on the pressed steel rear axles, which prior to this operation appear as in Fig. 15. The

casting is done by standing them on end in a mold and pouring molten phosphor-bronze around the ends; they then appear as in Fig. 16, the bronze castings being shown with runners and risers still in place. As a rule, in fusing one metal onto another, considerable extra metal is run through the mold, but in this case it is not necessary, as a perfect union takes place between the tubular steel axle and the

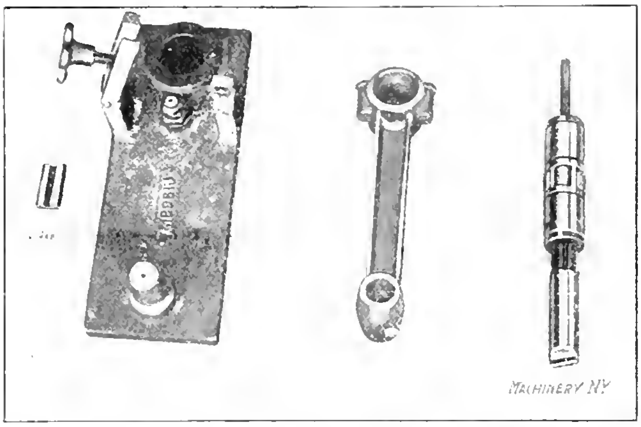

Fig 13 Rolling Tool and Chuck for Sizing Bronze Connecting-rod Bushings

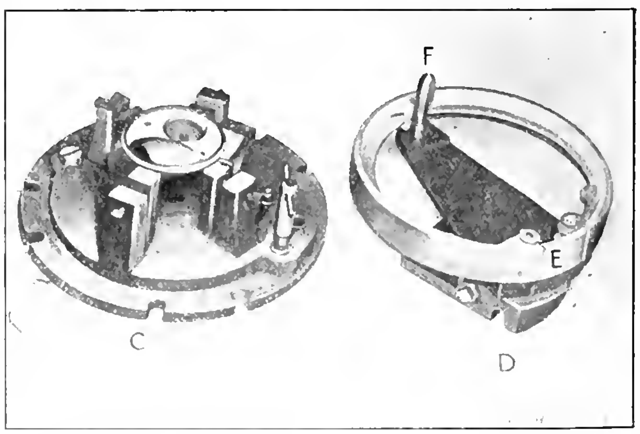

Fig 19 Fixtures used in Surfacing Part of Muffler and Cutting Brake Band

bronze without extra metal other than shown. After one end has been cast on, the axle is reversed and the other end ...ked in a fresh mold and cast as before.

Turning Balls

...e simplest ball turning tool imaginable is shown in Fig. ... It consists simply of a hardened cylindrical piece of steel ... to a shank for the tool-post, as illustrated. The hole ... cutter is just the size of the ball wanted, and it is notched on one side just enough to go over the ball arm nicely. The forging on which the ball is to be finished, is held in a chuck with formed jaws, and the tool is fed straight onto the forged ball, cutting it to size quickly and smoothly and leaving no teat on the end, as so many other tools used for this purpose do. No rake is necessary on this tool, but it should be ground perfectly square on the end, which can easily be done by holding the end against the side of an emery wheel if no other means is at hand. This tool is, of course, only used for finishing or smoothing up balls already formed, such as forged ball-cranks, ball-levers or parts of universal joints, and it is not intended for cutting balls from the solid.

At A, Fig. 18, is shown an indexing jig for holding the body

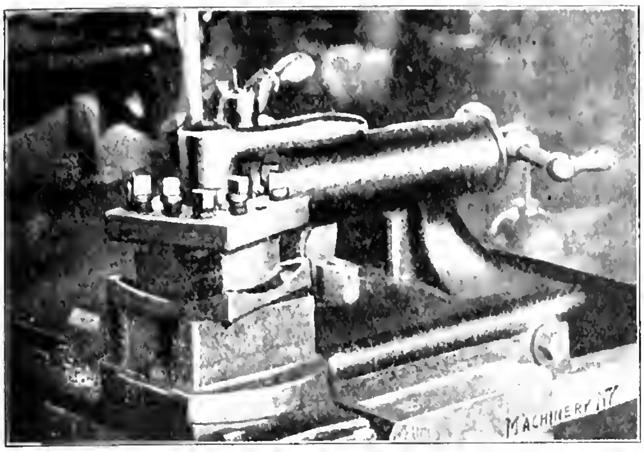

Fig. 20. Lathe Turret Tool-post for Holding Four Tools

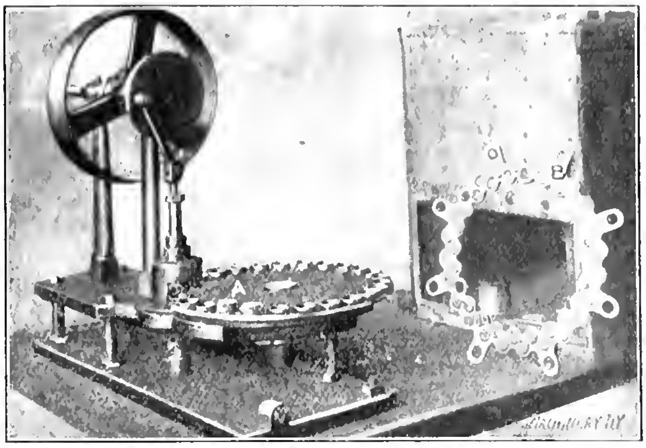

Fig. 21. Friction Disk Cork-inserting Machine

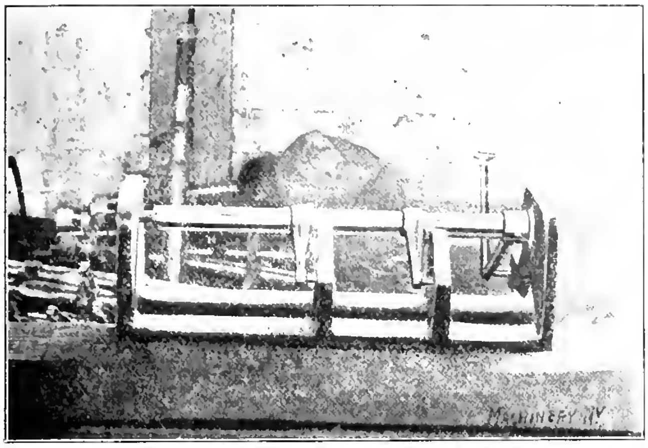

Fig. 22. Jig in which Foot-lever Pin-holes are drilled

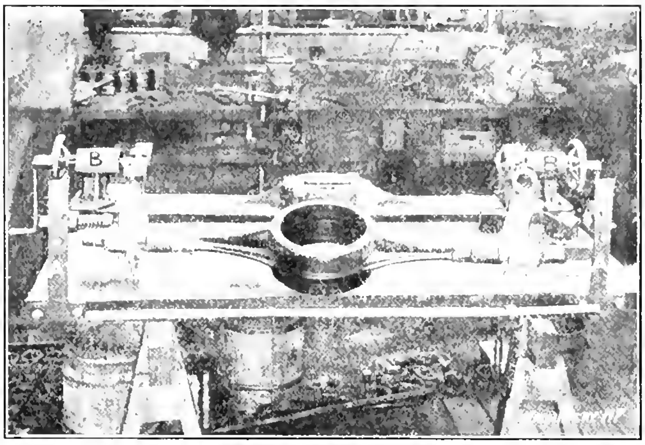

Fig. 23. Centers for Testing and Reaming Rear Axles

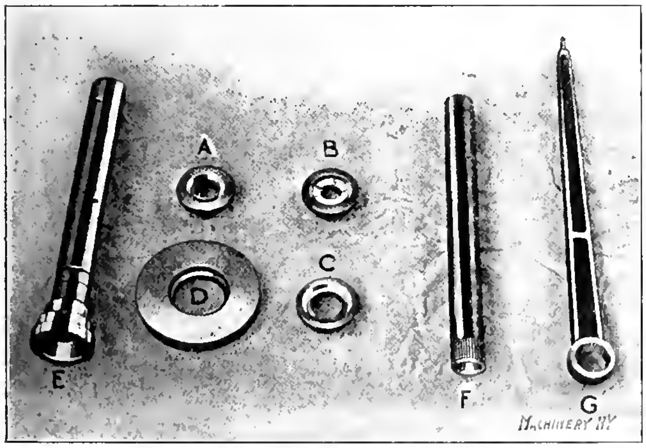

Fig. 24. Tools for Corrugating Ends of Shafts, and Sample of Work

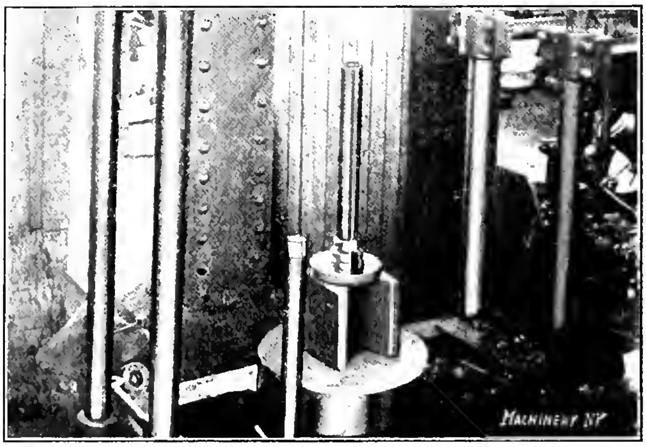

Fig. 25. Hydraulic Press in which Shaft Ends are corrugated

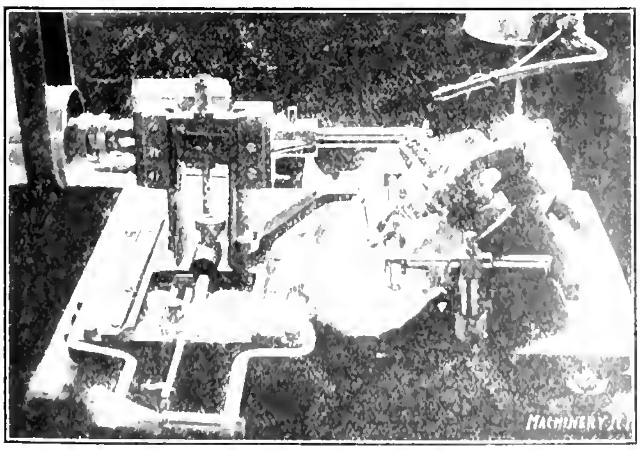

Fig. 26. Change Gear Tooth-chamfering Machine

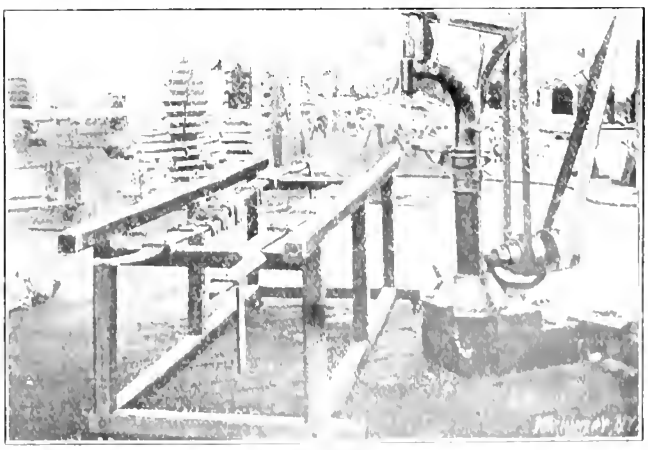

Fig. 27. Frame [illegible] Stand and Jigs

of a small oil gear-pump while facing it off and boring out the recesses for the gears. The indexing of the work from one center to the other is common enough, but the method of clamping the casting in the jig (which is plainly shown) is not so well known, though it is very effective and leaves no parts projecting above the surface of the casting to interfere with the tool. At B is another indexing jig used to hold change gear lever quadrants while milling the ends with an

end mill. In Fig. 19 the jig *C* is another application of the indexing idea for turning two circular parts not concentric. The part shown is the cast-iron end of a muffler drum. Owing to the irregular shape of part of the casting, it is rather a difficult piece to hold, as the only regular part on it is the thin flange, the upper part of which must be turned. The clamping bas been successfully accomplished, however, by using "posts" on the upper, inner edge of which has been turned a shallow L-shaped circular groove, into which the flange of the casting fits. These posts, though of cast iron, will stand a certain amount of springing and are tightened onto the rim of the casting by means of the set-screws in the

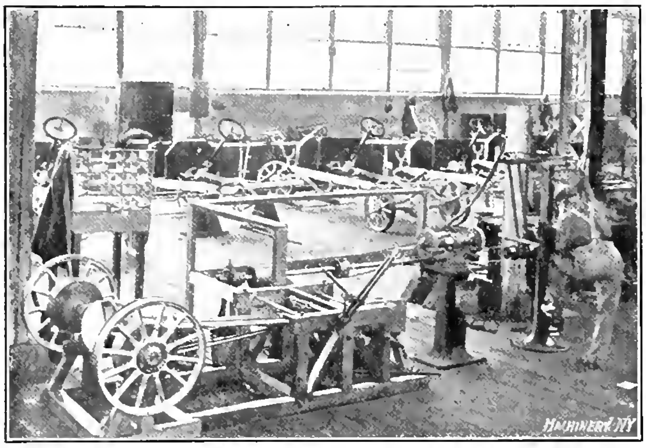

Fig 28. Assembling Stands for Rear Axle Mechanism

heavier posts back of them. The jig *D* is used to hold brake rings while sawing out the part *E*. The cuts are taken as indicated in the engraving. As they are radial, only one milling saw is used. After the first cut is made, the handle *F* is moved over against the other stop for the last cut.

Many of the lathes in the shop have been fitted with the handy four-tool turrets shown in Fig. 20. Rockers are fitted to the bottoms of the holders to center the tools properly. These turrets save tool changing and the consequent annoyance and delay on many lathe jobs.

Formerly the clutches on Marmon cars were made with cork inserts. While this type of friction disk is no longer used here, the machine used to put the corks into the disks will be of interest because of its simplicity and the rapidity with which it did the work. Guide plates like *A* (Fig. 21), with flaring holes in them corresponding to the holes in the

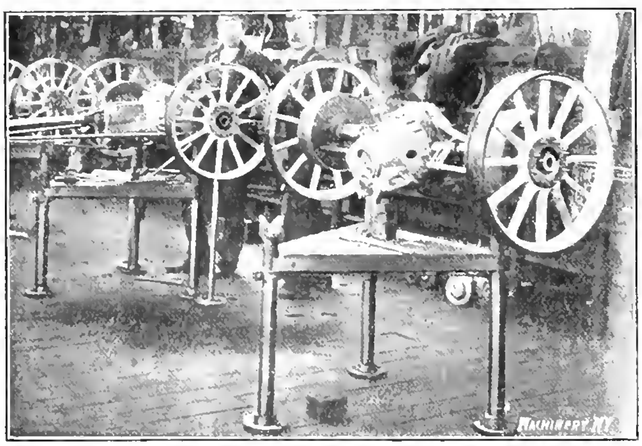

Fig 29. Apparatus for Testing Rear Axle Mechanism

friction plates into which corks were to be inserted, were used, and corks were placed into these holes and automatically fed under the plunger which pushed them down into the disk beneath. A friction plate with a double row of corks, is shown at *B*, but these were put in by using a taper tube and hand punch, none of the style for which the machine was intended being in stock.

Fig. 22 is a jig for holding foot levers in the proper position on the shaft while drilling and pinning, previous to brazing.

Fig. 23 shows a fixture used for testing rear axles and center reaming them. At *A*, *A*, are the centers on which the axle is spun when it comes from the foundry after having the bronze ends cast on, in order to see if it is straight enough for turning. If it isn't, it is sprung or bent into correct alignment before it is strapped into place at *B*, *B* and the ends center reamed, ready for turning in a lathe.

Instead of keying or just pinning levers onto the ends of the rocker-shafts in the usual way, all end levers have the hole corrugated and are pressed onto the corrugated end of the shaft and then pinned. The hole in the lever is corrugated by broaching, and the shaft ends are made to correspond by using dies like *A*, *B* and *C*, Fig. 24. A die of the right size is placed in the collar *D*, and the end of the guide tube *E* is placed on top. The shaft is then forced down the required distance through the die, in a hydraulic press, as shown in Fig. 25. A shaft and lever is shown at *F* and *G*, respectively, in Fig. 24.

Sliding gears have the ends of the teeth chamfered in the semi-automatic machine shown in Fig. 26. In this machine the feeding is done by hand, but the indexing is automatic, the gear being moved one tooth as the feed lever is drawn back.

Frame sides are drilled while clamped to the stands shown in Fig. 27, the drill jigs lying on top of the stand being used.

The stands used while assembling the rear axle mechanism, which in this case includes both the change gears and differential, are shown in Fig. 28, and in Fig. 29, is shown the apparatus used to test out the assembled mechanism. A very thorough try-out is given the various parts before allowing them to be placed in a machine.

NEED OF A GOOD APPRENTICESHIP SYSTEM

J. F. RICHMAN*

Every day finds us getting farther and farther away from a satisfactory solution of the apprenticeship problem. In this age of high speed and rapid production, the heads of manufacturing companies have neglected this one important stone—the foundation of the future army of mechanics. Only about one man in fifty applying for a position, can truthfully say that he is an all-around machinist. The employers are not entirely to blame; employes are responsible to a greater or less degree (judging by years of experience) as the following illustration will show:

Sam has served his apprenticeship and worked as a journeyman for fifteen or twenty years, and is capable of doing any job in the factory; on account of his skill and industry, he is given a job on the milling machine at a rate of 35 cents per hour. Joe comes in from the farm and is put on a similar machine and rated at 17½ cents per hour. In three or four months Joe goes to his foreman and demands a raise. The foreman remonstrates with him on account of his inexperience. He replies, in a sort of braggadocious style, "Well, I am doing as much as Sam and he is getting 35 cents," and he threatens to leave. The foreman, rather than break in a new man, grants him the raise. In a few months the same process is repeated, until Joe is receiving the same amount as Sam. Then Joe requests a change, but is informed that he has no practical knowledge of other machine tools. Joe is aware, by this time, that he cannot command 35 cents except on a special class of work, and is not willing to work for lower wages; consequently he remains a milling machine hand all his life.

The writer has seen many such cases and has them under his supervision. On the other hand, manufacturers have found that when a man is kept on one job continually, he can accomplish better results than an all-around man working on all types of machine tools, and making no one a specialty. For this reason they desire to make specialists as much as possible.

I would like to ask the mechanical world where we are going to get our foremen, superintendents, and managers in the future? It is true that the technical man is coming to the front; but he, too, must have the practical experience, as well as the support of the well-trained, all-around mechanics.

THE UNITED STATES CREAM SEPARATOR

ITS DESIGN AND MANUFACTURE

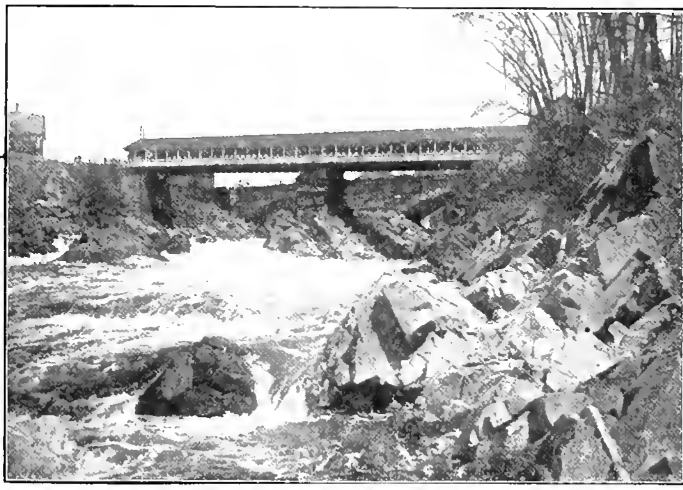
RALPH E. FLANDERS*

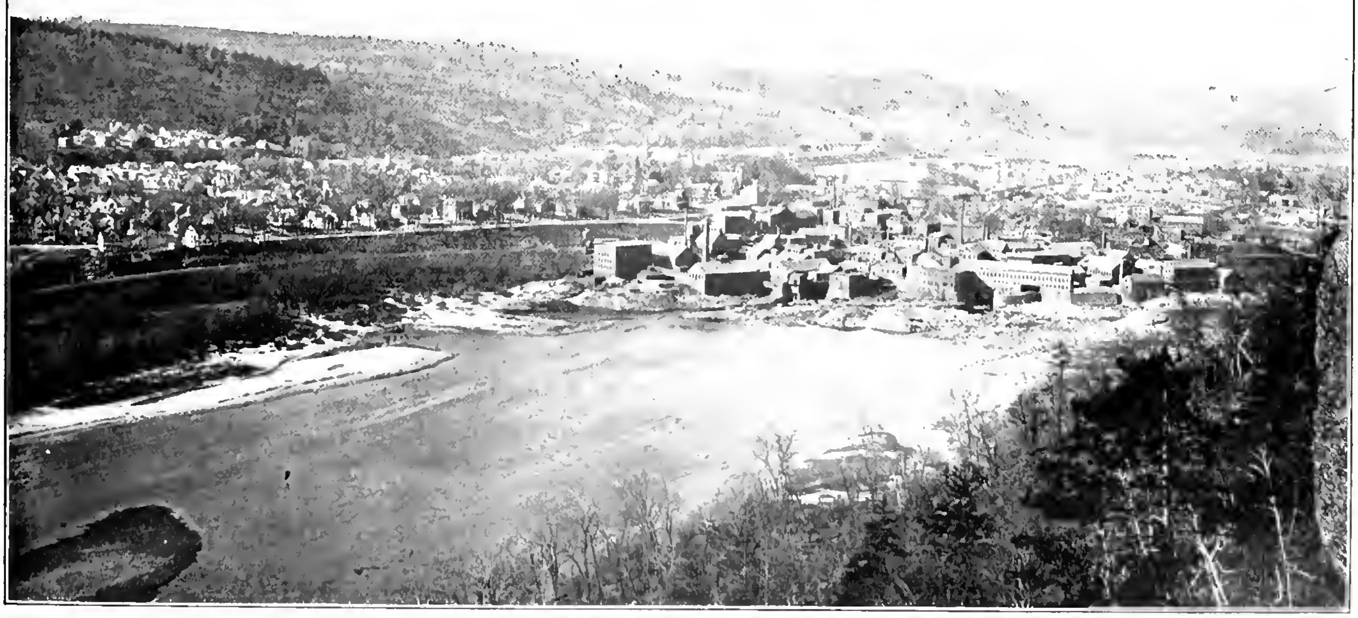
The village of Bellows Falls, Vt., was foreordained by Nature, when she laid out the geography of New England. For the past forty odd miles the Connecticut River has been pursuing a placid and unobstructed course, but here it finds the way barred by an outcropping ledge, set like a dam, between high hills on each side. Over and through this ledge the water has worn a rough, crooked passage. The first pulp mills were built here many years ago, the owners being drawn by the fine water power, and by the vast drives of spruce logs, which each spring are floated from far-away forests on the Canada border, to mills in this and other towns nearer the centers of civilization.

The town is famous for its bridges, as well as for its pulp mills. The latter are located on an island between the main bed of the stream and the power canal, which at ordinary times carries the greater part of the flow. Means of communication have to be provided to reach this island from both sides. Furthermore, the town is an important railroad center. The main Connecticut valley line of the Boston & Maine R.R. crosses the river here, the station being located on the island. An important branch of the Fitchburg division climbs down from the hills on the New Hampshire side, while a main line of the Rutland Railroad climbs up into the still higher hills of the Vermont side. All these lines of transportation, with the local electric car line, require no less than sixteen bridges in the little one-quarter mile square space about the island.

Among these bridges may be found fine examples of almost every one of the important types in use. Spanning the river above the island is shown, in Fig. 1, a famous two-hinged arch which was described in the various civil engineering papers at the time of its erection a few years ago. In Fig. 2 are shown two older examples, the one in the rear being a solid masonry arch, while the one in front is an excellent example of the interesting structures found the whole length of the Connecticut valley, built by local "bridgewrights" as they may be called. This one has a lattice frame and a central pier, and is built of timber. Others of these homemade bridges have Howe truss frames, while still others combine the lattice frame with a wooden arch as a reinforcement.

The writer has seen bridges of this kind in which not an ounce of iron was used. All the joints were mortised and tenoned, and fastened with wooden pins. The floor boards were pegged to the beams. The roof boards were pegged to the rafters, and even the hewn shingles were fastened in the same way. Perhaps the longest of these Connecticut River bridges is the one at Springfield, Mass., which many readers of MACHINERY must have seen. Some one has compared them to huge caterpillars crawling across the stream. Anyone who has seen one of them from the distance, with its long, dark and oftentimes crooked body, its stumpy legs resting in the flowing stream, will appreciate the aptness of the comparison.





Figs. 1 and 2. Bellows Falls, Vt., Famous for its Pulp Mills, Bridges and Cream Separators. Two Examples of Bridge Construction. The Homemade Toll Bridge and the Masonry Railway Bridge

The United States Cream Separator

All this is digression, however. The chief thing of interest to the mechanic in Bellows Falls, is the plant of the Vermont Farm Machine Co., whose best known product is the United States separator, used by farmers throughout the country for separating milk into cream and skimmed milk. Through the kindness of the management the writer was permitted to visit the shop and study the various operations which go

* Associate Editor of MACHINERY.

into the making of their product. The work done here proved to be of such interest as to suggest the writing of this article.

Mechanics in the past hundred years have added tremendously to the productiveness of the individual farmer. The mowing machine, the reaper, the threshing machine, the portable engine and other tools have enabled him to cultivate tens and hundreds of acres with better care than he could formerly give to one. The cream separator is a later addition to this list of farm machinery. It has only come into common use

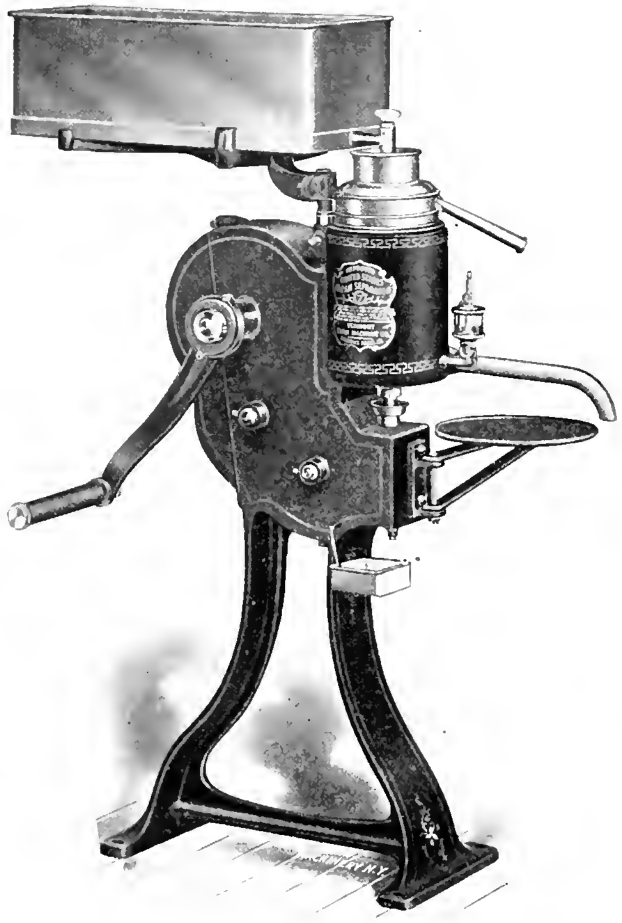


Fig. 3. The United States Cream Separator

in the past twenty years and is still in process of improvement. It enables the farmer to separate the cream immediately after milking, without waiting for the slow and uncertain influence of gravity. The cream is skimmed much cleaner than by the old process, leaving less of it in the milk. The thickness of the cream is under absolute control and is of a better quality, being cleaned from the dirt which is almost sure to find its way into the milk pail. It leaves the skimmed milk fresh and in the best condition to feed to growing cattle.

All these are agricultural features, however. From a mechanical standpoint the separator is interesting because it requires the highest grade of work of any machine used on the farm, being on a par in this particular with the best grade of machine tools. At the same time it has to be so designed and constructed as to be used by people comparatively unskilled, without danger of seriously injuring the mechanism. The important points of durability and easy replacement of parts in case of breakage must also be provided for.

Description of the Separator

The United States separator is shown in elevation and section in Figs. 3 and 4. The milk is emptied into pan *A*, from which it flows through a faucet into the feed cup *B*. A float in this feed cup, entering the faucet, serves to regulate the flow so as to keep an even level in the cup and a consequent even rate of flow through the machine. From *B* the milk passes down into a rapidly revolving bowl *C*, whose construction will be described later. Here the cream is separated from the skimmed milk, the former leaving the machine at *D* and the skimmed milk through spout *E*. The bowl is revolved at some 8,000 or 9,000 revolutions per minute by power, or, as in the case shown, by hand-crank *F*. This drives the train of gearing shown. The last member of this train is the worm-wheel *H*, which, contrary to the usual office of the worm-wheel, drives the steep pitch worm *J*. This worm is cut on the spindle of the bowl which thus receives its rapid motion.

The gears run in a bath of oil which lubricates all the teeth and all the bearings. The easy running of the machine is naturally of extreme importance. The bowl is geared up from the handle in the ratio of about 150 to 1, and with this tremendous increase a slight amount of friction will mean a great difference in the amount of work imposed on the operator. This is one of the points which necessitates very careful work in the construction of the machine. So well are the gearing and journals made and fitted that the weight of the handle will start the bowl in motion.

The bowl and spindle rest on a thrust bearing *K* in the base, formed of a single hardened ball between the hardened stationary and revolving thrust faces. A compressed felt cushion under the lower face supplies elasticity to prevent undue shock. The crank *F* drives shaft *G* by means of a ratchet which permits the bowl to be revolved only in one direction. If it were attempted to drive it in the other direction, there would be a tendency for the bowl to unscrew from the worm and lift out of the frame. The same tendency would be met with if the handle were rigidly fastened to the shaft and it suddenly met with an obstruction, stopping the movement of the train of gears. The ratchet prevents damage

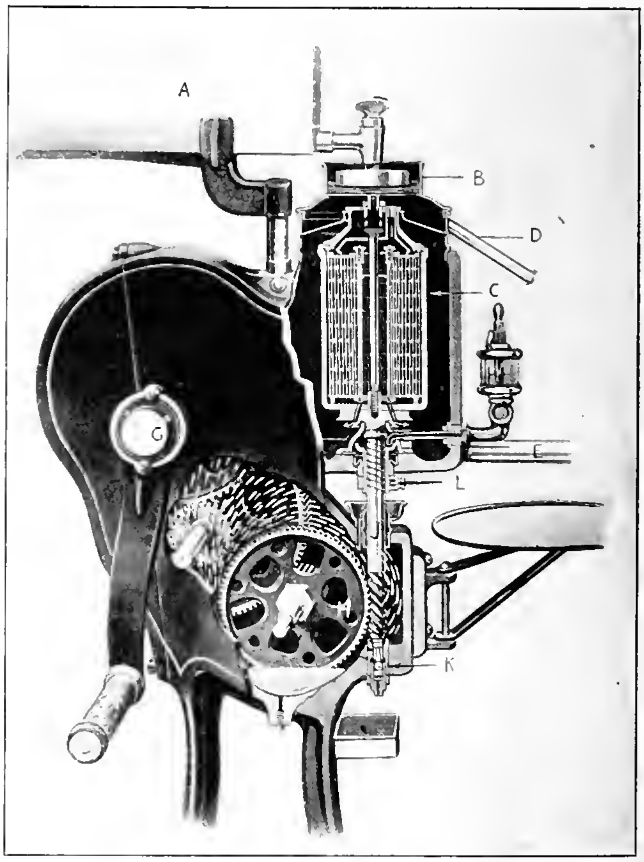

Fig. 4 Mechanism of the United States Separator

from these causes. When the machine is stopped, the bowl and its connected spindle may be easily lifted out for cleaning.

Worm-wheel *H* revolving in the bath of oil, lubricates all the gears and bearings of the train, as well as the worm and step-bearing. The upper neck bearing, *L*, of the spindle, is oiled by a sight-feed lubricator, and is held in a central position by an elastic steel washer, whose compressing effect may be increased or diminished by means of the thumb-screw shown. This adjustment of the spring washer makes provision for steadying the spindle under varying conditions of running balance.

How the Cream is Skimmed from the Milk

In the centrifugal machine the cream is separated from the milk very much faster, but in exactly the same way that it is done in a pan on the "swing-shelf" in the cellar—that is to say, the cream rises to the top because it is lighter, while the milk globules sink to the bottom because they are heavier. The sole function of the separator is to hasten this process by intensifying the force of gravity and by making it a continuous operation, automatically skimming the cream as fast as it rises to the top. The way in which it does this will be understood by reference to Fig. 5, where is shown a section

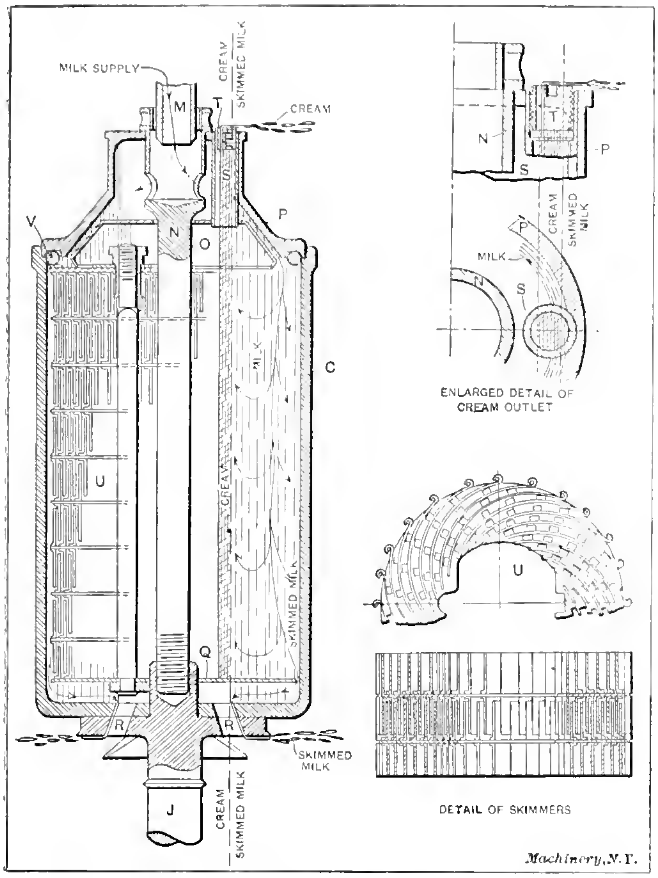

Fig. 5. The Bowl of the Separator, showing the Flow of the Skimmed Milk and Cream

through the bowl. All the parts shown revolve at a high rate of speed with the exception of the stationary nozzle M for the milk.

It was said that the separator is a machine for intensifying gravity, thus hastening the rising of the cream. In the bowl shown, which is 3⅜ inches inside diameter, and revolves normally at 9,000 revolutions per minute, the centrifugal force at the outside edge would be

$$\frac{0.000341 \times 1^{11}/_{16} \times 9{,}000^2}{12} = 3{,}880$$

times the forces of gravity—in other words, an ounce located at this point would weigh 3,880 ounces. This result is obtained from the regular formula for centrifugal force.

Now this centrifugal force acts horizontally, and it so far surpasses the vertical force of gravity that the milk stands in a vertical wall against the side of the bowl, forming a hollow cylinder within it as shown at the right side of the bowl section in Fig. 5. A section at the left of the center line is shown with the skimmers in place. These, as will be explained, intensify the action but do not alter the principle.

In Fig. 5 the milk enters through a nozzle M, into the hollow top of the cover bolt N, and out through the side holes into the cover P. From here it passes through the narrow space between the cream chamber O and the cover into the main body of the milk within the bowl. Here, having attained the speed of the bowl, the centrifugal force begins to separate the cream globules from the milk as has been described, the former moving toward the center, and the latter settling close to the shell of the bowl as shown by the separating arrows. The skimmed milk passes downward through the bowl, and around the outside of diaphragm Q, which evidently prevents the escape of cream, since none of the light fat globules will be found at the outlet passage, so near the periphery. From the space below the diaphragm Q, the skimmed milk finds an outlet through the drain holes R, from which it is thrown outward against the casing in which the bowl revolves, running out through tube E in Fig. 4.

It will readily be seen that the distance of holes R from the center determines the inside diameter of the hollow cylinder of milk and cream. The inside diameter above diaphragm Q is smaller than that below, owing to the fact that there is no cream in the lower space. This layer of cream, prevented from escape at the bottom, spreads over the whole inner wall of the cylinder of milk, reaching up through the cream tube S above cream chamber O. The upper end of this tube is closed by cream screw T, which has drilled through it a small eccentric hole. Through this hole the cream is thrown out against the inner wall of the cream pan and its cover, from which it is drained by the cream spout D in Fig. 4.

The purpose of the eccentric hole in the cream screw T is to control the thickness of the cream. By turning this screw the outlet hole may be brought closer to or further away from the center, draining the cream either at the inner stratum, where it is thickest, or at a larger diameter, where it begins to be more diluted with milk. A very slight change of this screw will make a great difference in the consistency of the cream. It is to be understood, of course, that the machine takes practically all the cream, in any case, but it will take as much milk with it as may be required to give the desired consistency. Too thick cream is difficult to handle and unsatisfactory to use.

This whole process of continuous separation will be understood more clearly, perhaps, if Fig. 5 is turned a quarter way round, so that its right side becomes the bottom of the

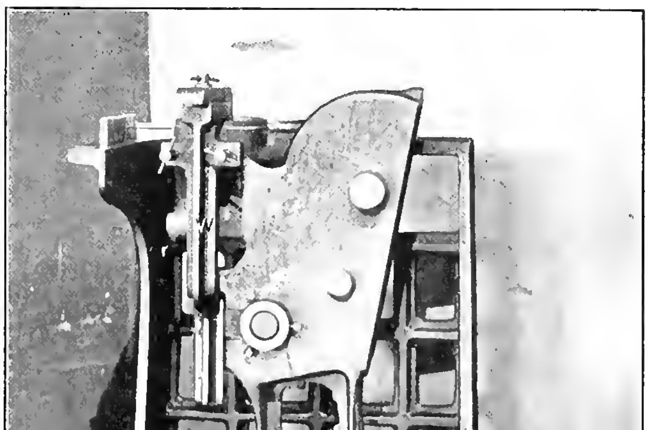

Fig. 6. Lining up the Frame in the Cradle which holds it for the Various Drilling and Finishing Operations

view. If then it be considered that the layers of cream and milk be acted on by gravity, or by a similar force many times as great, it will be seen that the milk flowing in through tube M, through the bowl and under diaphragm Q and out at R, becomes separated from its cream, the latter escaping at tube S.

Details of the Bowl Construction

The machine as just described, works very much as the earliest forms did. It is found by experiment, however, that the capacity and clean skimming qualities of the machine can

be greatly improved by filling the space between diaphragm *Q* and cream chamber *O* with a series of guides or "skimmers," *U*. These skimmers serve three purposes. First, they rapidly bring the cream up to the velocity of the bowl; second, they encourage an even, steady flow of milk through the machine without stagnant areas, guiding the milk outward and toward the bottom and the cream inward and toward the top; and third, they so prolong the passage of the milk that it is thoroughly subjected to the action of this separating centrifugal force, so that the cream is more thoroughly removed.

The form of skimmer used in this machine is shown in place in the bowl at the left of Fig. 5, and in detail at the right of the engraving. The whole space between *O* and *Q* is filled with these skimmers, which interlock with each other, as shown, in such a way as to double the number of milk passages, thus increasing the tortuousness of the flow and making the separating action more efficient.

A point in the construction of this bowl which should be noticed is the method of packing the joint between the cover *P* and the bowl *C*. After the skimmers *U* have been placed in the bowl, rubber ring *V* is loosely laid on the upper one and the cover *P* is placed on top of this, making a metal to metal joint with *C*, and enclosing the ring in the groove shown. Cover bolt *X* is next tightly screwed in place with a spanner wrench, clamping *P* and *C* fast together. This, however, would not make a tight joint against the enormous centrifugal pressure. It remains for the rubber ring *V* to do this, under the influence of the centrifugal force, which, at high speed, causes the ring to hug tightly into the joint, effectively preventing the escape of milk. The higher the speed and the higher the consequent milk pressure, the more effectively will the ring make the joint, thus sealing it against the escape of milk.

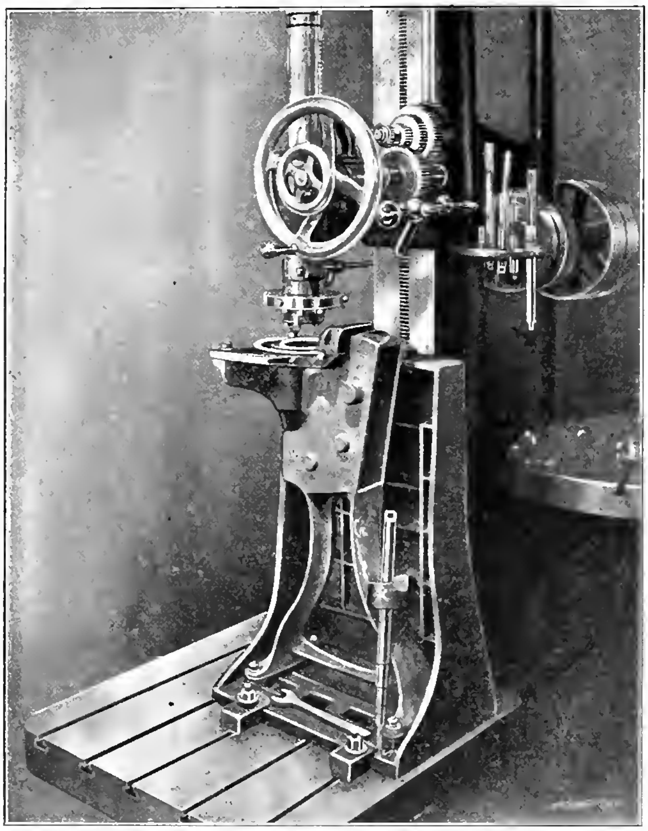

Fig. 7 Machining the Holes and Cylindrical Surfaces about the Axis of the Bowl and Spindle

Machine Work on the Frame

As intimated, a study of the manufacturing methods employed at this plant gives one a very high regard for the quality of workmanship required for making these separators. It is out of the question to describe all the operations involved, so certain of the more interesting ones have been selected as examples of the remainder of the work.

In Fig. 6 is shown a fixture used for lining up the work. Several of these fixtures (or "cradles" as they are locally called) are provided. A man is continuously engaged in setting the work up in these cradles, so that all the holes and surfaces will machine out. For this purpose he uses various height gages, squares, scratch gages, etc., locating from the finished surfaces of the cradle, using as well the special tool *W*, which shows how to get the proper relation between the spindle and the worm-wheel shaft, with the proper amount of finish around the hubs. One man is thus engaged in laying out the work continuously, while other men perform the drilling operations. While this is a practice which has often been mentioned and universally commended, this is the first time that the writer ever remembers having seen it in actual use.

After thus being lined and set up in the cradle, the frame, still mounted therein, is carried through the various drill-press operations required to finish it. The first of these is the machining of the holes on the axis of the bowl and spindle. This is done on a drill press, as shown in Fig. 7, with various special cutter heads, boring bars, etc., carefully supported and strongly driven to secure proper alignment. The head shown in place on the machine is cleaning out the inside diameter of the bowl casing and finishing the edge or rim. Roughing and finishing tools, both mounted in the same head, follow each other in this operation. Boring bar *X* is provided with the necessary cutters for boring the various surfaces of this axis at one cut, thus giving assurance of their true relation to each other.

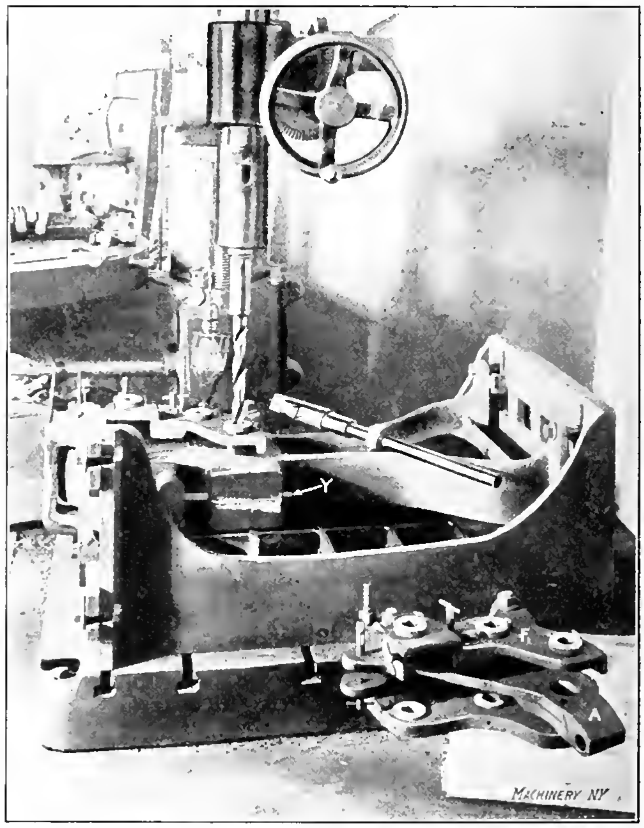

Fig. 8. Drilling, Reaming and Counterboring the Bearings for the Gears

In Fig. 8, the frame, still mounted in its cradle, is shown laid on its side and having the shaft holes for the driving gears drilled, reamed and counter-bored. One of the jigs for doing this is shown dismounted from the work at F_1 in front of the cradle. This jig has a central tongue *A*, entering the opening in the side of the frame, and provided with a hole through which passes the arbor *Y*, shown in the frame being machined. This arbor, fitting in the spindle bearing holes in the frame, locates the jig, and with it all the centers of the gearing train, in proper relation with the spindle. The counter-boring bar *Z*, as shown, is used for facing the hubs for the gear shafts, being fed down on them for cutting on the upper side, and drawn upward with the cutter reversed for finishing on the lower side.

After these operations have been completed, together with one or two more of less importance, the frame is thoroughly inspected. The outfit for doing this is shown in Fig. 9. Mounted on the axis of the spindle bearings is shown a sensi-

tive test indicator B_6 attached to the end of arbor A_6. By revolving this arbor, the test indicator tells whether or not the spindle bearing holes are concentric with the finished surfaces at the upper end of the bowl casing. By the use of a series of multiplying levers on the same arbor, it is also possible to use the same indicator for finding out whether the lower spindle bearing holes are in line with the neck bearing at the lower end of the case.

The center distances for the gearing are also carefully tested by means of gages like that shown at C_6. This consists of a strap with a fixed plug at one end and a movable plug at the other. With the fixed plug in one hole, it should be

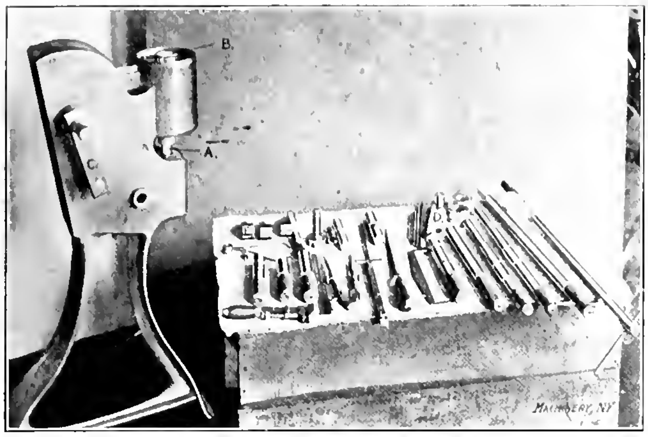

Fig. 9. Tools used by the Inspector in testing the Work done on the Frames

possible to push a standard plug through the other end of the strap into the hole in the casing, if the drilling and reaming has been done properly. This is tested on both sides of the frame, and a similar strap is provided for the second gear reduction, as shown at D_6. Various other plugs, test arbors, etc., are shown. The gage at E_6 is mounted on an arbor passing through the worm-wheel bearings. When swung up and down, it must just barely touch a corresponding arbor placed in the spindle bearings.

Machining the Spindle

The spindles of this machine are made of high carbon steel drop forgings, and are roughed out on the Potter & Johnston automatic chucking machine. It might seem at first as though this would be an impossible job, but the machine has been equipped with special tools which make the operation quite practicable. The spindle (see J, Figs. 4 and 5) is first held

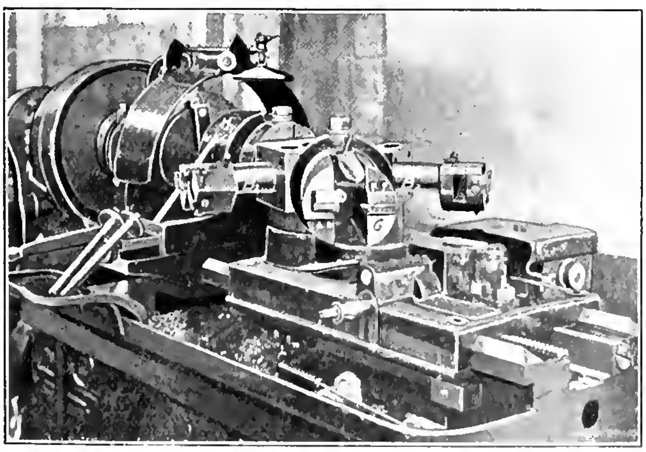

Fig. 10. Rough-turning and Centering the Spindles on the Potter & Johnston Automatic Chucking Machine

in the chuck of the machine by its stem while the flange end is machined. This is a commonplace operation for the automatic. The second operation, shown in Fig. 10, is more unusual. The finished flange of the spindle is held in the chuck with the tail of the work projecting forward. In the turret of the machine are mounted two sets of two tools each, a finished piece of work being delivered at each half revolution of the main cam drum.

The tool at work in the illustration is identical with that shown at G_6, which will perform the same operation on the next piece placed in the chuck. This is a turning tool which commences at the chuck end of the work and feeds outward. The purpose of taking the cut in this way is to permit back resting from the beginning of the cut on the finished diameter left by the first operation, and at the same time to obtain the better results expected in feeding outward on a slender piece, as compared with what would be obtained by feeding against it.

To produce the desired result, the back-rest and cutting tool are mounted on swinging jaws in the heavy holder shown. These jaws are normally held outward by a spring so that they pass over the work freely, when being brought up to the cutting position next to the chuck. When they have arrived at this position, however, both follow rest and blade are closed in onto the work by two special cross-slides (one slide is shown at H_1) which are given the form of one-half bearings, and encircle the finished cylindrical surfaces on the outside of the jaws of the turning tools. The movement of the two cross-slides toward the center, to bring the blade down against the work, is effected by a right- and left-hand cross-slide screw operated by a modification of the regular cross-slide cam mechanism. After the shank of the spindle has thus been rough turned, the second tool, B_6, turns the small diameter at the outer end and centers it.

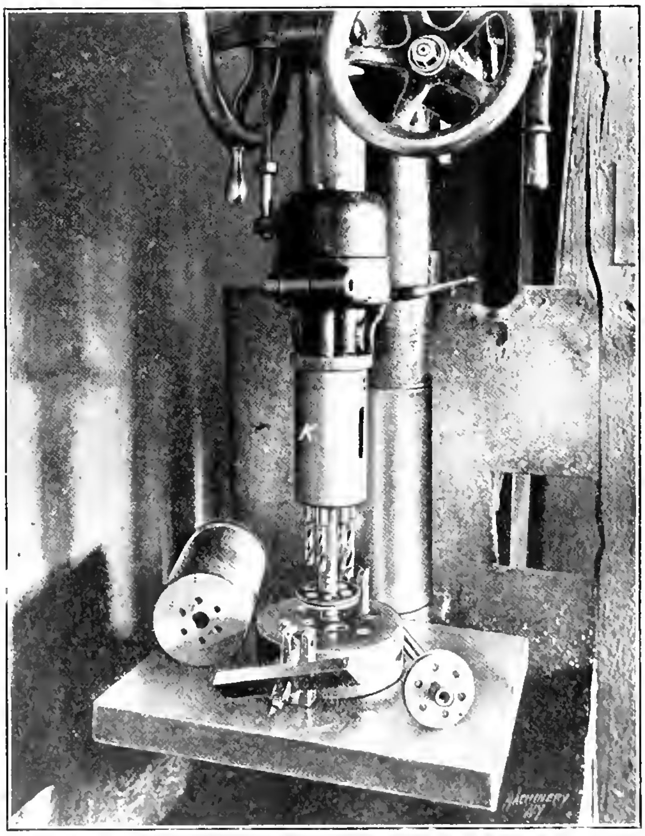

Fig. 11. Multiple Spindle Attachment for Drilling the Rivet Holes in the Spindle Flange and Bowl

The next interesting operation on the spindle is the drilling of the six holes by which it is riveted to the bowl. This is done in a drill press provided with a special multiple spindle attachment, as shown in Fig. 11. The drill spindles are operated by a crank mechanism similar to that used in other devices of this kind, permitting a strong drive at very close center distances. The center of the attachment is hollow, permitting the spindle to pass up through it as shown. The bowls are drilled with the same device, the outside diameter of body K being small enough to enter the bowl. The same attachment is used for countersinking the holes in both pieces.

From this point on, the operations on the spindle become merged with those on the bowl, as will be described.

Machining Operations on the Bowl

Cream separator bowls have to be made of first-class material. A four-inch bowl running at 11,000 revolutions per minute (a peripheral speed of two miles per minute) is subject to a very high strain, and when it is considered that there is always a possibility of some husky dare-devil hired man getting hold of the crank and turning it about twice as

fast as it ought to be turned, it will be seen that provision has to be made for emergencies.

The bowls are therefore made from cold or hot-drawn seamless blanks of high carbon steel, and before sending them out in the machines, they are tested at a speed nearly double that at which they will run normally. This means that the centrifugal strain will be four times as great as the normal, since this increases with the square of the velocity.

The cup blanks of the bowls first have a hole drilled in the center of the bottom by means of a simple jig which centers itself accurately. This hole is the one into which the plug end of the spindle projects, as shown in Fig. 5. It is drilled

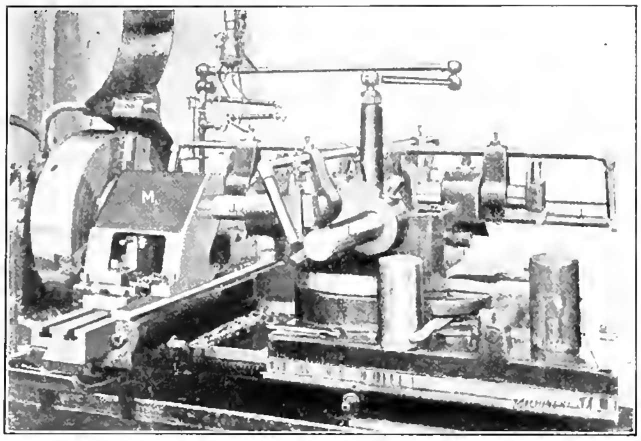

Fig. 12. Turning and Facing the Outside of the Bowl with Supported Tool-holders of Special Construction

first, in order that it may serve to locate and steady the outer end of the blank in the outside rough turning shown in Fig. 12.

This is another Potter & Johnston automatic operation, and is performed with an interesting outfit of tools. The work, of which a rough and a turned sample are shown on the turret slide, is held in a special chuck which grips it ou the inside of the rim, while the outer or closed end is steadied by a projecting plug on the end of a pilot solid with the chuck. This leaves the whole of the exterior surface of the bowl free to be turned, without interference with the chuck jaws or other holding devices.

On this machine, as in Fig. 10, two sets of tools are mounted in the turret, so that the machine completes two pieces of work at each revolution of the cam drum. The first operation is the rough turning and facing of the blank. In the

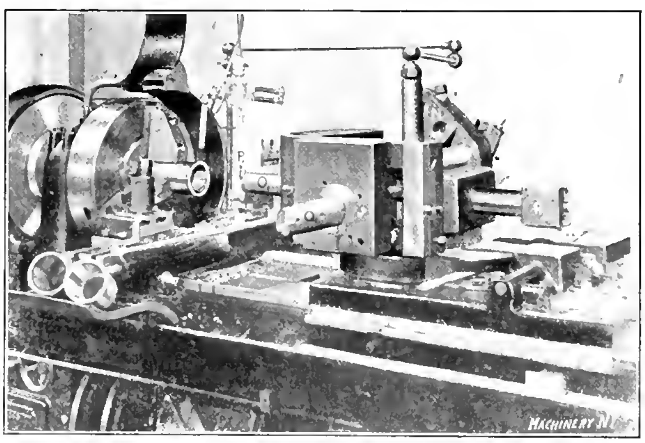

Fig 13. Boring and Facing the Bottom of the Bowl with Turret Tools manipulated by the Cross-slide

second operation the blank is finish turned and the corner is rounded. The unusual feature of the tool equipment is the provision made for steadying the outside turning tools. These are mounted in long overhanging bars J_1 and L_1, as shown. To give the maximum of stiffness with this long overhang, a bearing M_1 for these tool-bars is immovably bolted to the cross-slide bed. This bearing is bored out to form a seat for the bars and in this seat they are supported during the cut, so that the turret is under no strain except that for feeding the tool ahead. There is no deflection in the turret mechanism of a kind that will limit the rate of feed, or impair the accuracy of the cuts. Oiling arrangements are provided, as shown, to bring a stream to the point of each tool when it comes into operation.

The next automatic operation on the bowl, that of finishing the bore, is shown in Fig. 13. Here also a special tool equipment is provided. The bowl is held by its outside diameter in soft jaws, turned in place, so that the first and second operations run true with each other. An oil pipe passes through the hollow spindle and discharges oil through the hole drilled in the bottom of the bowl, so that the flow outward clears away the chips as fast as they are made in the boring operations. A valve at the nozzle of this oil pipe opens automatically when a piece of work is pressed into the chuck, and closes again when it is removed.

The first cut taken in this operation is that of rough boring and rough turning the end, which is performed by the standard combination tool N_1 at the back side of the turret in the engraving. The second operation is that which is shown about to commence, and consists in rough facing the inside of the bottom. The projecting tool-holder O_1 for this operation is mounted in a cross-slide on the face of the turret, and is normally pressed back by a stout coiled spring. The turret is fed up until the blade has reached the proper depth, when the rear cross-slide comes up, carrying a roller abutment P_1 which feeds the turret cross-slide tool forward on its sliding base, facing the bottom of the cut from the center in toward the side.

The third tool Q_1 and its cut are like the second, being first a finish facing operation performed in the same identical

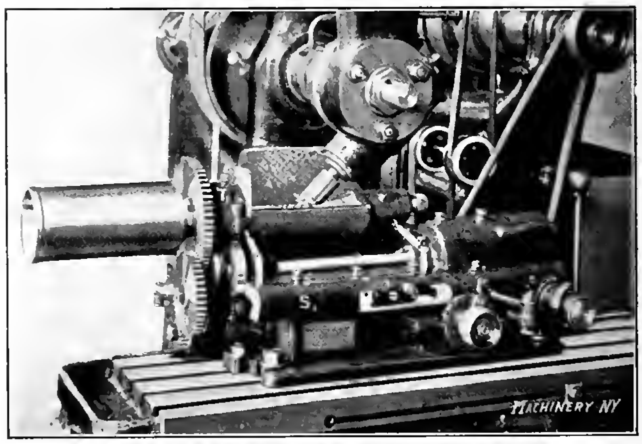

Fig. 14. Milling the Spindle Driving Worm in a Completely Automatic Attachment for the Plain Milling Machine

way. At the end of this operation, however, the cross-slide abutment remains stationary, while the turret is fed backward with the back side of the tool bar held up to its work by the roller on the abutment. By this means the same blade is made to face the bottom of the hole and finish the bore.

The fourth and last cut is taken with the inserted blade reaming or counterboring tool R_1, which finishes the outer edge of the bowl very accurately to size. After this operation the bowl is drilled in the attachment shown in Fig. 11, and the bowl and spindle are riveted together.

Reasons for the Use of Automatic Machines

It struck the writer that the tool equipment illustrated in Figs. 10, 12 and 13, together with others of a similar nature not here described, make up the most ingenious and highly developed equipment he has ever seen used on an automatic turret machine. All of those illustrated, it will be seen, adapt the machine for taking long cuts with rapidity and precision, thus bringing it more closely into competition than usual with the engine lathe and with certain forms of highly specialized hand-operated lathes for the same work. This brings up the question of the field of the automatic machine—a question which is never ending, because of the ever-changing conditions under which it is decided in different shops.

A natural thought in looking at Figs. 10, 12 and 13 is that the tool designer has taken considerable pains to adapt these automatic machines to work for which they are not usually employed. But that this process of adaptation has been well done, there can be little doubt to any one who watches these

machines at work. They require very little attention, and produce work up to the high standard required of them.

Various other advantages are urged for this type. That of low labor cost is taken for granted in successful automatic machinery. Besides this, a less expensive grade of labor may be employed, and men may be more easily changed from one job to another. On hand-operated machines working at a high efficiency, there is a tendency for the workman to specialize, and his production, when he is broken in on a new job, suffers more than does that of the automatic machine and its operator under the same conditions. The use of the automatic thus gives a greater flexibility to the organization.

One experienced man is employed to look after the tooling and setting up of the twenty odd turret machines used here. By giving proper care to the cutting edges, the automatic machines under his control can be depended on to produce work of a high degree of uniformity in dimensions, hour after hour, and day after day. Neither he nor the men under him are rushed in getting out the maximum production of the machines—the duties of the operatives being, ordinarily, simply that of putting in and taking out the work.

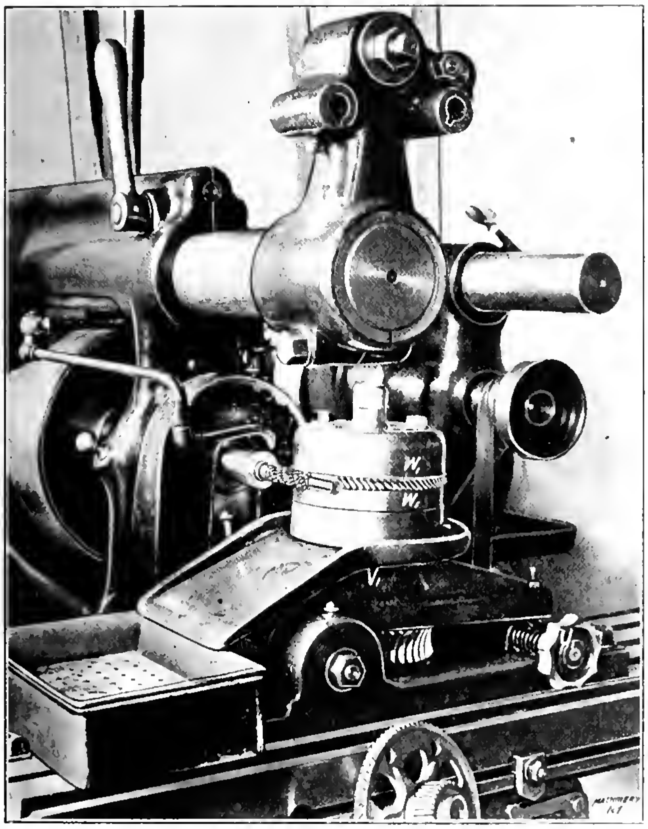

Fig. 15. Hobbing Attachment for Cutting the Teeth in the Driving Worm-wheels; Overhanging Arm turned back to show Hob

Against these advantages must be weighed the advantages of hand machines in other respects, such, for instance, as the lower capital investment, the (sometimes) higher output per machine, the more constant personal supervision, and the less elaboration required in the tool equipment. In striking the balance between these advantages and disadvantages, the management of this shop feels that it has reached the right conclusion for conditions as they occur in the work here.

Finishing Operations on the Bowl and Spindle

After being assembled, the bowl and spindle are finish turned on the outside over the whole length in the engine lathe, the work being held on an internal expanding chuck, which accurately centers and holds the bowl by its interior surface. This gives assurance that the outside of the bowl and the whole length of the spindle will be turned true with the inside of the bowl. The neck bearing, next to the flange of the spindle, is, in this operation, turned and filed to its finished size, which is required to be accurate within 0.0002 inch. Stock is left for grinding at the lower or step bearing end of the spindle. The reason for finishing the neck bearing at this time will be understood in connection with the operation shown later in Fig. 16.

The bowl and spindle being thus finish turned all over, the work is next taken to the milling machine department to have the worm thread cut on the spindle. This is done in the special Brown & Sharpe milling attachment shown in Fig. 14. This attachment is entirely automatic. The main table of the milling machine is locked in position at the proper point to center the cutter with the work and set it to proper depth. The work is mounted on a supplementary slide S_1 in the fixture, whose feed-screw is geared (to give the desired lead of helix) with the quill chuck, which grasps the spindle by the neck bearing.

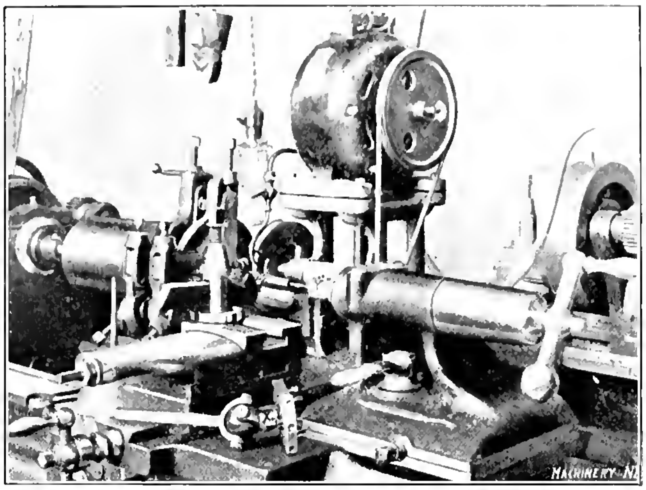

Fig. 16. Finish Turning and Grinding the Bowl Spindles

Properly set up in this way, the mechanism of the device feeds the spindle forward, cutting one thread. When this thread has been cut the proper length, an automatic stop throws in operation mechanism which first rocks the spindle, carrying head T_1 back away from the cutter, returning the slide to its initial position, then indexes the spindle for the cutting of the second thread, and lastly sinks the cutter in to depth again. Besides this, the device is "full automatic" to the extent that its feed movements are arrested when the required number of threads have been cut. The mechanism is connected to the regular telescoping feed shaft of the miller. The cutter is mounted on the regular vertical and angular milling attachment, set to agree with the desired helix angle of the thread.

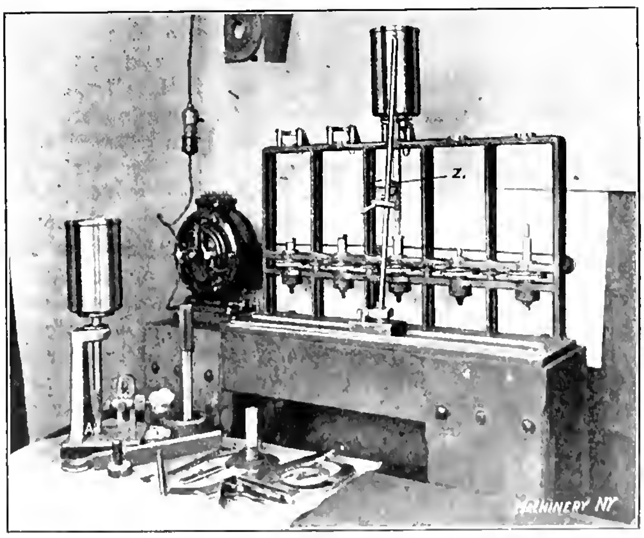

Fig. 17. Testing Outfit for Inspecting the Bowls and Spindles

The corresponding operation for hobbing the worm-wheel may be mentioned here though it is a little out of the strict order of operations we have been following. In this attachment (see Fig. 15) the worm-wheel is mounted on a vertical work-spindle on a special fixture in the milling machine, the table of which has been clamped in the desired position as in the previous case. This work-spindle is driven by worm-gearing and a train of spur-gearing connecting it with the spindle in the proper ratio.

The feeding of the hob in to depth is done by hand through the operation of knob V_1 shown at the base of the machine.

This, through suitable connections, rocks the work-spindle base V_1 about the axis of the work-driving worm, thus moving the work in toward or away from the hob as may be desired. The work is only located by the work-spindle, being held by special face-plate clamps W_1, which clasp the rim firmly, close to the cutting point. This prevents the distortion which would otherwise be inevitable in so small and light a worm-wheel.

In Fig. 16 is shown a lathe rigged up for the finishing operation on the worm-spindle. The work is held in two back-rests, one of which bears on the neck bearing, which was filed to size in the finish turning operation before described; the other back-rest bears on the spindle just above the worm bearing. As these surfaces were finish turned "in the air," while the bowl was held accurately by its interior bore, every assurance is given that the bowl is so held as to run true; and as the spindle was chucked by these same surfaces in the worm cutting operation, it may be assumed also that this will run true. The bowl is driven from the spindle of the lathe by a universal joint driver X_1, which is shown lying on the top of the carriage in Fig. 16. The four pins in its face bear on the bottom of the bowl and take the thrust of the cutting. The copper friction pieces at the sides are expanded by the taper screw shown so as to grip the sides of the bowl and drive it firmly without distorting it.

The lathe is provided with a turning tool for taking finishing cuts over the step-bearing, and with a motor-driven grinding attachment, as shown, for finish grinding the step-bearing. A suitable tail-stock holder is furnished for carrying drills, bits, etc., for finishing the hole in which the hardened step is inserted. This, with various minor operations, completes the work on the bowl and spindle.

Inspecting and Balancing the Bowls

The outfit shown in Fig. 17 is used by the inspector for testing the work on the bowl and spindle. The frame shown at the back contains a series of motor-driven spindles, each provided with a true running socket for receiving various designs of separator spindles and bowls. One of these is shown in place. The dial test indicator Z_1 is mounted on an adjustable swiveling and sliding post, so that the truth of any or all of the revolving surfaces, from one end to the other, may be tested by it.

The fixture shown at A_2 is for testing the truth of the worm cutting. The spindle is inserted in bushings in the fixture, which bear on the journals on which the spindle is to revolve in the completed machine. The dial indicator is mounted on a plunger which may be moved in to a positive stop, and is in turn carried by a standard on the base of this fixture. A forked point is provided for the indicator plunger, which straddles the worm thread and bears on the pitch line. By bringing this plunger over each worm thread in turn, the pitch radius at each thread is indicated; the truth of the tops of the threads is a matter of comparatively little importance; the question is, "Do the acting surfaces of the threads run out?" That question the indicator solves accurately and quickly.

The various other tools shown, consisting of depth gages, internal and external micrometers, snap gages, etc., are used in obvious ways to test the accuracy of the various diameters and lengths of the work. All this accuracy in the bowl and spindle is required to produce the proper balance for quiet running at high speeds. The more accurately the machining operations are performed, the less time will have to be spent on the costly and tedious work of compensating for errors in balance.

The balancing of the bowls is done with all the rotating parts assembled and (in this firm's practice) with the bowl full of liquid. This latter is an important improvement in this operation, as the distribution of weights in the bowl must inevitably be somewhat different when it is full from what it is when empty. It makes the balancing operating more costly but better results are obtained.

This job of balancing separator bowls is a peculiar one, being a trade in itself. So far as we know but one article descriptive of it has ever been written, and that was published in MACHINERY.* It is said that the men have to learn the business for themselves, it being almost impossible to teach it, and that different men work in different ways. Some men cannot learn to do it at all. What is reputed to be a fair statement of the case was made by a German in this shop, who tried for six months to get on to the job and finally failed. "First, I put in some solder on the top and then on the bottom, and then I put in some more, and then I fill her up with solder, and then I take it all out, and she run better than she did before." All of which is rather discouraging for the editor, who likes to set things down definitely in black and white.

This concludes the list of operations selected for this article, to show the character of work required and obtained in the building of cream separators. On hearing the name "Vermont Farm Machine Co.," a vision naturally arises in the mechanic's mind of a blacksmith shop sort of an establishment, where plows, shovels, harrows, cultivators and other tools of that kind are made. It is to be hoped that this article will dispel this illusion, and that the name will henceforth stand in the reader's mind for machine shop work of a very high grade indeed.

* See "Cream Separator Bowl Balancing" in the September, 1907, issue of MACHINERY.

DON'TS FOR PATTERN-MAKERS

H. E. WOOD*

Don't use watery glue.

Don't glue battens on a pattern.

Don't be afraid to ask for information.

Don't set a plane flat down on your bench.

Don't try to glue up a piece of wet lumber.

Don't forget to put draft on your patterns.

Don't use green or wet lumber; it is no good.

Don't forget to make allowance for your finish.

Don't try to trim work without a very keen-edge tool.

Don't nail a standard pattern unless absolutely unavoidable.

Don't forget to mark your loose pieces with the pattern number.

Don't sandpaper your work until you are all through with trimming.

Don't start to build a pattern before you understand the drawing.

Don't put on more than one coat of shellac without sandpapering it.

Don't forget to study other men's work, and profit by their experience.

Don't be in too much of a rush when you are working on a complicated job.

Don't put any unnecessary work on a pattern that is to be used only once.

Don't waste leather fillets in places where wooden ones can be used just as well.

Don't hold a hand lathe tool at right angles to the center line of a revolving piece.

Don't try to scrape a piece of work in a lathe, but hold the chisel so as to cut it.

Don't try to drive a nail through a piece of hardwood without first boring a pilot hole.

Don't make a pattern to suit your own liking, but remember that it goes to the foundry.

Don't make a coreprint so that it is impossible for the molder to get it out of the sand.

Don't put a leather fillet around a small curve without wetting it in luke-warm water.

* * *

An iron and steel scrap heap of enormous dimensions was shown in an illustration in a recent issue of the *Iron Trade Review*. The scrap heap is one of the relics of the great conflagration in San Francisco in April, 1906, the principal accumulations being those in the yards of the Great Western Iron and Steel Co., where four scrap heaps 100 feet square and 40 feet high were recently stored. All the scrap was cut in equal lengths of 18 inches and piled in one solid mass, with the sides practically as smooth and solid as a brick wall. Only one scrap heap now remains, the other three having been drawn upon as the material was needed for the furnaces.

DIE-BEDS OR BOLSTERS FOR PRESSES

DORBRO

The subject of die-beds or bolsters is one of considerable importance, and is deserving of greater attention than it often receives in the shop or designing room. It has been the experience of the writer that many of the troubles encountered in the use of press tools are due to this feature being badly designed or poorly constructed. Many a fine die has been ruined because it has not been properly secured in the die-bed and consequently has shifted while in operation; or because the holes in the die-bed through which the blanks or punchings are supposed to pass have not been made large enough to allow them to pass through freely. As a consequence the blanks get jammed in the die-bed and pile up into the die itself and are compressed by the pounding of the punch, until the punch or die breaks from the strain. The principal functions of a die-bed are: first, that of supplying an adequate support for the die, and a holder to hold the die in its proper position to be engaged by the punch; and, second, to furnish a means of attachment to the press. Two of these principal points to be considered therefore in the design and construction of a die-bed are first, the method of securing the die, and second, the method of securing the die-bed to the press. Due consideration, of course, should also be given to proportion and strength.

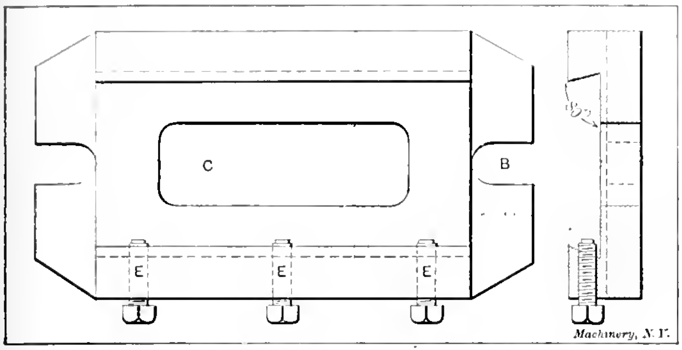

Fig. 1. Die-bed of the Style commonly used in Jobbing Shops

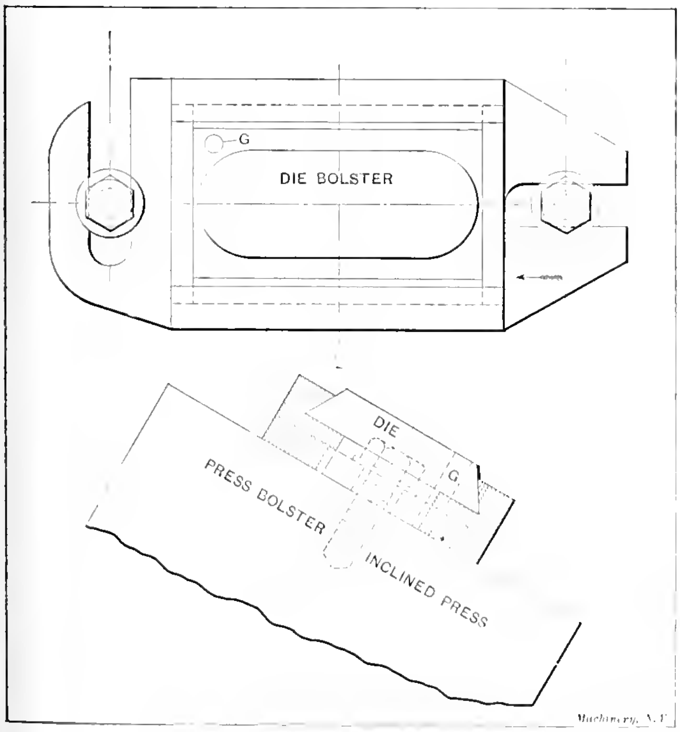

Fig. 2. Die-bed adapted to Inclined Presses

In Fig. 1 we have an illustration of a die-bed of the type generally found in the jobbing shop. The dovetail method of holding the die, with set-screws *E* to lock it in proper position, is employed. It is fitted with a flange *J* on each end with slots *B* to receive the clamping bolts which pass through them into the press bolster. In the center is a rectangular cored hole to let the punchings pass through. This style of die-bed is cheap and convenient for use where several dies are to be used in one die-bed. The dies can be easily slid into place and fastened by means of the set-screws, and are easily removed when another die is to be used. This bed has the following disadvantages: first, that of being held by set-screws which have always a tendency to jar loose in punch press work, and second, the cored hole *C* being necessarily made large to accommodate various shapes of blanks weakens the bed and gives less support to each of the dies. It is always better, if possible, to have a separate die-bed for each die.

In Fig. 2 we have a bed for use on an inclined press. In this bolster the dovetail method of holding the die is used, but without the use of set-screws. The dovetailed opening to receive the die is slightly tapered and the die is driven into place with a copper mallet, and is then made doubly secure by the insertion of a dowel which is driven through the die into the die-bed. The dowel is shown at *G*. The method of clamping this bed to the press bolster is different from that shown in Fig. 1 in that the bolt slot in one flange runs at right angles to that in the opposite flange. By having the slots in this position the die-bed may be attached or removed without the necessity of taking out the bolts, thus not only saving a great deal of time and trouble in setting the tools but also preventing the bolt holes from getting filled with scrap or dirt and the bolts from getting lost. This is an excellent die-bed for blanking and piercing work.

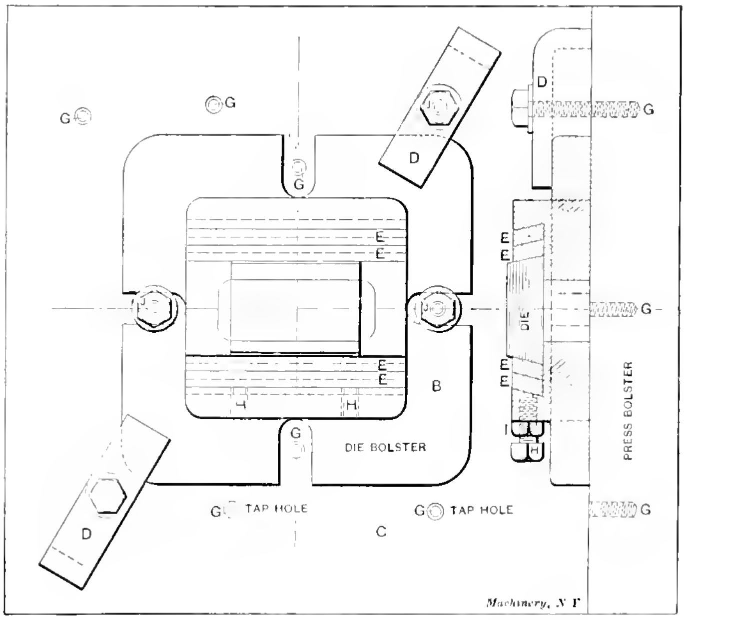

Fig. 3. Improved Form of Die-bed for General Utility

An improved type of die-bed for general utility is shown in Fig. 3. In this bed the dovetail method of holding the die is used. In the illustration it will be noticed that there are four parallel pieces or gibs *E* placed along the sides of the die. The object of this is to provide for dies of various sizes. When a larger die is to be used one or more of these gibs may be taken out. This bolster, in addition to four bolt slots, has a flange *B* all around it so that it may be clamped in any position. The set-screws *H* which hold the die in place should be provided with a lock-nut as shown at *I* to lessen the chances of jarring loose. The great advantage of having a flange all around the bolster will be apparent when it becomes necessary to swing the die-bed around enough to bring the bolt slots out of line with the tap holes in the press bolster. In a case of this kind the die-bed with a flange all around it may be clamped by means of clamps as shown at *D*, using the tap holes *G* located at different places in the press bolster *C*.

In Fig. 4 we have another die-bed of the dovetail and side set-screw variety, but with the additional feature of end-thrust set-screws. This end-thrust arrangement is an original and novel feature. In order to obtain this additional means of holding the die securely, two square grooves *B* are cut in each end of the die-bed at right angles to the opening for the die. Into these grooves a plate *C* is fitted in which is a set-screw in such position as to come in contact with the end of the die. With one of these plates at each end, and the set-

screws screwed tightly against the ends of the die, there is less likelihood of its shifting while in operation. When short dies for simple blanking or piercing are used the end-thrust plates may be used in the inner grooves as shown in Fig. 4, and if it be desired to use a long die such as is used for progressive work where there is one or more piercing operations before the work reaches the blanking punch, the plates with the set-screws may be placed in the grooves further from the center, and thus allow for the increased length of die. When the set-screws are used in these outer grooves, the heads of the screws will come directly over the slots in the flanges where the clamping bolts should be placed; for this reason the bed should be provided with two extra slotted flanges, as shown in the illustration, to be used when necessary.

In Fig. 5 we have an illustration of a die-bed for sectional forming or blanking dies or for split dies. This bed is provided with a square receptacle to receive the dies, and with two set-screws on each side to hold the dies in place. The square forming die shown is made in four sections *B* which are held tightly against each other by means of the set-screws *C*, and are held from lifting up by screws through the bot-

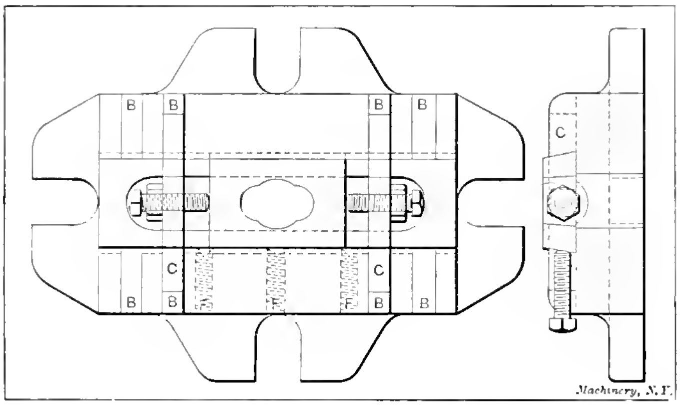

Fig. 4. Die-bed of the Dovetailed and Side Set-screw Type, also secured by End-thrust Set-screws

tom of the die-bed—one in each section of the die. The square recess is cast in the bed so that in preparing the bed for use it is only necessary to plane off the bottom and top of the flanges and mill the bottom of the recess, and drill and tap for the set-screws. The sides of the recess need not be machined as the dies have no bearing on them.

A very simple type of die-bed for bending and forming dies is shown in Fig. 6. It is simply a vise similar in some respects to a milling vise, but having two set-screws to take the place of the movable jaw. The die is simply set in the bed and clamped against the solid jaw by means of the set-screws. This type of bolster is intended for use only on dies that do not require a "push up," but where the bending or forming operations are done on a solid surface. In order to

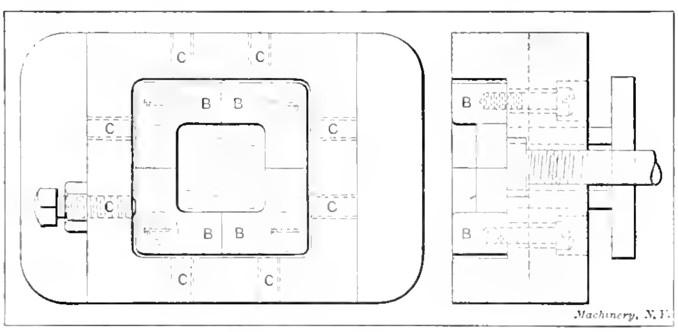

Fig. 5. Die-bed for Sectional Forming or Split Dies

obtain the best results from this die-bed, the complete outfit of punch holder, punch and die of the type shown in the sketch should be used. The punch holder and punch are made just the same as the die and die-bed. They are kept in alignment when in operation by the two guide pins *E* which are secured in the punch and which enter the die at every stroke of the press, making it practically impossible for the tools to shift while in operation. If it be desired to change the tools it is not necessary to disturb the punch holder or die-bed. They may be left in the press, and by simply loosening the set-screws in the die-bed and punch holder, the punch and die held together by the guide pins may be taken out and set aside and another set slipped into their places. There is an infinite variety of light bending and forming operations that can be done advantageously and cheaply with this outfit.

Fig. 7 represents a bolster for combination dies for round drawing work. This bolster requires but little explanation. It is circular in shape with two steps or extensions, two bolt

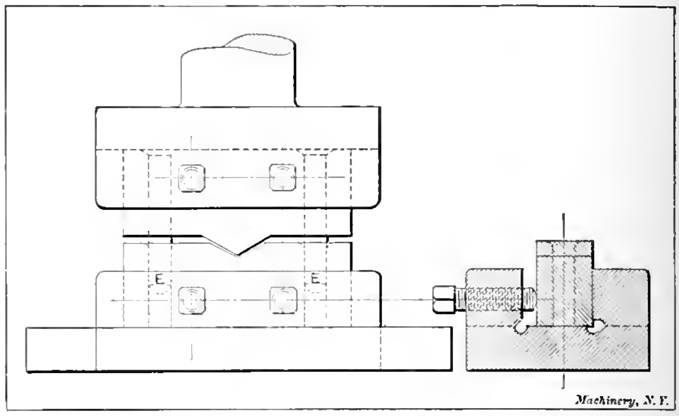

Fig. 6. Simple Form of Die Holder adapted to Bending Die

slots and a flange all around it to allow it to be clamped at any convenient place. When the combination dies are turned in the lathe the bottom die is counterbored to be a driving fit on the extension *G*, and is held down by screws that pass through the bed at *E* into the die.

STORAGE AREA RESTRICTION PLAN FOR MACHINE SHOPS

In shops where a large volume of heavy work is turned out on a comparatively limited floor space, there is a constant tendency to store work (rough, finished, and in course of machining) in areas which encroach on the passageways re-

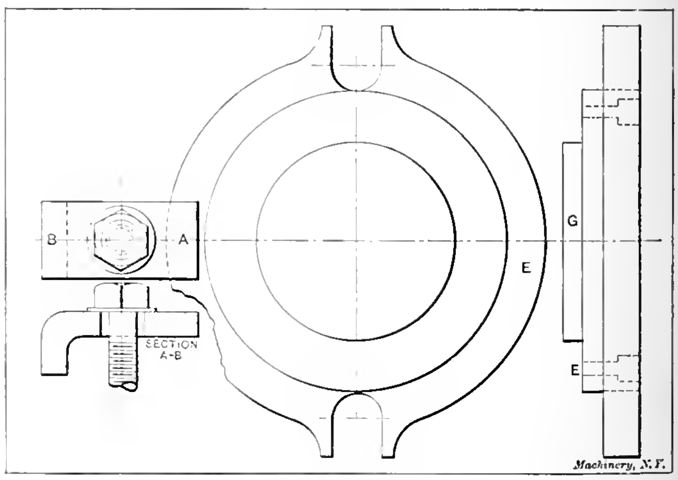

Fig. 7. Die-bed or Bolster for Round Drawn Work

quired for the movement of the parts through the shop. In the works of the Westinghouse Machine Co., at East Pittsburg, Pa., this tendency is restrained in a very simple way. The areas available for storage are marked off on the floor with lines of white paint. These areas provide for grouping work around each machine, and for using all available vacant spaces as well; but they are carefully laid out to avoid checking the freedom of movement of work and workmen. A single glance of the eye reveals any infraction of the regulations, as the lines are kept freshly painted. By this means the management has avoided that state of chronic congestion which is so fatal to economical production.

* * *

Following the example of the English Patents Act of 1907, the Australian Commonwealth has passed an amendment to the Australian patent act, which makes the manufacture of all articles patented in the Commonwealth compulsory under penalty of forfeiture of rights.

A FORMED TOOL PROBLEM

H. V. PURMAN*

One day the man who was making the formed tools came to me and said: "I want to make this master-tool with an angle of 15 degrees from the center line and with a clearance on the front of 25 degrees; and in addition to that I want to give it a side clearance of 2 degrees to keep it from dragging. I will set it in the planer vise tipped forward at an angle of 25 degrees and swing the vise around 2 degrees.

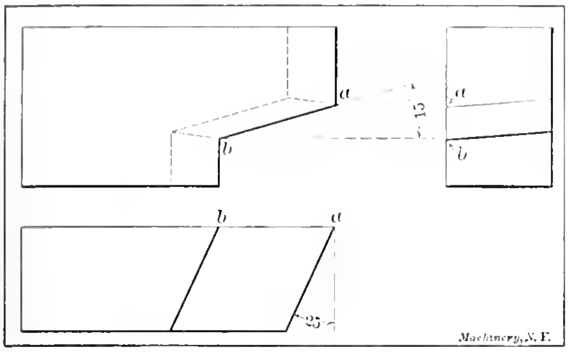

Fig. 1

Then to what angle must I set over my planer head to plane the tool so that it will measure 15 degrees on the cutting face?"

This is a sensible, practical question, but how many of our technical school men, either in or just out of college, could answer it? In the following is given a solution of this problem, worked out by the writer.

The master-tool is shown in three views in Fig. 1, where the plan, or face view, shows the side angle, 15 degrees, and the side elevation shows the front clearance of 25 degrees. In Fig. 2 the tool is shown as set in the planer vise ready for planing. In the top view the 2-degree angle is clearly shown, exaggerated, the vise and pieces being swiveled around as indicated by the divergence of the edge of the tool to be made from the line of the cross-rail. The side view shows the piece as seen from the side of the platen, looking squarely across, and the face view shows it as looked at in line with the platen travel, when the surface in which the points *a*, *d*, *c* and *b* are located appears as a line. This line is at the real angle of the tool-head from the vertical, and its angle with the vertical must be found.

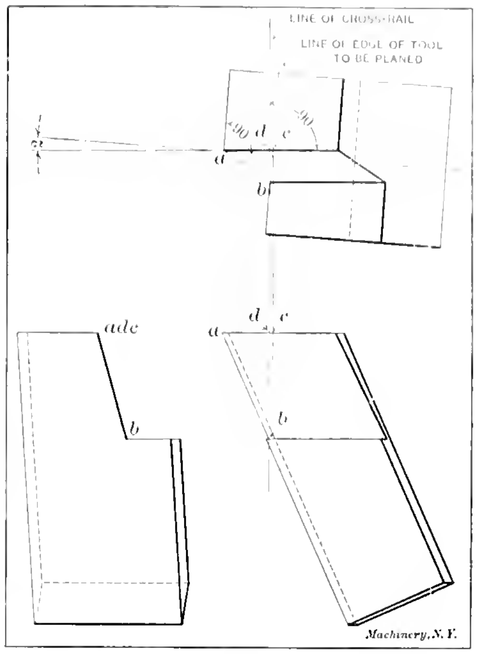

Fig. 2

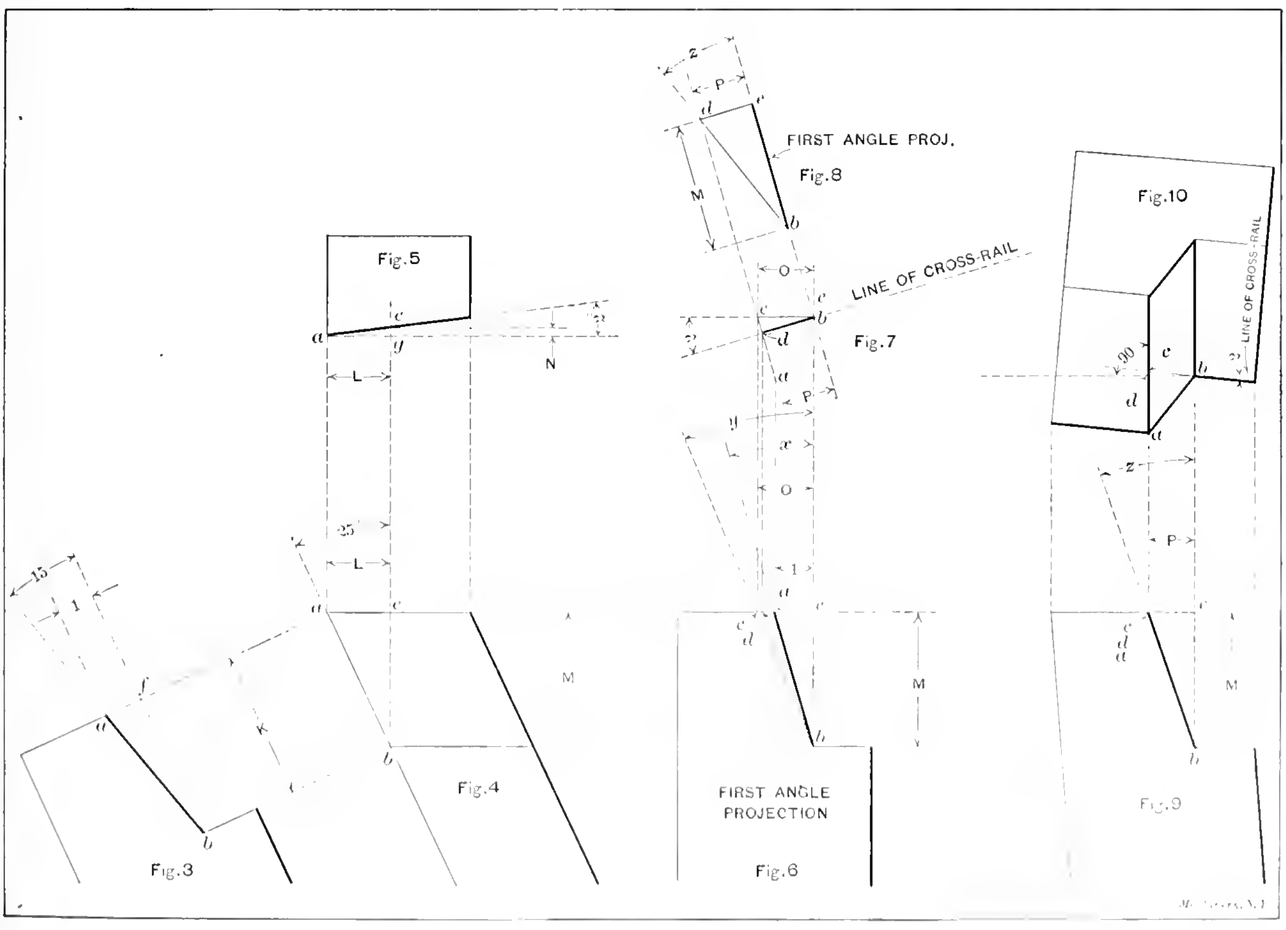
To do this we will use a series of diagrams, representing the essential lines of the tool in various positions. Fig. 3 shows the plan of the tool, Fig. 4 its side elevation, and Fig. 5 the top of the tool in the horizontal plane when the tool is tipped forward. Fig. 6 shows the face of the tool merely inclined but not swiveled; Fig. 7 shows a portion of the edge receding from the corner, when swiveled, and Fig. 8 shows a line in the surface of the oblique side of the tool, each of these last two diagrams showing also the lines needed to calculate the angles and distances involved. Figs. 9 and 10 represent the surfaces, front and top, of the tool inclined and swiveled, as in Fig. 2.



Figs. 3 to 10

Referring again to Fig. 2, it must be noted that point *c* is in the vertical plane containing point *b* and the edge terminating in *b*, while point *d* is in the vertical plane contain-

* Address: Winchester, Mass.

ing point b and parallel with the cross-rail, while a, d and c are all in the edge of the tool receding from a, hence in a straight line, as clearly shown in the side elevation; they therefore appear as a single point adc in the front elevation. Now ab is the cutting edge of the tool, and db is the line of feed of the planer tool, since the work is swiveled.

Throughout the views and diagrams the same points are designated by the same letters, but in the diagrams additional letters (capitals) are used to denote dimensions, for ease in calculation, and for clearness and accuracy, since the points appear in projection at different distances in different views.

Let the distance af, Fig. 3, or the actual amount the edge of the tool slants to the left, or the short side of the 15-degree triangle, be considered as unity, for simplicity, then

$$\frac{K}{1} = \cot 15°, \text{ or } K = \cot 15°,$$

$$L = K \sin 25° = \cot 15° \sin 25°,$$

$$M = K \cos 25° = \cot 15° \cos 25°,$$

and $\frac{M}{1} = \cot x$, or $M = \cot x$.

Angle x is the apparent or projected angle of the edge, or the angle of tool travel were the shoe not swiveled; but because of the swiveling, the tool travels over farther in rising a given height, that is, takes off more metal, and gives more clearance, and we must find what this added distance is. It is the distance cg, Fig. 5, equal to ca, Fig. 6, where g is the point directly behind a and on the line ce.

Let $cg = N$, then

$$\frac{N}{L} = \tan 2°; \quad N = L \tan 2° = \cot 15° \sin 25° \tan 2°.$$

$$\text{Now } O\ (= ce, \text{ Fig. 6}) = 1 + N, \text{ and } \frac{O}{M} = \tan y.$$

Angle y is the apparent or projected angle of tool travel when the 2 deg. clearance is given, and we look squarely at the face of the tool. But this is not the actual angle, which must be seen in the line of platen travel, as in Figs. 2, 8 and 9. The actual side motion, then, of the tool, in rising a vertical height cb or M, is $de = P$, Figs. 7, 8 and 9.

$$\frac{P}{O} = \cos 2°; \quad P = O \cos 2° = (1 + N) \cos 2°$$

$$= (1 + \cot 15° \sin 25° \tan 2°) \cos 2°.$$

In Fig. 8, $\frac{P}{M} = \tan z$. This triangle appears in Fig. 9 also, and angle z is the actual angle sought. Then

$$\tan z = \frac{P}{M} = \frac{(1 + \cot 15° \sin 25° \tan 2°) \cos 2°}{\cot 15° \cos 25°}$$

[The formula above can be generalized and somewhat modified as follows: If w = angle on face of tool (here 15°),
v = clearance angle in front (here 25°),
y = side clearance angle (here 2°),

$$\text{then } \tan z = \frac{(1 + \cot w \sin v \tan y) \cos y}{\cot w \cos v}.$$

But $\tan y = \frac{\sin y}{\cos y}$; substituting this in the formula and reducing, we have

$$\tan z = \frac{\cos y + \cot w \sin v \sin y}{\cot w \cos v}.$$

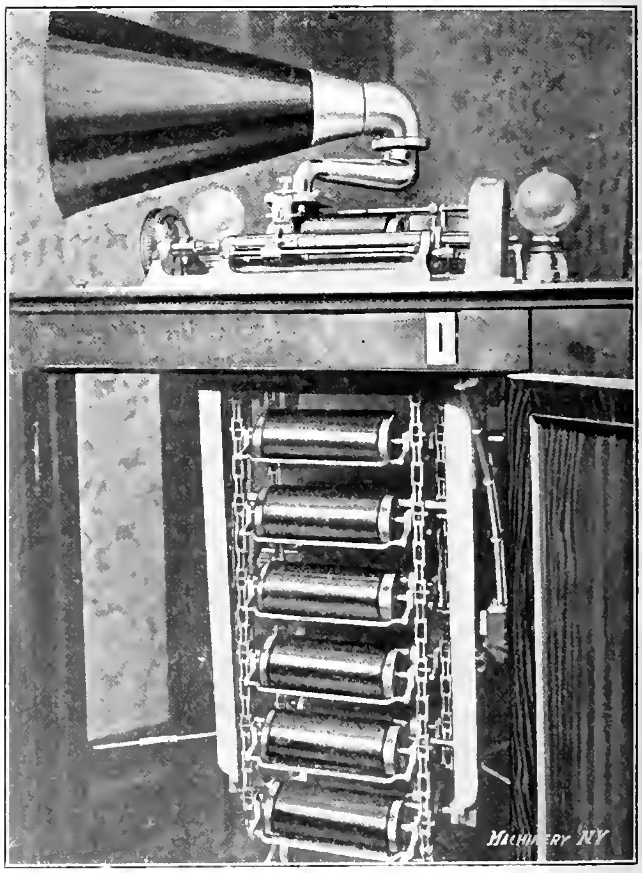
It will be seen that this formula is identical with the one given for planing Acme thread tools in the May, 1905, issue of MACHINERY.—EDITOR.]

By substituting the values for the angular functions in the formula above, we find $\tan z = 0.31174$, which gives us $z = 17$ deg. 19 min., nearly.

The result found can best be used by grinding an angular cutter to this angle as accurately as needed, gaging with a vernier bevel protractor, stoning it, and scraping the master tool with it. This was done, and the angle obtained was so close to 15 degrees that the closest inspection with the magnifying glass failed to show any error in the tool.

CONTINUOUS PERFORMANCE PHONOGRAPH

Thorns grow with roses—evil may come out of good. It is not quite unknown that even the humble and industrious phonograph can be diverted from its peaceful pursuit and used, alas! as an instrument of torture. Many defenseless neighbors have been serenaded by conscienceless individuals with ragtime, classical and religious selections until their nerves and tempers were badly "frazzled." The drawback to the use of the phonograph for such unneighborly acts is the constant attention required of the tormentor to change the records, wind the machine and set it in motion. His own endurance may flag after hours of performance and, perforce, he will seek his bed in sheer weariness of evil-doing without, it may be, having reduced his enemies to a state of complete physical, mental and moral collapse. What is needed for this sort of warfare is a "continuous performance" machine, driven by a motor, that can be started on a choice selection of the "gold molded" and left in the solitude of its chamber, the



The Iddings "Multinola," or Continuous Phonograph

horn facing the open window to do its malevolent work through the long hours of the stilly night without rest—or hesitation at the most frightful threats.

It is characteristic of American ingenuity to discover and fill wants before they are even vaguely felt by the mass of unthinking humanity. Lo! the wished-for machine is even now in our midst, and the dreadful tortures that were dimly forecasted by hand-worked phonographs will soon, no doubt, be realized by many writhing victims who, cursing inventors and all their works, die miserably to the sound of phonographic ragtime. Behold in the illustration of the "Multinola" by Dr. George L. Iddings of Cleveland, Ohio, a devilishly ingenious mechanism that changes its own records with cunning and despatch, and proceeds relentlessly, having no bowels of compassion whatsoever. The roosters crow and crow again at the dawn; the dogs bark when the moon is full; the cuckoo clock cuckoos, and is done, but the continuous phonograph goes on like the brook—forever. Yea, verily!

* * *

Contracts have been awarded for steam turbines to drive the new 26,000-ton battleships *Wyoming* and *Arkansas*. It has been stated that a combination of turbines and reciprocating engines was considered, but the authorities decided in favor of Parsons turbines.

OLD NEW ENGLAND WATER-WHEEL

ALLEN HAMMOND*

Some interesting features of an old water-wheel which was built by the Franklin Foundry & Machinery Co., of Providence, R. I., and erected in the New England company's mill in the year 1860, are shown in the accompanying engravings. The wheel was started in November of the year of its erection, and, with the exception of about a year, it has run regularly since that time. In spite of its forty-eight years of service, the wheel was in such good condition at the time of its removal, judging from the appearance of the woodwork, that it was capable of running for twenty-five years more. It was of the type known as a breast wheel, and was 24 feet in diameter by 18 feet in width.

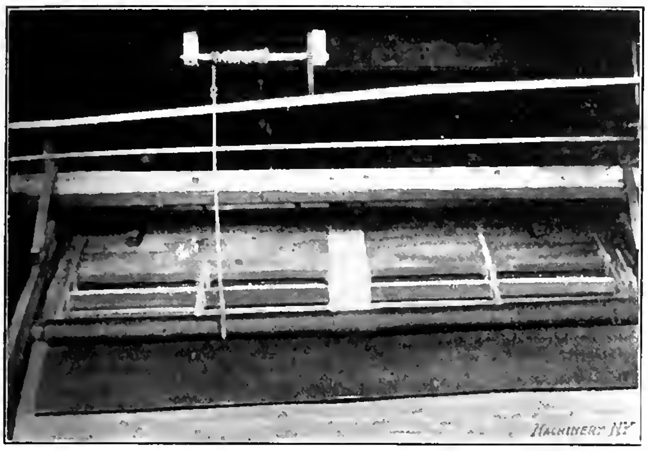


Fig. 1. Curtain Gate which, in conjunction with a Governor, controlled the Flow of Water to the Wheel

The breast or bottom of the flume through which the water entered into the buckets, was approximately 5 feet, 10 inches above the center of the wheel. The flow of water was regulated by a governor having a differential gear which gave power enough to work a long roll on which an "apron," extending across the breast, was wound and unwound up or down on the convex face of the breast. This apron, which is shown in Fig. 1, was made of sheet rubber and was fastened at the lower edge so as to be water-tight. The roll was

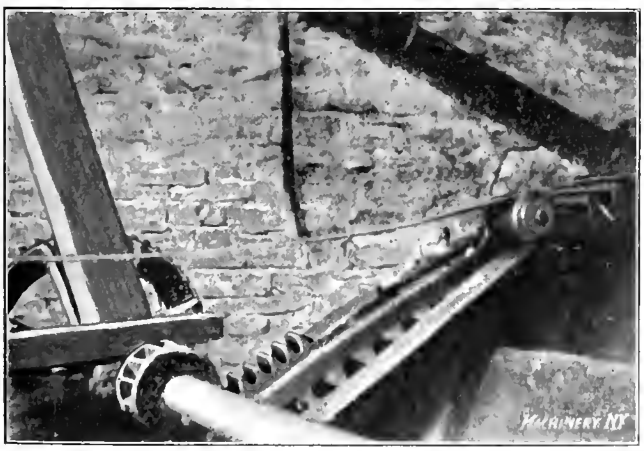

Fig. 2. Rack and Pinion by which the Curtain was wound or unwound

counterweighted and it was moved by a shrouded pinion which meshed with a rack free to move on the face of the breast. This rack had the teeth cut away at each end, and when the pinion came to this smooth surface, the roll reached the limit of its travel, owing to the lack of teeth on the rack which prevented further movement. The end of the rack was provided with a flange-like tooth or projection, which prevented it from moving out from under the pinion. Both pinion and rack are shown quite clearly in Fig. 2. The counterweight attached to the roll was heavy enough so that after the latter reached the limit of its travel, the pinion would be kept in contact with the rack; hence the teeth of the pinion readily came into engagement with the rack when its motion was reversed by the governor.

* Address: 1016 E. 12th St., Erie, Pa.

Guide vanes were inserted in the breast so that the water entered the buckets perpendicularly. These vanes, which may be seen in Fig. 1, were made of wood which was driven into castings that formed part of the breast. They were 6 inches

Fig. 3. View of the Back of the Wheel showing part of Driving Gear and Method of Bracing Buckets

wide and $3\frac{1}{2}$ inches apart. The space between the buckets at the top was 10 inches and at the bottom 4 inches, and the angle between each bucket and periphery of the wheel was 36 degrees.

To prevent the air from being pocketed in the buckets, openings were made in the bottom which allowed the air to

Fig. 4 Spokes and Bracing at the Center of the Wheel which was without a Shaft

escape and the lower buckets to be partly filled. These buckets were set into grooves in the rim and were secured in place by spacers and bolts, as shown in Fig. 3, which is a view of the back of the wheel. In this illustration the driving segments on the rim are also shown.

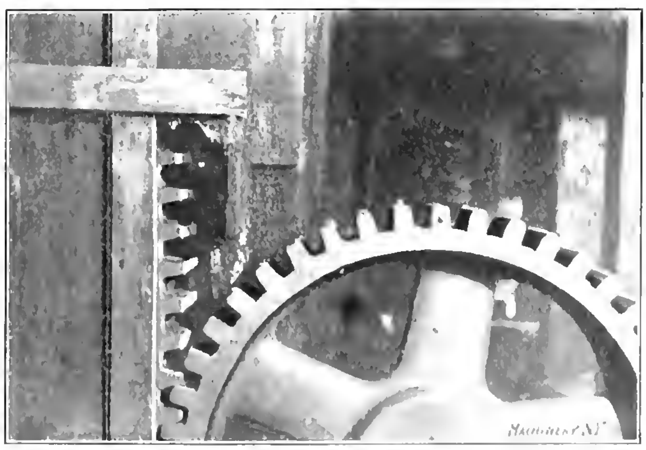

Fig. 5. Section of the Driving Gear, and "Jack" Gear with which it meshed

One unusual and interesting feature of this wheel is that it had no shaft, as will be seen by examining Fig. 4, which quite clearly shows the construction. The spokes and braces rested on flanges which were separated by wooden spacers through which long bolts passed from one side of the wheel to

the other, clamping it together. One of these bolts is clearly shown in the view just referred to. The spokes were 11½ inches by 4¾ inches, while the braces were 4½ inches by 5 inches. The segments of the rim were 11 inches by 12 inches. The bearings or gudgeons of the wheel were 10 inches in diameter by 11½ inches long.

Fig. 5 shows a section of the segment on the rim and also the "jack" gear, which was one of a set of three gears that was used for driving the mill. This gear had 44 teeth, 2½ inches circular pitch, and a face width of 7 inches. The second gear of the train had 114 teeth, and it was meshed with one having 38 teeth. The drive from the second shaft was by belts which ran over pulleys or drums, and some of these belts were as old or nearly as old as the wheel itself. In fact, one is said to have been older, it having been in use since about 1847. This wheel has worn out several sets of segments during its long and useful life.

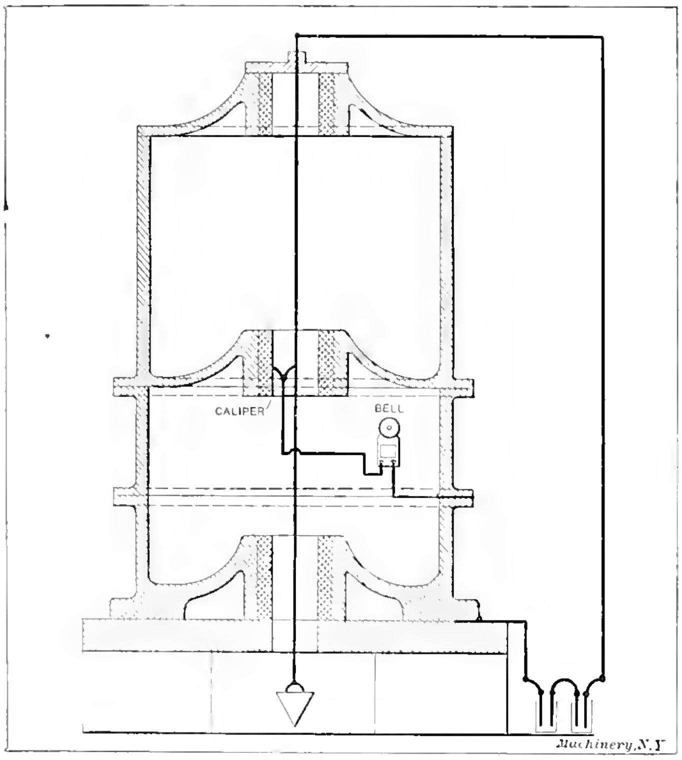
ASSEMBLING VERTICAL HIGH-SPEED TURBINES

HOWARD M NICHOLS*

The following method of assembling and lining up vertical steam turbines is employed in one of the large turbine works, and the same general scheme could be used in erecting most any large vertical machine.

The bed-plate is set on a special iron erecting floor and is very carefully leveled, and the turbine is then assembled



Aligning Vertical Turbine Bearings by the Aid of an Electric Caliper

without the shaft and rotating parts. The wheel casing, bearing brackets, bearings, generator stator, and all other stationary parts are bolted in place. The bolts are left a little slack so that the parts can be slightly shifted during the process of lining up. A length of steel piano wire is weighted with a heavy plumb-bob and is suspended from the exact center of the top bearing, as shown in the accompanying illustration. Since the machine has been carefully leveled during the process of erection, the piano wire will locate the exact center of the shaft. The wire is suspended from the top bearing by a block of hard wood and is not allowed to come in contact with any metal part. The end of the piano wire is connected to one pole of a few cells of dry battery, while the other pole of the battery is grounded onto the frame of the turbine. One binding post of an electric bell is also grounded onto the turbine frame, and the other is connected to a pair of inside calipers by a long flexible lamp cord as shown. These calipers are used to locate the middle and lower bearings central with the center of the turbine shaft, as represented by the piano wire.

In calipering, whenever the calipers just touch both the inside of the bearing and the piano wire, the bell will ring and thus give the workman a better indication than he could obtain by the sense of touch. If it is so desired, a small battery lamp can be used in place of the bell with equally good results. After the bearings are located exactly central with the center of the shaft, the parts are doweled together and then taken down and reassembled with the shaft and other rotating parts in place.

GAS ENGINES IN SHOPS

A. S. ATKINSON*

Generally speaking, the gas engine is rapidly becoming an important factor in machine shop work, and the facility it furnishes in operating cutting, stamping and machine tools, makes it of widespread importance to the trade. Until quite recently the installation of any kind of gas engine for shop and factory purposes was of such limited scope that the question of cost and maintenance was not seriously considered; but now that the gas engine for small as well as large shops has come to stay, any data that will throw light upon the subject should be of more or less value.

Economy in operation is the one thing aimed at, and this, in the case of the gas engine, means an economy in fuel. In my experience with gas engines in shops where only a part of the whole number of machines are in use at one time, the mistake is frequently made of installing an engine which is too large. Suppose, for example, a shop with half a dozen machines requires a full 15-horse-power engine to drive them all at once; but an examination of the records shows that only half these machines are in operation for the greater part of the time, and only occasionally does the work demand the running of them all at once, and then only for a limited period. What power engine should such a shop have to produce the most economical results? This is a point that engineers and manufacturers differ on. One will say the full 15-horse-power, and another ten or even eight, which will allow a fair margin over the average requirement. Here is an experience of the writer. A shop that had run along nicely with an 8-horse-power gas engine was enlarged by the addition of three more machines. The question arose as to the increase of the power. One engineer advocated the withdrawal of the inadequate 8-horse-power engine and the substitution of a 15-horse-power engine. Another recommended the installation of an auxiliary engine of 7 horse-power. A compromise was made by purchasing a small 6-horse-power motor, which could be coupled and uncoupled by belt to the line shafting as needed. The economy of this was shown in the first year's work. The auxiliary engine was used only 120 hours that year. For the rest of the time the old 8-horse-power engine did all the work, for the work was of such a character that only a part of the total number of machines was in use at once during the greater part of the time.

There must be some allowance for overload made in every shop, or otherwise work during rush times must be handicapped. It is unsafe to depend upon an 8- or 10-horse-power engine in a 15-horse-power shop, but does not the single big engine waste fuel where a medium-size one and a smaller auxiliary will save it? This is a question that a shop manager must consider carefully. To get fuel economy out of an engine, it should be run at something like its normal capacity. We cannot expect economy in using an engine twice as large as is required to do the normal work. On the other hand, in a shop where nearly all of the machines are needed in operation for the greater part of the time, the problem is easier of solution. The big engine is then more economical than two smaller engines, as there is less waste through friction and slipping, and less expense in operation in other ways. The cost of maintenance of two small engines is greater than a single big one of equal horse-power.

The location of the gas engine is also of importance. It should be somewhere near the middle of the long line of

* Address: Box 1189, New York.

shafting if the different machines require about the same amount of power. An engine installed at one end of a line of long shafting must of necessity lose much of its effectiveness. Where a smaller auxiliary is used this should be installed with a view to running special machines not often in use. These should be grouped, so far as possible, at one end of the shafting, and in such a way that when the auxiliary is started up it will exert its power directly upon these machines. This means an equipment which will permit the cutting off of at least a part of the line shafting when not needed. It costs a little more in the initial installation to secure this result, but the saving in fuel far more than counterbalances it in the end. If there is a heavy planer at one end that requires considerably more power than any of the other machines, the engine should be located pretty close to it, but on the side nearest the other group of machines.

The gas engine has not been satisfactory in many shops through the inability of the operators to understand the new power plant. Gas engineering is a distinct and new branch, and it is impossible for an old steam engineer or one accustomed to electric drives to change to the gas engine without experiencing some difficulties. Not infrequently, engineers look upon the gas engine as such a simple machine that anybody can understand its operation without much previous study and experience. It is one of the simplest and easiest engines to operate, but it does not follow that it can be run by an ignorant man, and without some technical skill. To some extent the gas engine manufacturers are largely at fault; in their zeal to advertise their goods they say that a child can run their engines and that it takes no skill to manage them. Nothing is further from the truth. Your gas engine can get out of order and run poorly, consuming twice as much fuel as it should, if you do not understand it. The symptoms of gas engine troubles should be understood just as much as those of the steam engine or electric motor. In my experience with gas engines for shop work I have found that the symptoms of trouble are generally indicated by pounding, excessive fuel consumption, back firing, heavy explosions at the exhaust, smoke, poor speed regulation, difficulty in starting, and general lack of power. These symptoms of trouble should all be understood by the engineer, and if understood the difficulty can be quickly regulated. The life of a gas engine depends entirely upon how well it is handled at all times, and here is where the skill of the operator counts. With a thorough knowledge of the meaning of the different symptoms of trouble, the engineer can quickly apply the remedy. Pounding is generally due to the fact that the engine and gasoline are too cold. This trouble is particularly noticeable in winter and in cold climates where the engine is exposed. In a shop where the heating is good it is not so noticeable. The air intake pipe may be too cold, and the gasoline for the first charge may also be too cold. Sometimes the pounding at starting is due entirely to the jacket water being turned on too freely or too soon.

Where there is excessive fuel consumption it can be stopped by a little study of the conditions. The most common cause is the use of poor or dirty gasoline which has not been strained. Straining of the fuel should always be attended to. Water in the gasoline or cylinder will cause excessive waste. Sometimes the waste is due to defective cylinder or cylinder head castings; in such cases there is no remedy except to put it up to the manufacturers and make them furnish new parts. Again the excessive consumption of fuel may be caused by cylinder gaskets being leaky or, as sometimes happens, by their being blown out. The remedy may be applied in such cases without much trouble.

Back firing is often simply the result of incorrect setting of the spark or valve mechanism, and until this is remedied the trouble will persist. If back firing is noticeable, look for the cause first in the spark, and see if it is not out of time; in the make-and-break system the spark points may not touch. If the ignition system is all right, then examine the exhaust valve which may be out of time, or as often happens, may not close or fully open. Finally, see if the governor mechanism is not out of adjustment. Any one or all of these troubles may be caused by incorrect setting at the beginning, and proper adjustment will remove the whole difficulty. Heavy explosions at the exhaust may be due to defective ignition or because the mixture is too weak. Smoke at the end of the exhaust pipe generally means that lubricating oil is being wasted. If the smoke is of a bluish color this is quite evident, but if it is black it indicates that the mixture is too rich. If the smoke appears at the open end of the cylinder there may be a sand hole in the cylinder or a leak past the piston ring.

Poor speed regulation may be caused by defective ignition or because the governor is not properly adjusted. Again it may be caused by lack of proper lubrication of parts, or incorrect mixture. Sometimes moving parts are gummed and bind so that the regulation is very poor. If there is any lost motion in the moving parts the speed regulation must be imperfect.

Difficulty in starting is sometimes experienced and causes a great deal of trouble. This may be due to any one of many troubles, the removal of which may prevent other troubles developing later. First ascertain whether the fuel is being supplied in sufficient quantities. This is the most fruitful cause. Next examine the ignition system, and then ascertain if the mixture is properly proportioned. A cold engine or cold gasoline will sometimes cause difficulty in starting. If batteries are too weak, the spark coil defective, or if the sparking circuits are short circuited by dust and dirt, naturally there will be trouble. Too much emphasis cannot be placed upon the necessity of keeping the ignition system clean and in perfect order. This is the main part of the system, the nerves of the engine, as it were.

General lack of power may be caused by insufficient fuel or incorrect mixture also. Overheating and friction of engine parts are other fruitful causes. Likewise insufficient cooling water and insufficient lubrication will cause general lack of power in the engine. Frequently the whole trouble can be traced to a poor grade of lubricating oil which gums the moving parts and prevents free action. Heating of the piston by pre-ignition has caused many an engine to give poor results. Another thing to look for is the heating of the piston by escaping gases. There may be leaks in the compression chamber which may be the result of worn or bent valve stems or weak or broken valve springs. In new engines this trouble will not be noticeable, but others equally important will show. For instance the piston rings may not be true in circular form or they may be set with all breaks in line, thus causing a leak. In new engines sometimes the piston rings stick in the grooves and cause a constant leak. If the valve cages are not properly packed or ground into place there will be a general lack of power. In old engines dust or dirt in the carburetor, air passages, or admission valves, may be responsible for the trouble.

One does not have to study these possible defective points long before being convinced that an intimate knowledge of the gas engine and its parts is essential to good economical operation. Many times the same defect shows itself in one or more symptoms, and to remove the cause is to give the engine immediate freedom of action. Sometimes, for example, an exhaust pipe causes all of the symptoms. It is too long, too small, or has too many bends in it to permit a free expulsion of the exhaust gases. As a result the engine is constantly clogged in its operation, and other troubles will quickly set in. The only way to handle a gas engine is to find out the trouble when the first symptom shows itself. Then its life will be greatly prolonged, and there will be an economy of operation.

* * *

What are claimed to be the two largest shears of the lever type ever built have recently been completed by the Mesta Machine Co. for the Indiana Steel Co., to be used at the steel plant at Gary, Ind. The knives of the shears are 36 inches long and will make 12 cuts per minute, cutting off cold soft steel $6\frac{1}{2}$ inches square or 7 inches round. Each of the machines is driven by a 150 horse-power induction motor. The total weight of each shear, not including the motor, is $112\frac{1}{2}$ tons.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD, NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall, Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1910

PAID CIRCULATION FOR DECEMBER, 1909, 23,041 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

IMPRACTICABLE IDEALS IN INDUSTRIAL EDUCATION

There is danger that the leaders in the movement for industrial education will aim too high, and that the courses of instruction will suffer from the same false reasoning which has based our high school courses on college entrance requirements. There is grave danger that the primary aim will be to enlarge on fundamental principles in a way that would appeal to the exceptional boy who is to become a superintendent or general manager, instead of helping the average workman directly with the problems of his daily work.

The danger of such a course lies in two directions. In the first place, it is exceedingly difficult to keep boys interested in studies which they see no opportunity to apply practically. In the second place, there is the ever-present possibility of spoiling good workmen by inspiring them with ambitions for positions which they are incapable of filling.

There is no injustice to the exceptional boy in this setting of a low standard for industrial education. He can readily be interested in the instruction, elementary though it may be, and once in contact with other students of lesser abilities, his own attainments stand out in high relief, permitting him to be picked out from the bunch and given such advice and assistance as he may need in preparing himself for better things.

Don't aim too high.

APPRENTICESHIP CONDITIONS

The difficulties which surround the apprenticeship question have been a subject of discussion for many years, and will continue to be until employers and apprentices get closer together than they now are on some points of difference. On the manufacturers' side we hear of the reluctance of young men to learn a profitable trade, and the difficulty of holding them to the terms of apprenticeship contracts. The young men look at the low wages they receive as apprentices, and make no allowance for the time spent in teaching them a trade which will greatly increase their future earning capacity. If the average young man can earn a couple of dollars a week more in some other and possibly easier occupation, he is seldom likely to sacrifice that amount of money to acquire a trade at which in a few years he can earn twice as much as in some occupation that offers little chance of development. The question really narrows down to this—Is the manufacturer willing to pay more than his apprentices' services are worth to him, either on account of the general benefit to his industry, or because it will pay him in future to educate such employes for his own organization? That this policy does pay has been satisfactorily demonstrated by many of the largest concerns in the country, who still maintain their apprenticeship system at more or less loss to themselves. The present need is for an action of the employers which will attract the boys and hold them.

The indentured apprentice of fifty years ago would be as much out of place under present conditions as the spinning lathe, the hand loom and the flail of our grandfathers' time. The master-and-servant situation was but one step removed from the days of the bond slave, and many of the cruelties of slavery were felt by the old-time apprentice. He was poorly paid, had to work long hours, often slept in the master's house and ate at his table, and could be corporally punished for delinquencies. To-day, of course, most of these conditions no longer exist. The manufacturing business has developed beyond the wildest dream of the old-time employer of a few men, and the apprentices of to-day are treated as well as journeymen in the matter of working hours, shop surroundings and other working conditions. But in addition to these improvements, apprentices of the desirable sort apparently must be attracted to the machine shop by higher wages and an educational campaign which will clearly make known to the average boy and man the possibilities that lie before the good machinist and toolmaker, as compared with other trades or the professions. Although in some places trade union rules are a strong deterring force, low wages at the start and ignorance of the chances for improvement are much to blame for the reluctance of young men to enter these trades. The boy sees chiefly the grime and the forbidding conditions that are common to many shops, and does not understand that brains and ability count for as much in those gloomy interiors as in the counting house or department store, with the chances for rapid promotion and good wages much greater.

* * *

THE FUTURE OF THE MACHINE TOOL INDUSTRY

A prospectus recently sent out by one of the great New York banking houses setting forth the stability and value of a new security which they are offering to investors, inspires a comparison between substantial enterprises of that character which offer legitimate opportunities for investment, and the machine tool industry as a whole.

The development of manufacturing in America is still in its infancy, notwithstanding the enormous investment already made therein and the number of men employed. Every increase in its many ramifications will call for more and more of the tools required for building all kinds of machinery—that is, machine tools. The automobile industry alone has absorbed a large number, and will continue to absorb more for some time to come, although no doubt in a diminishing ratio. Then, supplementing the demand from automobile manufacturers, will come that of the automobile and gas engine repair shops which in time will dot the country roads in somewhat fewer numbers, perhaps, than the blacksmith shops now employed in shoeing horses and repairing wagons and farming utensils—and each of the former will require at least one lathe, shaper, drill and grinder.

The railroads are large users of machine tools already; but their potentiality as buyers in the machine tool market is enormously greater. The present equipment of many railroad repair shops is of the poorest character imaginable, the tools frequently being of a type obsolete twenty or thirty years ago. The development of high speed steel and the great increase in power and capacity of locomotives, have already put many of these old tools out of commission, and still greater numbers must be thrown out and replaced by modern tools as soon as railroad earnings warrant the necessary expenditure.

In several other directions we can see a great and widening demand for machine tools—a demand that will be larger than the present manufacturers can supply unless the capacity of their plants is greatly increased. Many new concerns will therefore start the manufacture of standard and special machine tools within the next decade, because the industry is a stable and profitable one, and as the field widens its product is less liable to fluctuations in demand than heretofore. The machine tool business is therefore one to inspire the confidence of hard-headed business men who want to know that their money is safely invested where it will yield a fair return and multiply.

Much depends in the machine tool industry on business ability,—more than mechanics generally think; but the talent required for the organization and management of new machine tool concerns exists in the trade, and the next ten years will doubtless see many mechanics who have the ambition and ability leave the bench and strike out for themselves, at the head of new enterprises.

* * *

HAND AND AUTOMATIC TURRET LATHES

In December MACHINERY we published an article on shop practice which included many excellent examples of operations on the hand-operated turret lathe. In the current number is an article containing descriptions of several equally interesting operations performed on the automatic turret lathe. While the work in the two cases is somewhat different, it is conceivable that if these two shops should swap managing officers, the methods of machining would change with the management, and that the work, in time, would be changed from hand to automatic machines and *vice versa*.

The condition mentioned is an important one. It meets every machine manufacturer in the country, and a close understanding of the subject is most essential. There is, of course, no fundamental competition between the two methods of machining. Each is supreme in its own field, and it is only on work which is on the border land between the two classes that any uncertainty should be felt. We are going to try to present, briefly, the considerations which should guide the manufacturer in deciding to which class his work belongs.

First let us consider the advantages of hand-operated machines. The hand turret lathe receives constant supervision which renders it less liable to shut-downs from any cause save that of neglect of duty. Accuracy in the work can be maintained with more rapid tool deterioration, and consequently with heavier cuts, due to the feature of constant supervision, combined, in a well-designed machine, with ease in changing and adjusting the tools. Changes of tools and adjustments can be more quickly made, and less complicated tools are required, profitably adapting the machine to smaller lots than the automatic machine can be rigged up for. The same factors also facilitate changes and improvements in the product.

Another and most important advantage of the hand machine is the higher output possible per dollar of capital investment, because the machine itself and the tool equipment are less expensive, and under many conditions a higher output per machine is possible. Again the profitable use of the hand machine on small lots permits the rapid flow of work through the shop, with a consequent reduction of the capital tied up in work in progress. All these factors—the less expensive machines and tools, the possibly smaller number of machines, and the smaller stock of rough and finished parts—are reflected in smaller and more compact buildings, with the consequent reduced expense for interest, insurance, taxes, salaries and other overhead expense.

The advantages of the automatic machine may be summarized as follows: It makes possible a lower labor cost per piece, and this is true practically in all the conditions under which the automatic machine would be considered. It may be arranged to take full advantage of the possibilities of using multiple tools, and on a large proportion of turret machine work this means that the hand machine will be unable to produce the same output per machine, in spite of the closer personal supervision which the latter receives from the workman. In the matter of accuracy it may be assumed that with properly arranged tools and proper setting up, the invariable mechanical action of the automatic machine is highly suited to the production of accurate work, uniform in all its important dimensions.

Besides those just mentioned, the automatic possesses other advantages over the hand machine which must appeal to shop managers from the standpoint of administration. It does not cease to be productive, even if the operator leaves it for a time, and it does not stop until its work is completed. One skilled mechanic can supervise the work of a large number of machines, and the direct attendance of the machine, for keeping it supplied with work and inspecting its operation, can be left to a less expensive grade of labor. This consideration means also a more flexible organization, as it is easier to shift men from one machine to another.

High production for a given piece on the hand turret lathe comes in part from the skill of the operator on that particular piece, and is checked for the time being by shifting to work of another character. The same considerations also apply in the matter of breaking in new men to the work. Attendants for the automatic machine, sufficiently skilled for its requirements, can be obtained with little trouble. The importance of these considerations can best be understood by those actively engaged in shop management.

In balancing the various advantages and disadvantages mentioned above, the shop manager should take into consideration the conditions covering his particular case, among which may be mentioned the following: Is the work of such a character that the multiple cuts obtainable from the automatic machine can be used? Are changes in the design or character of the work sufficiently frequent to make the adaptability of the hand machine an important consideration? Is the product built in sufficiently large lots to make automatic machines profitable? Is the capital available for the business sufficient to warrant larger initial expense when the more expensive machines figure out to be cheaper in the long run? Is the product of the shop, as determined by careful analysis of accurate cost accounts, of such a character that the labor cost is relatively high, or relatively low, as compared with the charges for material, overhead expense and interest? What are the labor conditions? Are wages for good men relatively high or low? Is the working population a shifting one, and is there a large supply of skilled workmen to be drawn on?

It will be seen that this problem is one difficult to solve by purely logical, mathematical processes of reasoning. The factors are too many and too complicated. Reasoning will carry the shop manager part way toward his conclusion. But when all the facts in the case have been gathered, in coming to a final decision from them that necessary and indefinable attribute we call "judgment" will have to be invoked.

We cannot refrain from calling attention to one point in which the automatic machines, in general, have a fundamental advantage over hand-operated machines engaged in the same work. This consideration may be criticised as being a purely ideal one which ought not to be considered in a practical discussion of the subject such as we have been carrying on. It is a consideration, however, which inevitably strikes the mind of the observer who has an opportunity to compare the conditions in two shops where both classes of machines are being operated with high efficiency. With hand operation, the workman tends to become the servant of the machine. The possibility of increase of production through constant supervision is so great that the operator is kept constantly on the alert in changing feeds, speeds and adjustments. With automatic operation, it is the man who is the master, and the machine the servant. It is a sight distinctly inspiring to see banks of automatic machines steadily chewing away, while the operator walks leisurely from one to the other, putting in a new piece here, examining the condition of the tool there, and occasionally changing the adjustment. This consideration, we believe, brings the automatic machine directly in line with the current of human progress.

Why don't the grinding machine operators wake up and write something of general interest on grinding?

PRACTICAL SAFEGUARDS IN THE NATIONAL CASH REGISTER CO.'S PLANT*

ETHAN VIALL†

No plant in the world is more up-to-date in every respect than is that of the National Cash Register Co. at Dayton, Ohio. It has been looked upon as a model for years, and its fame as such has attracted visitors from all over the world, over fifty thousand being shown through the various departments annually.

Every effort has been put forth and no expense spared to beautify the factory grounds, a noted landscape gardener being employed for the purpose. Employes are encouraged to buy their own homes and are given expert advice as to the best way to make them attractive. Good wages are paid, and women employes are given shorter hours than men and a recess twice a day. Rest rooms are also provided for them, and a doctor and trained nurse are within easy reach. The men are allowed twenty minutes for one shower bath a week in winter, and forty minutes or two a week in summer at the company's expense, there being 228 series of showers in the factory. No person with a contagious disease is allowed to work. Four-fifths of the wall space is glass, affording plenty of light and saving the employes' eyes. The ventilating system is as nearly perfect as modern science can make it. The company has its own laundry and furnishes clean towels and aprons twice a week, and in every possible way the employe is taken care of, not merely because the company wants to be philanthropic, but because it is sound business policy. The old, revolting idea that found expression in: "When he's dead we'll get another man just as good," has no place here; but the policy toward the employe might be expressed in this way: "We have spent time and money to train this man (or woman) in our way of doing work, and it is far easier and better to take care of him and keep him in good shape physically and mentally, than it is to neglect or mistreat him and, in consequence, have to break in a new one every few weeks or months, thereby lowering our average of efficiency, quality and output." The different ways by which all this is accomplished are almost infinite, but it isn't within the scope of this article to deal with anything more than those methods or devices by which life or limb are protected, though in many cases the margin between mechanical safeguards and sanitary ones is so narrow as to be practically indistinguishable and no attempt will be made to hold strictly to mechanical devices as such are usually defined.

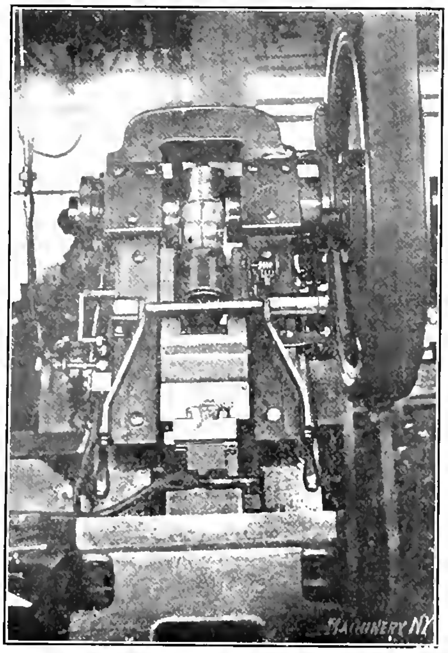

Fig. 1. Two-handed Trip for Punch Press, which proved Defective

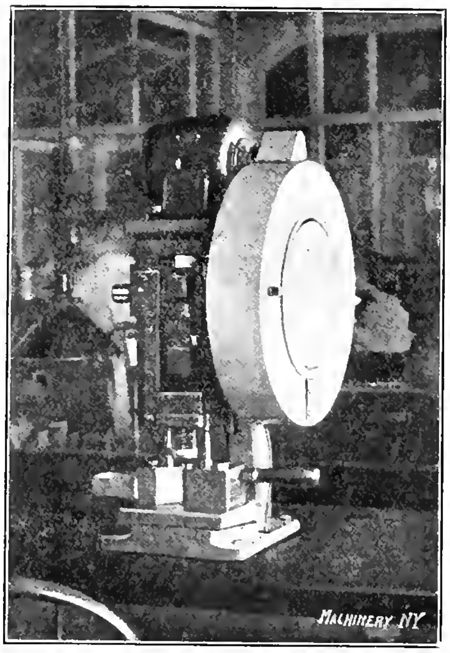

Fig. 2 Guard over Pinion and Gear of Motor-driven Press

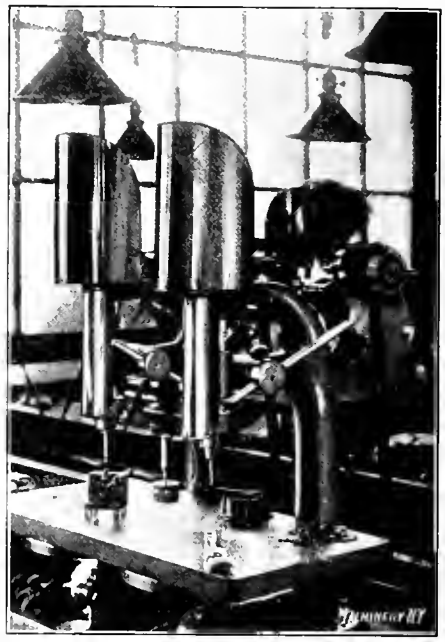

Fig. 3. Hair Guards on Small Drill Presses which are operated by Women

Probably no class of machines, unless for woodworking, has been the cause of more serious accidents than punch presses, yet no other class of machinery has had fewer successful safety devices. In many cases, on the more powerful machines, even the gearing, now almost universally covered on other machines, is left without a guard or shield of any kind, a man's finger or his arm hardly being considered worth looking out for, regardless of the fact that one damage suit is likely to cost enough to buy a hundred or even a thousand guards. Carelessness and indifference on the part of employes has, to some extent, been responsible for the lack of proper safeguards, for what an employe doesn't insist on or doesn't want, isn't usually given him, especially if it costs the employer anything. Instances are common where an operator, after a press has been fitted, at considerable expense, with an automatic lever or guard to protect the fingers or

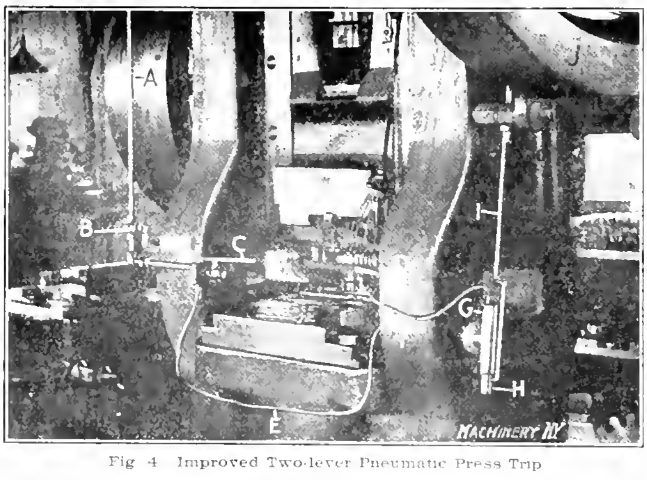

Fig 4 Improved Two-lever Pneumatic Press Trip

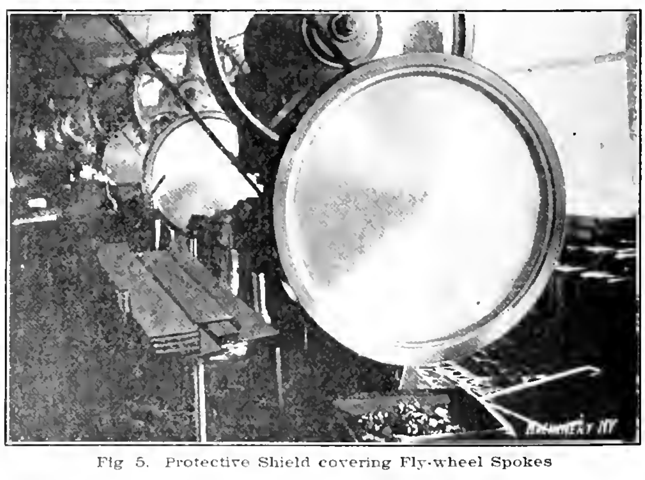

Fig 5. Protective Shield covering Fly-wheel Spokes

* See note referring to the safety appliances used by the U. S. Steel Corporation, in MACHINERY, February, 1909.

† Associate Editor of MACHINERY.

hands from the descending punch, has, at the first opportunity, thrown it aside and gone back to the old unguarded way. Too much trouble is the verdict, but it *isn't* too much trouble if the device is going to save a man's hand or arm, no matter what he says of it.

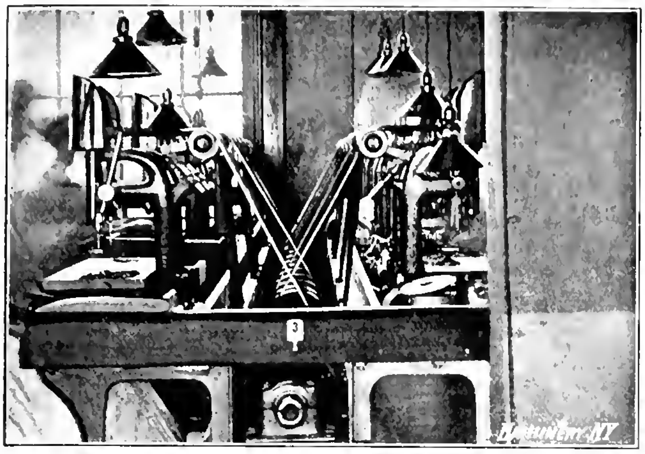

Fig. 6. Hair Guards and Arrangement of Belts and Pulleys on Small Drills

Only a few instances of discarded devices serve to convince a thinking foreman that any appliance intended to prevent a man getting his fingers under a punch, must be absolutely "fool-proof," and to devise something of this kind has been one of the hardest problems that the shop officials of the National Cash Register Co. have had to solve, but recently they hit upon what appears to be the only really successful, fool-proof appliance yet devised. It has taken a long time to work out and correctly apply the idea involved, but the principle is very simple, the whole idea being to *make the operator use both hands to trip the press and to make it impossible for him to do so unless he does use both hands.* That is the whole thing in a nutshell, and the idea is being applied to every punch press in the plant and, of course, in compelling a man to use his hands to trip the press, the dangerous foot treadle is discarded and one great source of accidents thereby eliminated, for it is so easy for something to fall on the treadle at the wrong time or for a man to stumble on it or else press his foot down unintentionally.

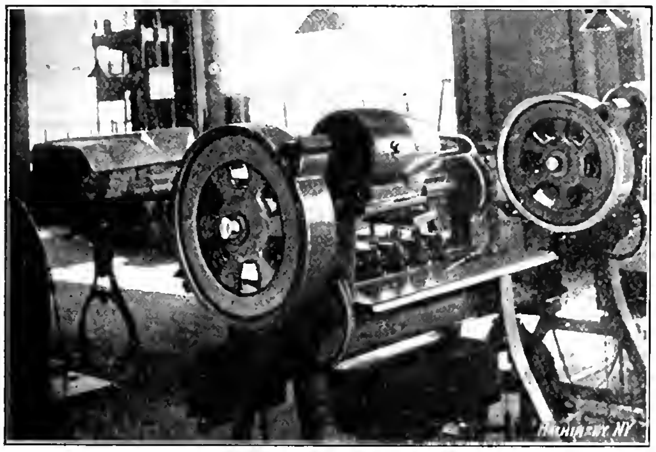

Fig. 8. Neat Style of Gear and Pinion Covers

Fig. 10. Corner of a Rest room for Women Employes

The first application of a device embodying the two-handed trip idea was on a punch press fitted with a forming punch and die, and is shown in Fig. 1. This was purely a mechanical device. Both levers had to be pulled to trip the press, as the pulling of one alone would not accomplish it, but as this device soon proved to be anything but fool-proof, it will not be described in detail. An additional safeguard on this machine consisted of an automatic air valve mechanism (shown on the left side of the press frame) and a hose which was so arranged as to direct a powerful jet of air onto the punching and blow it out of the die as the ram raised. The principal reason for condemning this lever system was that the operator, to gain a fraction of a second, would, unless watched, prop out one of the handles with a stick and work the trip with one hand, for which there was no valid excuse as the company's piece work rates allowed a very liberal mar-

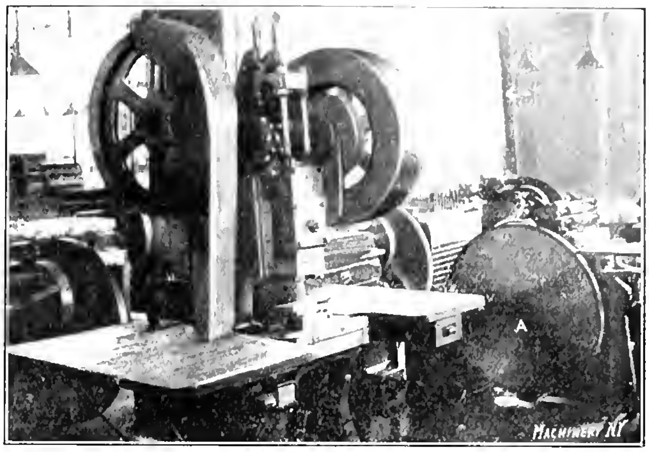

Fig. 7. Belt Guard and Fly-wheel Dress Guard

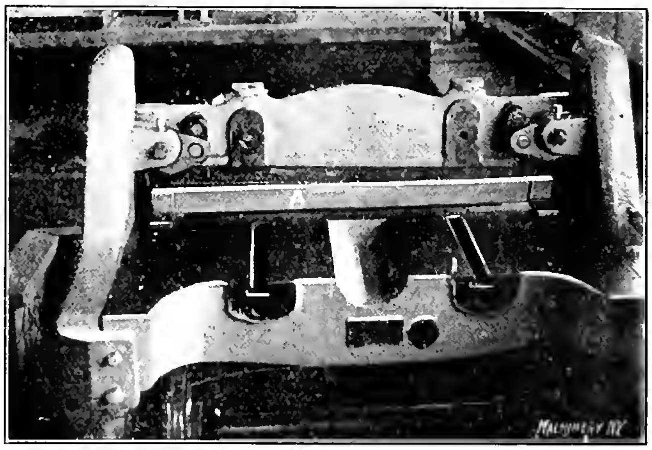

Fig. 9. Finger Guard on Small Trimming Shears

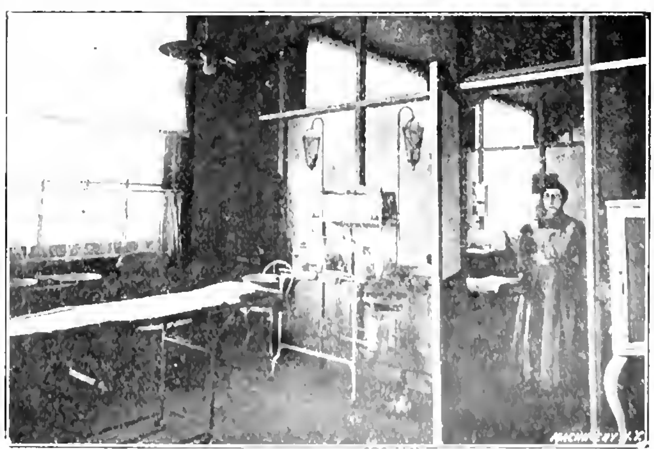

Fig. 11. View of a Corner in the Shop Hospital

gin; nevertheless the fact remained that the levers could and would be tampered with at the first opportunity, so the next move was the fitting of the pneumatic device to the presses, shown in Fig. 4, and this is practically the form of trip that is being put on all the machines at the present time. Refer-

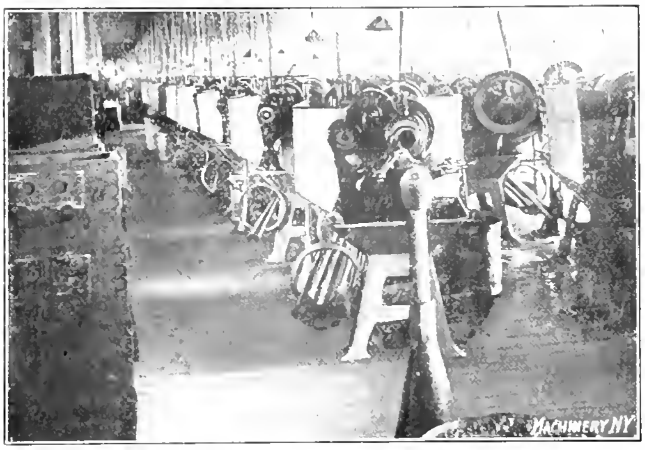

Fig 12. Battery of 340 Automatic Screw Machines, equipped with Splash Guards

ring to the engraving, A is the air supply pipe containing air under heavy pressure; B is a cut-off valve; C is the left-band trip-valve lever, and D is the right-hand trip lever. Both trip-valves are of the same pattern, and are connected by the small air pipe E. The air pipe F leads from the valve D to the

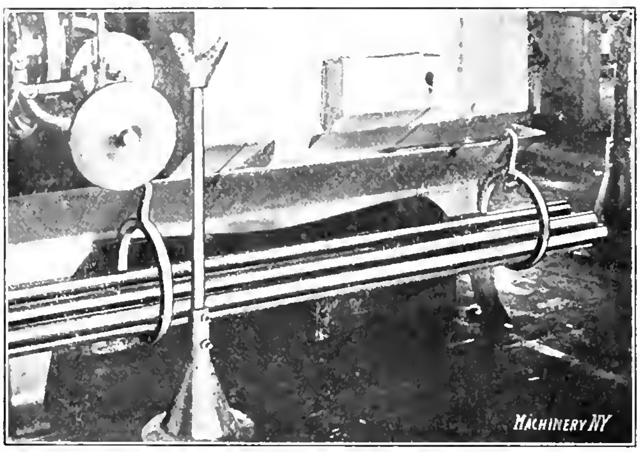

Fig. 13. Safety Stock Rack on Screw Machine

cylinder G, which is so arranged that when air is let into it the plunger H is forced downward, pulling the rod I with it, and thus causing the press to trip. Now to operate this trip, the line valve B is first opened, letting the air in as far as the valve C; but the pulling of lever C cannot trip the press,

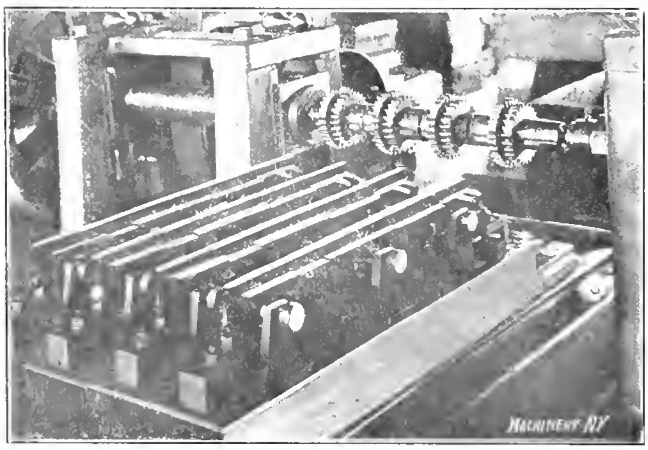

Fig 14 View of Jig on Milling Machine, showing Clearance between it and the Cutters

as the air cannot reach the cylinder until lever D is pulled, and on the other hand, the pulling of lever D alone cannot trip the press, since valve C closes automatically and shuts off the supply. It is plain, then, that if both valves are arranged to close automatically the instant the levers are released, it is impossible to trip the press unless both are held open at once. The form of the levers themselves and the angle at which they project when the valves are open, make it highly improbable that they can or will be successfully propped open. At J, in this engraving, is also shown a partial view of an excellent type of gear guard. Not only are all gears guarded as they should be, but all fly-wheel spokes are covered, where they are low enough to catch anything, as shown in Fig. 5.

In Fig. 2 is shown a good example of a covered gear and pinion on a small motor-driven press in one of the women's departments. Wherever women are employed in a shop, additional safety precautions must be taken on account of long fluffy hair and flowing skirts, and in Fig. 3, are shown two small drill presses with shields to prevent hair catching in the spindles or belts, and in Fig. 6 is shown a compact battery of these drill presses equipped with hair guards. These guards are also very effective in preventing oil being thrown

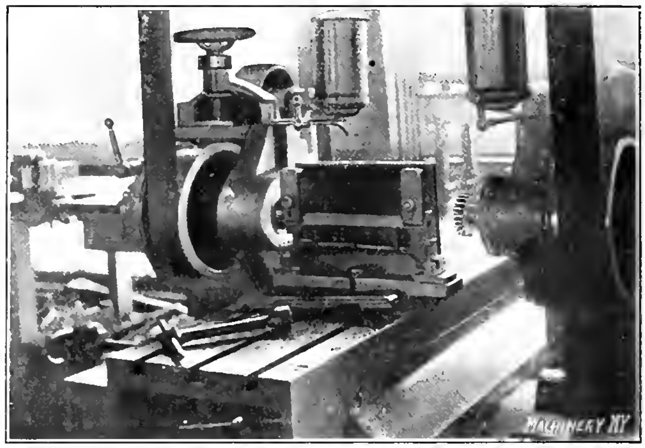

Fig. 15. View showing Position of Milling Fixture with Reference to Cutter, when Stationary

on the operator. The driving belts and pulleys are arranged in such a way that it is impossible to get caught in them in any manner.

At A, Fig. 7, is shown how the low fly-wheels are guarded to keep the skirts from catching in them, and at B is shown a

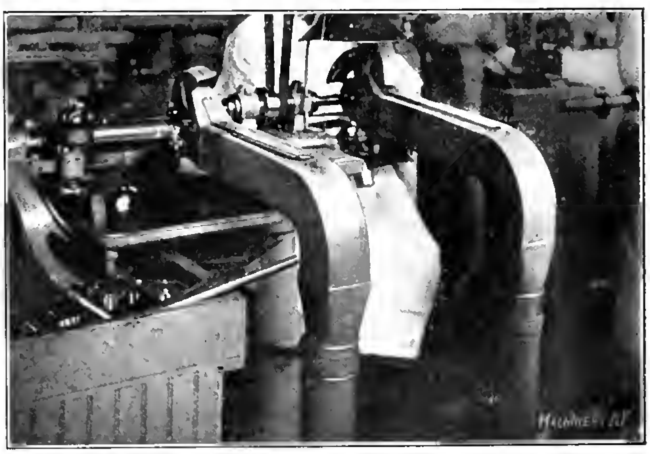

Fig 16. Dust Pipes and Wheel Guards on Universal Grinder

good belt guard. No overhead belts of any kind are allowed in the women's department, all driving being done by carefully boxed motors, and where these motors are mounted on the machines, they are carefully covered as in Fig. 8, and if belted in any way, the belts are guarded.

To keep the operator's fingers from under the blade of the light trimming shear, Fig. 9, the guard A, has been fastened to the bed, the opening being high enough for any possible work, but not high enough for fingers.

In connection with the brief mention of the employment of women, one of their rest rooms is shown in Fig. 10, which is provided with chairs, cots, lounges and other comforts so that they may rest or lie down at any time, if sick or indisposed In Fig. 11 is shown one corner of the hospital, where a trained nurse is always on duty during working hours, and a regular physician is within call at any time in case medical or surgical aid of any kind is needed. He also comes to the shop

hospital at a certain time each morning to prescribe for minor ills, if necessary.

Going now to the automatic screw machine department, with its three hundred and forty automatics, we find guards over gears and every other dangerous part of the mechanisms, and huge pans at the back and front of the machines, as in Fig. 12, to prevent the floor from becoming slippery and dan-

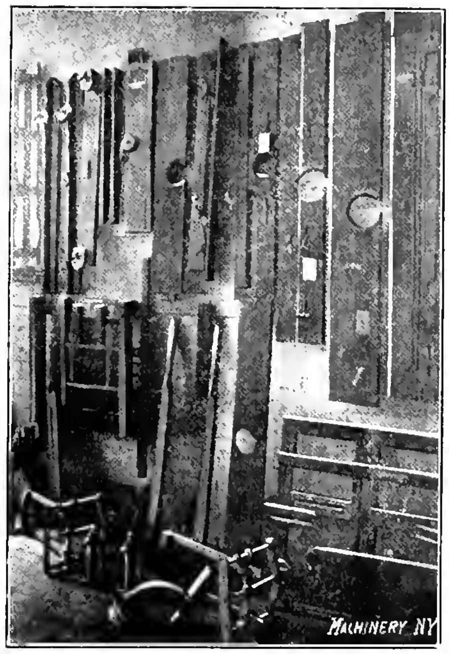

Fig. 21. Other Wood-working Jigs and Guards

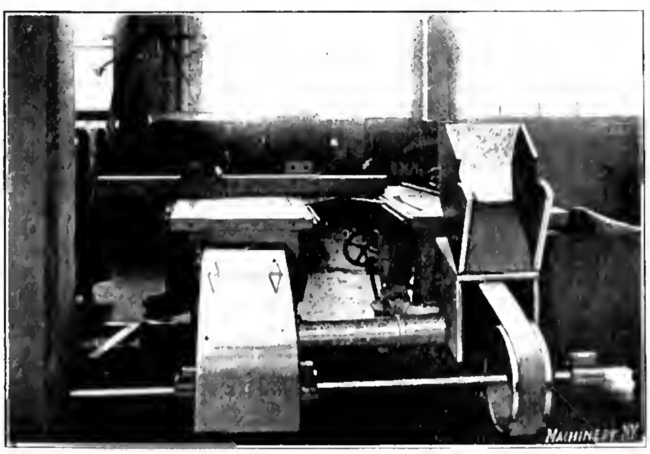

Fig. 22. Belt and Pulley Covers in the Wood Shop

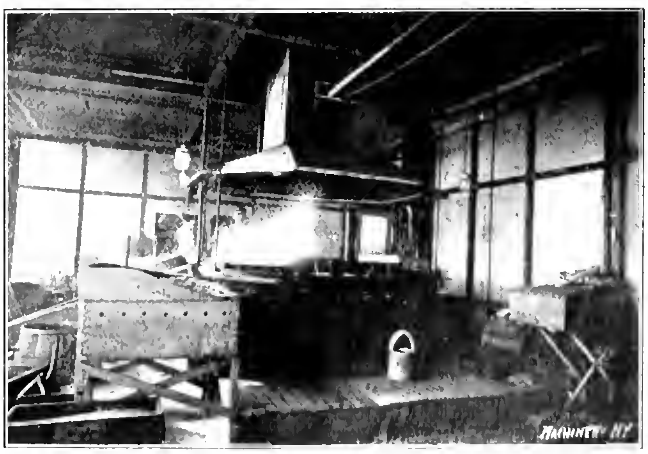

Fig. 23. Exhaust Fan and Hood over Acid Vat

gerous from spattered lubricant. Stock for immediate use is kept off of the floor by using the hook brackets shown in Fig. 13. Not only is this done for neatness and convenience, but also to prevent accidents caused by stepping on bars that are likely to roll.

All jigs used on milling machines and the like, are so arranged as to be drawn back and well away from the cutters while placing or removing the part. A good example of this type of jig is shown in Fig. 14. In many cases the reversing of the table is automatic, but in all cases plenty of clearance is insisted upon, and where possible the jig, when at rest, is back of the cutters as in Fig. 15.

Great care is taken in the tool grinding room to have the exhaust pipes arranged so as to carry off all dust. In Fig. 16 is shown the adjustable wheel covers and telescoping tubes used on the regular two-wheeled universal grinders, while in Fig. 17 is shown the method of piping a grinder with a swiveling head. Every wheel in this large department is thoroughly equipped and the air is as free from dust as in any other place. Fig. 18 is a surface grinder of the planer type equipped with a wheel guard and a large suction funnel just back of the

wheel, that catches and carries off all the metal and emery.

In the polishing department, a splendid exhaust system is in use as shown in Fig. 19, and here even the overhead pulleys have the spokes covered in order to avoid the fan action as much as possible.

In the woodworking department, there are guards of all kinds to prevent accidents, and special devices are used to cover as much of the cutters as are not actually in use. Wooden jigs are used for holding various parts while machining them on shapers, saws, etc., in order not to get the hands too close to the tools. A number of these jigs and special guards are shown in Figs. 20 and 21. All dangerous parts or

Fig. 24. View showing Suction Openings in Plating Room

places in the wood shop are painted a bright red, belts and pulleys are boxed as in Fig. 22, and band-saws are covered as much as possible.

Acid and other fumes in the plating or lacquering rooms, are drawn off through hoods placed over the vats or tanks as in Fig. 23 or else by suction hoods at the back of the tanks as in Fig. 24, the powerful suction being shown by the way steam is drawn in from the tank next to the window.

The big potash tanks are equipped with mechanical dipping devices, so that the men will not get their hands into the biting stuff. This dipping machine is shown in Fig. 25. It consists of a series of cages or frames fastened by chains running over pulleys, to a reciprocating bar worked by a pulley and crank, in such a way that the cages dip up and down in

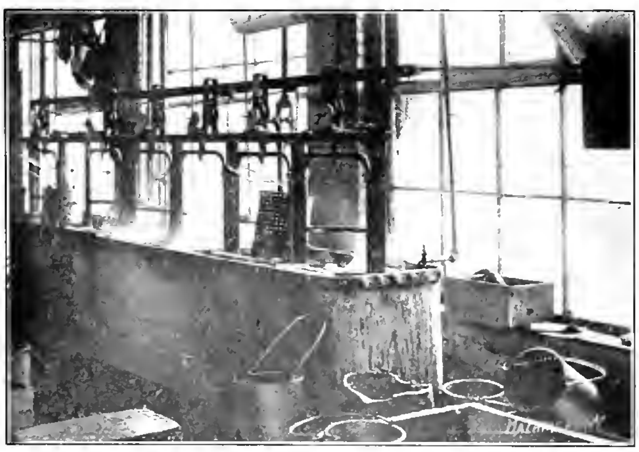

Fig. 25 Dipping Machine and Potash Tanks

the tank continually unless caught and held up by a hook or latch at the top of the framework. All but one of the frames are shown "hooked up" in the engraving. The perforated pails containing the oily parts, are placed in one of these cages and the hook pulled back; the cage then proceeds to automatically dip in and out of the potash until the operator again hooks it up. The parts are then allowed to drain awhile, after which they are removed from the bucket. Not only does this machine save the men's hands and bodies from the principal effect of the potash, but it also prevents the inhaling of the fumes that is the inevitable accompaniment of hand dipping. The machine is also a great time saver.

Going up the stairway from one floor to the other, one notices how even the stairs are railed and guarded with heavy wire screen as in Fig. 26, and in many places where trucks have to be run up long inclines, strips or belts of a cork-like material are laid in the floor to walk on and to prevent slipping and consequent injury.

While gathering material for this article, I was greatly assisted by Mr. Reeder, manager of the Welfare Department; Mr. Sager, machine supervisor; and Superintendent Oswald, and my thanks are especially due to the last-named gentleman, whose permission and kindly interest made possible this article.

JEWELERS' WAX

ARTHUR A. RACICOT*

To make jewelers' wax, take common rosin and heat it in a vessel until it flows freely; then add plaster of paris, stirring continually while adding the powder. Care should be taken not to make the mixture too stiff. When it appears of the proper consistency, pour some of it on a slate or marble slab and allow it to cool; then insert the point of a knife under the flattened cake thus formed and try to pry it off. If it springs off with a slight metallic ring, the proportions are right; if it is gummy and ductile, there is too much rosin; if it is too brittle and crumbles, this indicates that there is too much plaster.

Fig. 26. Railed and Guarded Stairway

This is what is sold for jewelers' cement at thirty cents for a half pound cake. It is used for filling gold headed canes, umbrella handles, cementing stones in ring settings, and also for holding very thin pieces of metal on a face-plate for drilling, cutting disks, or turning off the surface.

I gave this formula to a friend who had some very artistic tile for a fire-place, and after having set as many as he could one evening, he forgot that the wax only needed rewarming in order to use it the next day, so in order to keep it fresh he poured water in the iron pot; in the morning the wax had become insoluble owing to the action of the water on the plaster. So it is advisable not to wet the wax until it is put to its final use and place.

* * *

Iron castings that are too hard to machine or which have hard spots destructive to tools may be nicely annealed by packing closely in covered cast iron boxes with black manganese, and heating to a temperature of 1,500 or 1,600 degrees F. until thoroughly heated through. A large box packed in this manner with a closely-fitted cover luted with fireclay must be heated for several hours to raise the interior to the annealing temperature. To be sure of getting the interior heated properly, a number of witness wires should be placed in the box, projecting through the cover where they can be conveniently grasped with tongs and pulled out one at a time to show how far the heat has progressed. When the interior has reached a bright red heat the box should be hauled out and covered with ashes so that it will cool slowly. It is claimed that hard spots in gray iron castings can be softened with black manganese by applying the manganese and heating to a dull red, using a blow-torch or any other convenient means of heating.

ASSEMBLING A 48-INCH MOTOR-DRIVEN PLANER—2

ALFRED SPANGENBERG*

In the previous article it was stated that the principal points to be observed in planer erection are: housings parallel with each other and square with the bed; accurate fit of all sliding members and truth of all plane bearing surfaces; proper mesh and smooth working of gears; and a system that permits the various parts to be easily and quickly assembled, and avoids the necessity of fitting the members together for the laying-out operations. In the first article boring and drilling the bed, drilling the housings, and testing the housings were described, and in this, the concluding part, we will take up laying out the arch bars, assembling operations on the bed, setting the housings, assembling the driving, feed and arch members, laying out and setting the cross-rail and the final test and inspection.

Laying Out the Arch Members

The first drilling operation on the arch is for the housing bolts, the jig for this being shown at *C*, Fig. 4; then the arch

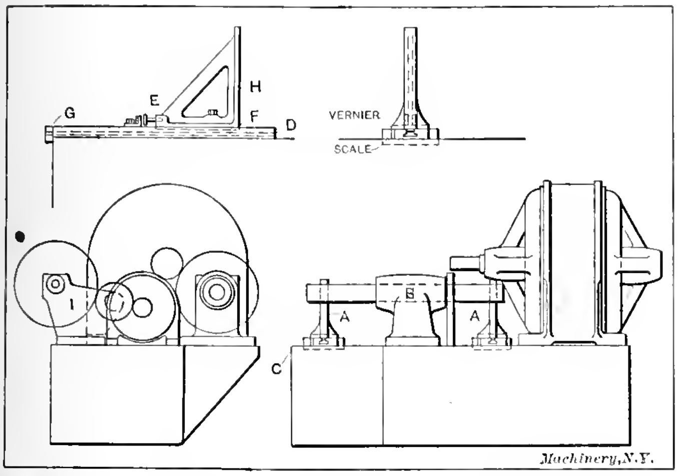

Fig. 8. Arch with Bracket Members and Motor in Position for Laying Out

is set under the drill in its normal position and the brackets and motors are located for marking off the bolt holes, as illustrated in Fig. 8. When these holes have been drilled and tapped, the arch members are bolted in place for drilling the dowel pin holes, this time more care being exercised in the setting. This is another instance where the varying character of the parts precludes the use of drill jigs, and a method of laying out the work must be resorted to. For convenience in obtaining accurate measurements, and to facilitate the work, a pair of adjustable angle-plates are used, as shown at *A*, the idea being to use an arbor in the bracket hole *B* and to provide a positive locating surface at each end, against which the arbor just touches.

The location endwise not being as particular, a line is scribed on the arch the correct distance from end *C*, and the bracket, with a scale held against the end, is set so that the edge of the scale coincides with the line just mentioned. As will be seen from the detail view, the angle-plate is adjustable on its base *D*, and may be turned end for end and clamped in any position as the case may require, fine adjustment being made by the screw *E*. Fastened to base-plate *D* is a scale, while attached to angle-plate *F* is a vernier, this combination enabling very accurate settings; all readings are taken from the lip *G* to surface *H*, and it is necessary, of course, to add half the diameter of the shaft to obtain the center distance. Bracket *I*, for the top elevating shaft, is set in the same manner, except that the angle-plates are reversed on account of the bracket being so close to the edge of the arch. With both brackets bolted fast and pinned, and their gears in place supported on short arbors, the motors are set so that their pinions mesh properly with the respective gears; then the motor clamping bolt holes are marked off, drilled and tapped, and the motors reset for pinning. In case the design is such that the entire top surface of the arch casting is not planed, *i. e.*, where finished seats are provided for the brackets and motors, additional spots are required for the angle plates. These spots are conveniently located on the casting and are finish planed with the other seats.

Assembling Operations on the Bed

The first assembling operations proper on the bed consist of drilling the various set-screw and oil pipe holes; drilling and fitting the track oiling device, a drill jig for which is shown in Fig. 9; and assembling the rack gear, its shaft, and the two intermediate compound gears and shafts. These operations, together with placing the housings on the bed, are done before the leveling operation, as otherwise the consequent hammering and additional weight of the housings might throw the bed out of level.

During erection, the bed is supported on cast iron parallel blocks placed about six feet apart along the whole length of the bed and also under the housings. Planed cast iron wedges, having screw adjustment, are placed between the parallel blocks and the bed, thus enabling very accurate leveling to be accomplished. The arrangement of all the blocking is such that none of it will interfere with the driving and feed mechanism during erection, and as these details vary in different machines, the blocking must be arranged to suit each machine.

Several methods may be followed in leveling a planer bed, any one of which will give good results if the work is carefully done. The prime requisites are, of course, a first-class, sensitive, spirit-level—one at least 18 inches long—and an accurate parallel that will reach across both tracks. It is obvious that since the tracks in a new bed are not worn, just as good results are obtained in leveling, by using the top surface on the tracks, as by using either V-shaped parallels or cylindrical pieces in the ways. The leveling is done as follows: The level is used on the top surface of one track, and that side of the bed is carefully leveled by moving the instrument short distances at a time, over the entire length. Then, by placing the level on the parallel, the bed is leveled crosswise; the operation of first leveling one side and then cross-leveling to the other is repeated several times, or at least until no further errors can be detected.

Setting the Housings

Fig. 10 is a top view of the planer, and shows the general method of setting the housings; the operation involves the

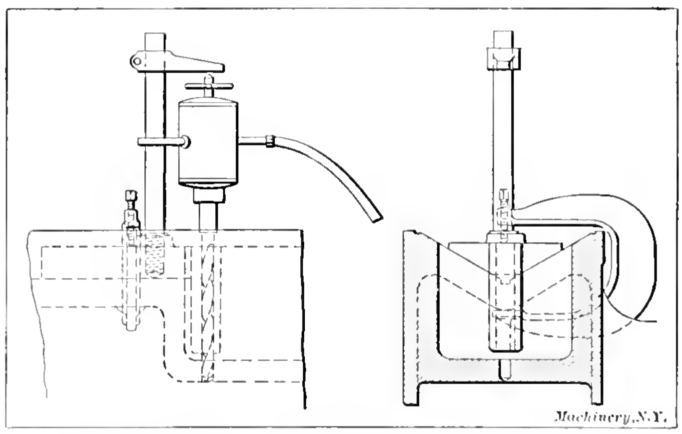

Fig. 9. Combination Drill Jig and "Old Man" for Drilling Hole in Oil Pockets for Oiling Device. Jig Insures Hole being drilled in Center of Way

alignment of the driving shaft bearing in bracket *A* with that in the bed at *B*, and also includes bringing the faces of the housings into the same plane. With the housings bolted to the bed only sufficiently tight to hold them in place, and with driving shaft bracket *A* bolted and pinned fast to the front housing *C*, an arbor *D* is used as indicated. This arbor is ground true and is a wringing fit in the bed at *B*, and, being of smaller diameter where it passes through bracket *A*, permits it to be easily introduced into the bed bearing even though the bracket hole is out of alignment. This condition is possible, of course, since the clamping bolts *E* have 1/8 inch clearance in the housings. Now, with bushing *F* in position to enter hole *G*, the front housing is driven with a babbitt hammer, either forward or backward as the case may require, until the bushing enters the hole freely without springing the arbor.

* Address: 951 W. 5th St., Plainfield, N. J.

To set the back housing, a straightedge is laid across the bed as shown at H, and narrow strips of tissue paper are introduced at I and I_1; then, by moving the back housing until papers I are tight and I_1 can just be moved, it is determined that both housings are in proper alignment. The fact that the outside papers are slightly loose is due to conditions already stated. After reaming the housing dowel pin holes by means of an air drill, and driving in the pins, measurement is taken for arch casting J, and the housings are calipered over surfaces K just above the bed, and at the top, to test their parallelism.

While an attempt is made at interchangeability with respect to the length of the arch member, it sometimes happens that certain elements make it necessary to slightly deviate from the standard measurement. For instance, the above test may show the measurement over K to be from 0.002 to 0.003 inch wide or narrow at the top, in which case the housings are made parallel by means of a jack-screw, or tie-rod, as the case may require, and then the arch is machined to suit. The arch is now bolted in place, and set to match the housings at L and M, after which it is pinned.

Assembling the Driving, Feed and Arch Members

The cross-rail, side-saddles, and the various driving and feed units are assembled in a department separate from the erecting department, and these parts usually are duplicated in quantities and come from the store-room to the erectors completely finished. In all cases where possible in assembling these units, standardization is provided for, and in this way much time is saved by the erectors avoiding unnecessary adjustments.

Referring back to Fig. 1, the feed box E is next bolted in place, and after assembling the driving shaft F with its members, and bolting on the bracket member G, the outboard bearing H is bolted in position. The arch bearing for the flywheel shaft I, already being secured in place, this shaft is red-leaded and tried in its bearings to test their alignment. When proper care is exercised in the aligning operations, very little scraping is necessary on these bearings.

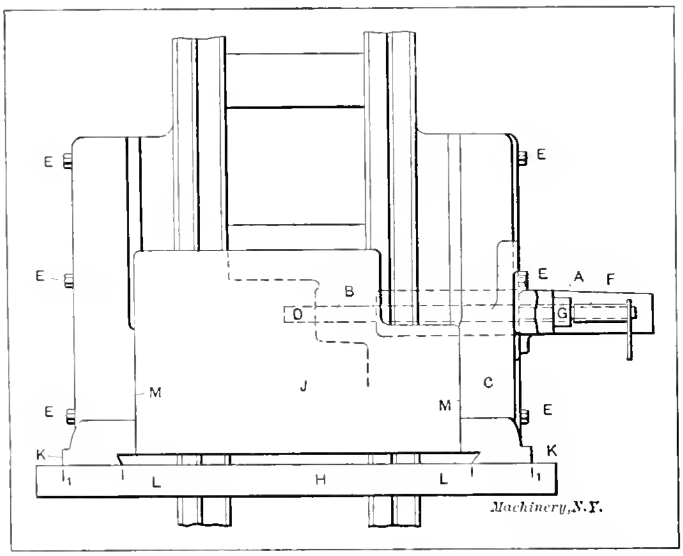

Fig. 10. Method of Setting the Housings. First the Front Housing is set for Alignment of Driving Shaft Bracket "A," then the Back Housing is brought into the Same Plane by means of Straightedge "H"

While work is proceeding in assembling the top works, elevating screws, and motors, other erectors are busy with the side-heads D, rocker mechanism J, and the feed mechanism for the side-heads and cross-rail; each unit is assembled in logical order, and as many operations as possible are carried on simultaneously. The planer is now ready for the cross-rail K and table L, preliminary work on these members being completed far enough ahead so as to cause no delay at this point.

The operations on the table consist of drilling and reaming the stop-pin holes, drilling and bolting on the rack, and rough scraping the tracks; the oil grooves were cut in the machining process. A large motor-driven multi-spindle drill is used for drilling and reaming the stop-pin holes. This machine carries sixteen spindles, arranged in two rows; one row of spindles carries the drills, and the other the combination mills and countersinks. After the first row of holes is drilled and the table is indexed along the space of one row, the combination mills and countersinks are inserted, and the sixteen tools are used simultaneously, thus producing very rapid work. The table is supported on a special truck running on a track between the drill uprights, and a suitable mechanism for moving and indexing the table completes the equipment. Previous to placing the table on the bed, the ways on the latter are also rough scraped, and then the bearing surfaces receive a coat of red lead which serves the double purpose of marking material and lubricant.

Laying Out and Setting the Cross-rail

The stud holes A for the cross-rail gibs are drilled in the manner shown in Fig. 5. As will be seen, spots are planed off at B which serve to square jigs C and C_1, and the holes for

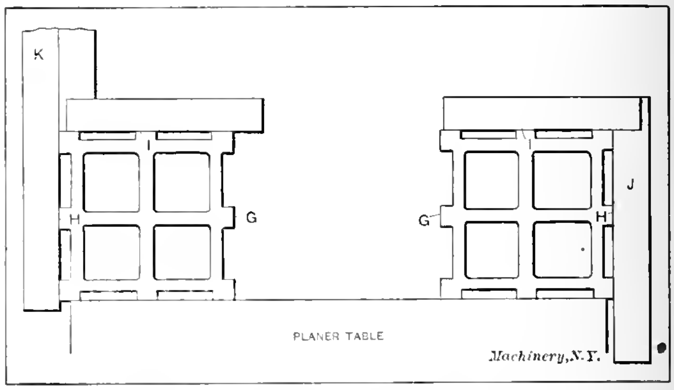

Fig. 11. Method of Testing Accuracy of "Planing Square" when using the Side-heads

the elevating screw nuts are utilized for clamping the jigs by means of bolts D. Endwise location of jig C is determined by matching the end of the cross-rail as shown; then jig C_1 is set by transferring the measurement from the housings by means of the wooden straightedge E. A flat scriber, shown at F and F_1, is used to mark lines on the straightedge which is chalked for this purpose, and when corresponding lines on the jigs coincide with those on the straightedge, jig C_1 is properly set.

When the studs are screwed in place and the back surface of the cross-rail is scraped, the cross-rail is placed in position on the planer and clamped by its gibs. Squaring the cross-rail with the housings is accomplished by holding the bar of a sweep in the angle M, Fig. 1, and applying an indicator to the front housing at N and N_1 (Fig. 1). The low end of the cross-rail is raised a sufficient amount by either moving the teeth in bevel gear O or O_1, as the case may require, in relation to its pinion, or by adjusting one of the nuts on the gear end of the elevating screws, final adjustment being obtained by the latter method. It is always better to raise the low end rather than lower the high end of the cross-rail, on account of the fact that this will take up any lost motion or backlash between the nuts, the feed-screws, and the housings. As the studs have 1/16 inch clearance in the gib, it is necessary to pin the latter after setting the cross-rail.

Final Test and Inspection

With the motors wired up, the belts in place, and the machine thoroughly oiled, the driving works are run for a while before moving the table into mesh with its rack gear, the idea being to prevent possible heating of the bearings by running without load. Next the table is brought into mesh and the bed is again carefully leveled in the same manner as before. When this is accomplished, the ways and tracks are scraped to a bearing, after which the ways are oiled and one or more cuts taken across the table to true it up for the purpose of testing the planer. A straightedge tried on the table crosswise, lengthwise, and across corners, is used to test the truth of the planing.

The side-heads are next tested for "planing square" by the method illustrated in Fig. 11. Two cast iron parallels G are clamped one on each side of the table as shown, and then light cuts are taken down faces H with tools in the side-heads.

Now, with the faces *H* clamped to the table, cuts are taken down faces *I*, after which the parallels are turned back to their original positions and a square tried as at *J*. To "prove" the square, it is used in connection with a straightedge (on the same parallel) as at *K*, any error detected between the blade of the square and the straightedge showing double the amount of actual error.

The accuracy of setting the cross-rail is now determined by taking a light cut across faces *I*, using a tool in one of the cross-rail heads, and testing with the square and straightedge as in the previous case. The object in making these tests is a precautionary measure, for by testing the planer under actual working conditions, the accuracy of the tests made during erection are thus proved.

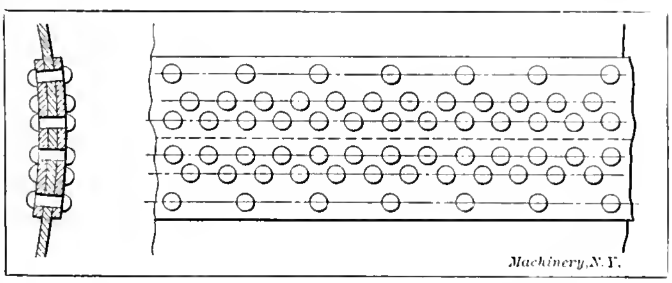
Final inspection includes running the cross-rail to the top of the housings to test the elevating mechanism and ascertain the fact that there is clearance between the cross-rail and arch. All gearing is tested for quiet and smooth running; the fits of all bearing surfaces are inspected; the slides and saddles are run by hand to test the parallelism of their ways and also the ease with which the slides operate, after which the power feed is applied and tested in various ways; the balance of the driving motor armature, and of the fly-wheels and pulleys also, receives careful inspection; in fact, no part is neglected and all errors must be within allowable limits of variation. All tests are made under the personal supervision of an inspector, who enters all data on a form prepared for the purpose, and this report bears the serial number of the planer, and is filed away for future reference.

As opportunity offered during erection, the filling, rubbing down, and priming has progressed, so that after inspection, all that remains to be done is to give the bright parts their final polish, and apply the last coat of paint.

* * *

LONGITUDINAL JOINT FOR BOILERS*

It has been generally accepted in this country that the best form of butted longitudinal riveted joint for boilers is that in which the inside strap is wider than the outside, and has one or more rows of rivets which pass through the shell and the inside strap beyond each edge of the outside strap. The pitch of the first row of outer rivets is double that of the rows that pass through both straps, and if there are other outer rows they may or may not have a still greater pitch. In England, where, until comparatively recently, boiler construction has been superior to ours, this form of joint appears to receive no recognition. It was first devised, as far as known, by Dr. E. D. Leavitt and Edward Kendall, both of Cambridge, Mass., and was first used in 1879 by Mr. Leavitt in some locomotive-type boilers designed by him for the Calumet & Hecla Mining Co. It is, of course, hazardous to state that this joint was never used before, and it is quite possible that it was used in England and discarded.



Recommended Type of Longitudinal Boiler Joint

While every boilermaker has for years been familiar with butt joints, this form made slow progress towards adoption in this country. One form of joint used to avoid the butt joint and get something as good was a lap joint with an inside strap bent at the edge of the lap and riveted on each side of it. This was used on locomotives exclusively, and was of little or no value, as it was simply a somewhat elastic bent tie connecting the two parts of the shell plate. Finally, and fortunately, this joint gave way to the butt joint first described. It has, however, been the author's opinion for some years that a one-sided boiler joint such as that first described, is also poor construction, and may sooner or later cause a crack in the plate. It is evident that unless the outside rivets fill the holes, they do very little good, and when they do fill them they form an overhung connection and to some extent possess, in themselves, the now recognized defect of the lap joint. Moreover the extended inside plate forms a bent connection between the different rivets at different distances from the center line of the joint.

In many cases designers have placed the outside rivets at a considerable distance from the edge of the outside strap, and this is constantly overdone. It is obvious, on careful thought, that the outside rivets should be as near the edge of the outside strap as practicable, thereby diminishing the bent-tie effect. In order to diminish this effect still further, and also to render the overhung rivets more effective, the inside strap should be thicker than usual, and this feature can hardly be overdone. The inside strap should be at least as thick as the shell plate, and great care should be taken to have the holes match and the rivets fill the holes.

When a joint of this kind is tested to destruction in a testing machine, it will be found to fail somewhat in detail, the inside strap bending slightly and the outside rivets being the last to rupture after yielding a little. In a boiler the joint would be weaker than a flat specimen on account of the bent-tie feature. This could be prevented if it were practicable to calk the inside strap as it would thereby be compelled to maintain the circular form. The theoretical efficiency of this joint is greater than of any other kind, but in practice the efficiency is not realized.

In order to avoid the defects of the one-sided butt joint, the author has adopted a joint with both straps of the same width, as illustrated in the accompanying engraving. This has the merit of having all rivets in double shear and the strains all taken care of in the best manner. The efficiency of this joint can hardly be above 84 or 85 per cent, while that of the one-sided joint can be theoretically 91 or 92 per cent; but the certainty that the efficiency of the former is realized in practice is ample compensation for the use of slightly thicker plates. The pitch of the outer rows of rivets is rather great, compelling the use of a thick outside strap in order to stand calking and remain steam-tight. An equally thick inside strap is used in order to diminish the bent-tie effect. This effect is small, however, as the rivets are all near the center of the joint. It can be eliminated by calking the inside strap, which is practicable with this joint, and is done in the best marine practice.

* Abstract of a paper by Mr. F. W. Dean read before the American Society of Mechanical Engineers, December meeting, 1909.

* * *

The manner in which samples of air at high altitudes are collected shows an interesting example of the methods employed by scientists for ascertaining facts which cannot be obtained by direct personal investigation. Samples of air at a height of nearly nine miles have recently been obtained and examined for the purpose of ascertaining the presence of rare gases. The collecting apparatus is carried by a large balloon and consists of a number of vacuum tubes, each drawn out to a very fine point at one end. At the desired height, an electromagnetic device connected with each tube, and operated by a barometer, breaks off the point of the tube, thus admitting the air. Within a few moments a second contact sends current through a platinum wire around the broken end, thereby melting the glass and sealing the tube. The samples thus obtained have shown the presence of argon and neon, but no helium was found in air above an altitude of six miles.

* * *

High speed steel has made a great improvement possible in the speed of threading dies on bolt machines. At the Atlantic City conventions of the Master Mechanics and Master Car Builders' Associations, the Landis Machine Co. exhibited a bolt threader equipped with a Landis high speed die, working at a cutting speed of from 45 to 55 lineal feet per minute. Rough bolts were threaded with startling rapidity, a two-spindle machine keeping a man busily employed all the time when threading 5/8-inch bolts with, say, 1 1/4 inch of thread. The actual time required for cutting the thread of this size and length was only about three seconds.

SHOP PHOTOGRAPHY*

R. F. KIEFER†

The writer has read with interest several articles on shop photography which have, from time to time, appeared in MACHINERY. However, some of these articles disagree, to some extent, and are not as complete as they might have been. This prompts the writer to describe the methods used by him during a ten year's experience in the taking of pictures. When these methods are carefully followed, there is practically no excuse for failure or for poor pictures.

The Camera

For general shop work a double extension camera, equipped with rising, falling and sliding front, swing and reversible back, is recommended. It should be fitted with a level. A small T-level, such as can be obtained for twenty-five cents, is preferable. The best size of camera is 5 × 7 inches. Anything larger is more or less cumbersome and heavy, and if pictures larger than 5 × 7 inches are required, it is a comparatively simple matter to enlarge them. On the other hand, cameras smaller than 5 × 7 inches are apt to require the enlarging of many pictures, and this, of course, would be too expensive. While the best lens is none too good, an anastigmat working at F 5.5 is as fast and good as ordinarily will be required. An automatic shutter is desirable. As regards plates, pictures can be taken rapidly on "fast" plates; the writer is now using a plate which requires only one-quarter to one-third the length of exposure required with the ordinary plate.

The Dark-room

The dark-room is not usually given the consideration which it requires, and this is a fruitful cause of poor pictures. The dark-room should be of ample size to permit working without being cramped for room. It should have red or ruby light for ordinary dark-room work, and opportunity for daylight for printing. Good ventilation is also important, because it is just as difficult to do good work at an excessive temperature in the dark-room as anywhere else. An ordinary desk fan can be placed in a ventilator and used as an exhaust fan. This is a satisfactory and economical arrangement. Cold, running water is essential, and hot water desirable, this latter because trays, graduates, etc., can be quickly washed with hot water, and will be perfectly clean, especially if a few drops of sulphuric acid be added to the water and the utensils left to soak a few minutes. They are then thoroughly rinsed with cold water. If this is frequently done, it will save many pictures which might otherwise be spotted, streaked or stained.

Halation

Halation, which spoils many otherwise good negatives, can be intelligently guarded against. The writer disagrees with a previous contributor who says that "negatives entirely free from halation are as easily and truly made upon glass plates as upon films." This is true only if the glass plate is specified as "non-halation."

In photographs of interiors, the strongest high-lights, such as the windows, or the brilliant polished portions of machinery which in some cases reflect light sufficiently to cause the same results, are almost always blurred at the edges. This is due to halation, or reflection from the inner surface of the glass. When we consider the difference in thickness of a glass plate and film, we can readily understand why films show less halation than glass plates.

In order to overcome halation when using glass plates, it is necessary either to use non-halation plates, or, if they cannot be procured, exceptional care must be used when employing ordinary glass plates. The article in the engineering edition of MACHINERY, January, 1909, entitled "Industrial Photography" gives some good hints in regard to the avoidance of halation when using glass plates. The covering up of windows, for instance, is there mentioned.

It might not be out of place to mention here that in few, if any, shops are the windows kept as clean as they might be, and this fact alone is often of advantage. This is the only place in photography where dirt in any shape is desirable. Even with dirty windows, however, a picture should not be taken with the camera pointing directly toward the light. If a machine, for instance, is placed on the east side of the building, and we must take our picture from the west side, the picture should not be taken in the morning but rather in the late afternoon, at which time the light will be strongest behind the camera, and a much better picture will result. Furthermore, if choice of time is possible, take the picture when

† Address: Beaver, Pa.

the light is the softest or most even, so that the harsh contrasts which are apt to give the soot and whitewashed effects, are avoided. A reasonably soft light, long exposure with small diaphragm, and careful development, will give much better results than strong light, short exposure, and large diaphragm.

The operation of placing the dry plates in the plate holders is usually spoken of as "loading" the holder. Attention should be called to the advisability of cleaning the plate at this time. A soft camel's hair brush should be kept for this purpose only, and all plates should be carefully dusted before closing the slide, so as to remove all particles of dust which would

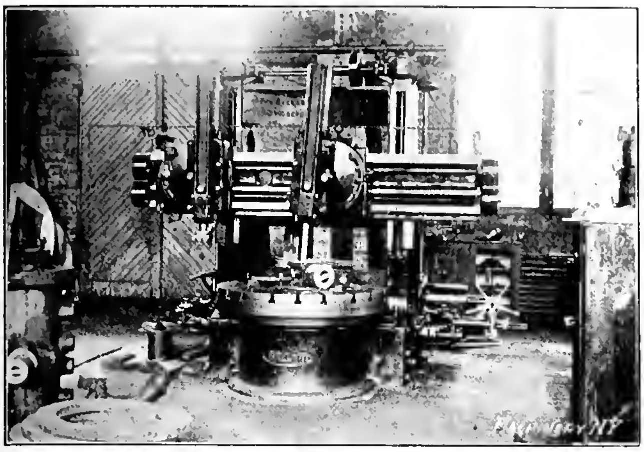

Fig. 1. Photograph taken 4.45 P. M. Diaphragm No. 32, Exposure 45 Seconds. Camera pointed toward the Light

cause spots in the finished picture. The plate holder as well as the slides should also be thoroughly dusted.

Focusing

In shop photography a different result is required than in portrait work, where "softness" is wanted. In machine photographs sharp lines are required. It is advisable to focus with the diaphragm set at No. 4, and after the image is as sharp and clear as possible, adjust to No. 16 or No. 32. This will give a much clearer picture and is well worth the extra length of exposure.

Exposure

A realization of the relation between the light, exposure and development, only comes to the photographer by experience and by a study of his prints. Correct exposure is only a relative term. Approximately correct is about as near as one can get to proper exposure in shop work. Experience and a certain amount of judgment enter into the decision as to the correct length of time. The exposure tables accompanying

Fig. 2. Photograph taken 4.55 P. M. Diaphragm 64, Exposure 2 minutes. Camera not pointed directly toward the Light

this article will, therefore, be found convenient, and if the directions for their use, given in the following, are faithfully followed, very few pictures will be spoiled on account of improper exposure. It is, of course, desirable that the length of exposure be as near correct as possible, as this will tend to make the general average of the results better.

The method the writer uses in arriving at the decision in regard to the length of time for exposure is as follows: Take a fresh strip of standard "printing-out" paper—"Disco," manufactured by the Defender Photo Supply Co., "Solio," manufactured by the Eastman Co., or "Actinos," manufactured by the Lumiere N. A. Co.—and fold it over so that it covers itself in a way to expose only a small portion to the light. This paper should be kept covered until we are ready to take the photograph. Then hold the paper as nearly as possible where the average intensity of light strikes the machine. Uncover it and note the time required for discoloring the exposed portion of the paper so that it just presents a plainly discernible difference from the unexposed portion. This may require anywhere from two or three seconds to half an hour, depending, of course, upon the intensity of the light. In a medium light, from ten to forty seconds will suffice. This length of time is now our "time factor," and by referring to the accompanying exposure tables, it is easy to see what use is to be made of it.

The photograph shown in Fig. 1 was taken at 4.45 in the afternoon, and some halation can be noticed, but this can be overcome to a certain extent by printing the picture somewhat longer. In so doing, however, more or less detail will be lost. Solio paper was used to determine the light factor, which was forty-five seconds; diaphragm No. 32, U. S. system, was used. The machine photographed was painted with the ordinary black color of machine tools; therefore, the required length of exposure is found in Table I, for dark-colored objects, in the column headed "45 seconds" and in the line denoted "F 22 Diaphragm 32" in the left-hand column. The required time of exposure thus is found to be forty-five seconds.

When the photograph, Fig. 2, was taken, "Disco" paper was used to determine the light factor, which in this case was one

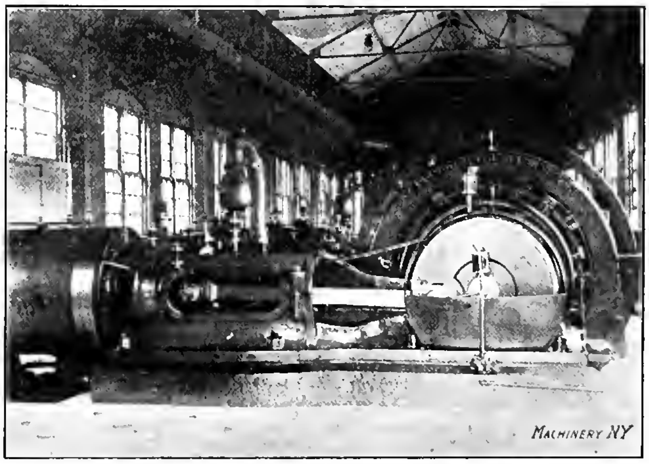

Fig. 3. A Picture taken on a Stormy Day, 11 A. M., with the Plate Reversed in the Holder, thus Reversing the Picture, but Avoiding Halation

minute. No. 64 diaphragm was used, and the length of the exposure was determined from the table in the same way as in Fig. 1, the time required being two minutes, as found in the vertical column headed "one minute" and in the horizontal line denoted "F 32 diaphragm 64." Comparing Figs. 1 and 2 a great difference is noticeable in regard to the tendency toward halation. Fig. 2 was exposed at 4.55 P. M., just ten minutes later than Fig. 1, both pictures being taken in the same shop on the same day. Fig. 1, however, was taken with the camera pointing directly toward the windows, while in Fig. 2 the windows are in a diagonal direction from the camera, this being the cause of the difference. In Fig. 2 the windows at the extreme left are very clear and distinct, while that toward the right, more nearly in front of the camera, shows a very distinct halation. This experiment proves conclusively the advantage of avoiding pointing the camera directly toward the light.

Fig. 3 was taken about eleven o'clock A. M., the sun shining very brightly. While this negative is fully timed there is practically no tendency toward halation. All these pictures were taken on plates. The reason that no halation is shown in Fig. 3, however, is disclosed by looking at the name-plate of the generator, which is reversed, or shows as it would in a mirror. This picture was taken "through the glass," that is, the plate was put into the plate-holder with the glass side out, which, of course, is the reverse of the usual method

This, however, bears out the explanation of halation as being governed by the thickness of the glass plate. The same view taken two minutes later with the camera in the same place with the same length of exposure and the same diaphragm, but with the plate in the holder in the usual way was very badly affected by halation. A non-halation plate would, of course, in this case do away with the difficulty.

The exposure tables (Tables I and II) are intended for the following brands of plates and films: Ansco Film; Cramer Crown; Cramer Instantaneous Iso; Cramer Tri; Defender King Eastman Film; Eastman Extra Rapid; Forbes Instantaneous; Hammer; Kodoid; Lumiere Blue Label; Lumiere Ortho A; Lumiere Ortho B; Lumiere Panchro C; Lumiere Non-Halation Simplex Ortho A; Monarch; Pacific; Premo Film Pack; Record; R. O. C.; Seed 27; Standard Imp.; Standard Ex.

Lumiere New (Sigma) Σ and Lumiere Non-Halation Simplex (Sigma) Σ require but one quarter the time specified in the tables.

Seed 26 x; Cramer Banner; Hammer Non-Halation; and Hammer Fast, require about one-half longer exposure than the tables call for.

Development

Assume that the plate has been exposed and that we are now back in the dark-room, ready to develop the plate. Before doing so, dust the plate again carefully with a camel's hair brush to remove any particles of dust that may have settled upon the plate when the slide was reversed after the exposure. Almost any developing agent will make a picture on a properly exposed negative, yet the writer has found it advisable to use a developer such as recommended by the manufacturer of the plate used. The development is a comparatively simple operation if undertaken in the proper manner. The most desirable color in a negative is a warm black, with possibly a slight tint of yellow through the image. The development should be carried only to the point where the highest lights are of a sufficient transparency to print details. This kind of negative prints quickly, and will be found the most satisfactory for printing on any class of paper. The temperature of the developer should never be allowed to rise above 70 degrees F. or fall below 65 degrees F. An all-glass dairy or bath thermometer, which can be purchased for about thirty cents, is very necessary for all dark-rooms. A too-cool developer produces thin negatives which have the appearance of being under-exposed. A too-warm developer, on the other hand, produces a heavy flat appearance in the negatives.

Table III, for which the writer is indebted to the M. A. Seed Dry Plate Co., gives the proportions of various developers. The numbers in the column headed "Factor" may require some explanation. The "factoral" system of development is a desirable one to use, exceedingly simple in its application, and insures the bringing out of everything that is in the negative. This system is based on the fact that no matter what the exposure, the development proceeds at the regular rate, and the time elapsing from the moment when the plate is placed in the developing solution until the appearance of the first high-lights of the image is a certain proportion of the total time required for the development. Suppose we are using Dianol developer, the factor of which is 18. The first high-lights appear twenty seconds after the plate has been placed in the solution. Then 18×20 seconds or 6 minutes total time is required for the complete development. When developed, the plate is removed from the developer, rinsed in fresh water and placed in the fixing bath.

A number of formulas for other common developing solutions with their factors are given below:

Pyro—Developing Factor 12

A. Pure water, 16 oz.; pyro, 1 oz.; oxalic acid, 10 gr.

B. Pure water, 16 oz.; sulphite of soda, 2 oz.

C. Pure water, 16 oz.; carbonate of soda, 2 oz.

To make the developing solution, use one ounce each of the solutions A, B and C, and add seven ounces pure water.

Eikonogen Hydrochinon—Developing Factor 12

A. Pure water, 48 oz.; sulphite of soda, 2 oz.; eikonogen, 240 gr.; hydrochinon, 60 gr.

(For more contrast, the quantity of water in the solution may be reduced to 32 ounces. Use boiling water. In cold weather a little glycerine will prevent precipitation.)

B. Pure water, 16 oz.; carbonate of soda, 2 oz.

To make the developing solution, use three ounces of solution A and one ounce of solution B.

Metol-hydrochinon—Developing Factor 15

A. Pure water, 64 oz.; metol, 120 gr.; hydrochinon, 120 gr.; sulphite of soda, 2 oz.

(Dissolve in the order given. Metol, to prevent precipitation, should always be dissolved in water before the sulphite is added.)

B. Pure water, 16 oz.; carbonate of soda, 2 oz.

TABLE III. DEVELOPERS WITH VARIOUS AGENTS

	A			B			Use			
	Pure Water	Seed's Sulphite	Developing Agent	Pure Water	Seed's Carbonate	Potassium Bromide	A	B	Pure Water	Factor
	oz.	oz.	gr.	oz.	oz.	gr.	oz.	oz.	oz.	
Metol*	16	1	120	8	1	..	4	1	5	25
Eikonogen	24	1	150	16	1	..	3	1	..	10
Hydrochinon**	16	1	160	16	2	80	1	1	..	4
Edinol	16	2	80	8	1	..	2	1	..	12
Tolidol	16	1	160	16	1	..	1	1	2	7
Glycin**	32	1	320	48	6	..	2	3	..	8
Imogen	16	1	240	24	3	..	2	3	..	7
Dianol	32	¼	40	..	..	..	..	..	..	18
Amidol	24	½	40	No alkali needed					..	30
Rodinal	To ¼ oz. add 10 oz. water								..	30

* Dissolve metol in water before adding sulphite.

** For hydrochinon and glycin use potassium carbonate and dissolve glycin in hot water. Hydrochinon is a contrast formula for over-exposed plates and for black and white line work. It is not suitable for ordinary use.

If crystal sodas are used, add 15 grains of bromide of potassium to 16 ounces of solution B.

To make the developing solution, use four ounces of solution A, one ounce of solution B, and four ounces of pure water.

Acid Fixing Bath

A. Pure water, 96 oz.; hypo, 2 pounds; C. P. sulphite of soda, 2 oz.

B. Pure water, 32 oz.; chrome alum, 2 oz.; C. P. sulphuric acid, ¼ oz.

See that the chemicals are entirely dissolved, and then pour solution B into A slowly while stirring A rapidly.

Clearing Solution for Pyro Stains

Iron sulphate, 3 oz.; water, 16 oz.; sulphuric acid, ¼ oz.; alum, 1 oz.

Fixing

The fixing of a plate after development is so simple a matter that it is hardly necessary to more than advise the use of an acid-hypo fixing solution for plates, especially in the summer time, in place of the ordinary plain fixing bath. The plates should remain in the hypo bath for ten minutes after all white has dissolved from the reverse side of the negative. Then it should be well washed, say for one hour, preferably in running water.

Before allowing the plates to dry, the film side should be gently and carefully wiped with a wad of absorbent cotton to remove any "specks" which may be on the negative. This is very important, particularly when the water is very hard, as the film side collects a sediment when having been washed for some time, and if it is not removed before the negative is dry, it makes it unfit for printing. After having wiped the surface of the plate, rinse it thoroughly, and set it to dry in a ventilated place free from dust.

Negatives, when drying, should always be so placed that a current of air can pass around, over, and between them. The warmer this current of air is, the more intense the negative will be, and *vice versa*. Never change the location or position of a negative during the time it is drying, as marks and spots are almost sure to appear, owing to the fact that different conditions of air produce a difference in the intensity of the negative.

HARDENING CARBON STEELS*

H. RALPH BADGER†

Originally the name steel was applied to various combinations of iron and carbon, there being present, together with these, as impurities, small proportions of silicon and manganese. At the present time, however, the use of the name is extended to cover combinations of iron with tungsten, vanadium, nickel, chromium, molybdenum, titanium and some of the rarer elements. These latter combinations are quite generally known as the *alloy* steels to distinguish them from the *carbon* steels, in which latter the characteristic properties are dependent upon the presence of carbon alone. The alloy steels are divided into the high-speed steels and the Mushet or air-hardening steels. The specific properties that distinguish these different steels are due in part to their respective compositions, that is, to the particular elements they contain, and, in part, to their subsequent working and heat treatment.

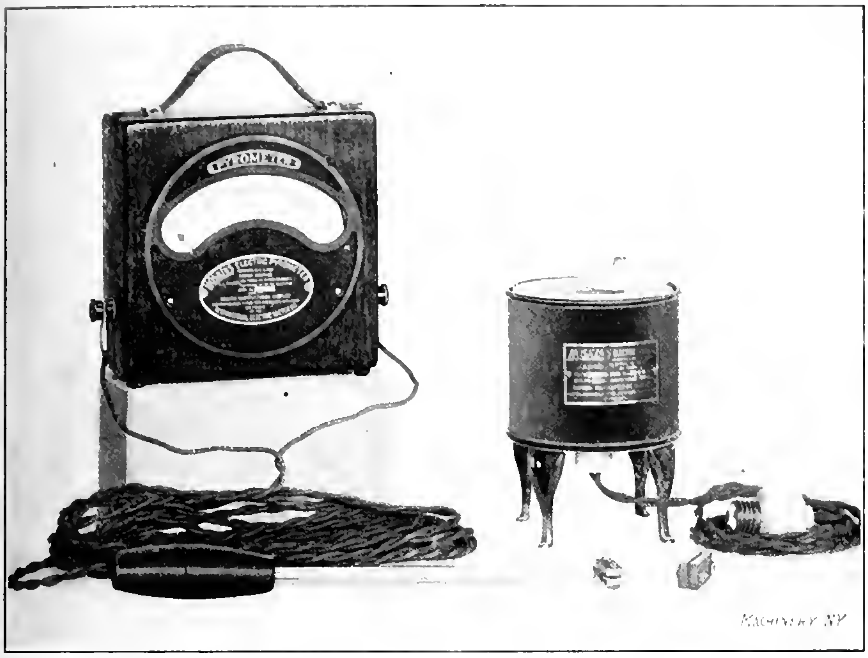

Fig. 1. Hoskins Electric Heating Furnace and Pyrometer used for ascertaining the Decalescence and Recalescence Points of Steel

Effect of Difference in Composition of Steel

In general, any change in the composition of a steel results in some change in its properties. For example, the addition of certain metallic elements to a carbon steel causes, in the alloy steel thus formed, a change in position of the proper hardening temperature point. Tungsten or manganese tend to lower this point, boron and vanadium to raise it; the amount of the change is practically proportional to the amount of the element added. Just as a small proportion of carbon added to iron produces steel which has decidedly different properties than those found in pure iron, so increasing the proportion of carbon in the steel thus formed, within certain limits, causes a variation in the degree in which these properties manifest themselves. For example, consider the property of tensile strength. In a "ten-point" carbon steel (one in which there is present but 0.1 per cent of carbon) the tensile strength is very nearly 25 per cent greater than that of pure iron. Adding more carbon causes the tensile strength to rise, approximately, at the rate of 2.5 per cent for each 0.01 per cent of carbon added.

Carbon steels are divided into three classes according to the proportion of carbon which they contain. The first of these embraces the "unsaturated" steels, in which the carbon content is lower than 0.89 per cent; the second, the "saturated" steels, in which the proportion of carbon is exactly 0.89 per cent; and, the third, the "supersaturated" steels, in which the carbon content is higher than 0.89 per cent.

Effect of Heat Treatment

With a steel of a given composition, proper heat treatments may be applied which, of themselves, will first alter in form or degree some of its specific properties, or second, practically eliminate one or more of these, or third, add certain new ones. Physical properties of size, shape and ductility are examples of the first case; an example of the second case is found in the heating of steel beyond its hardening temperature, which takes away its magnetism, making it non-magnetic; and an example if the third case is the fact that a greater degree of hardness may be added to steel by the process of hardening. In this connection it must be understood that, strictly speaking, hardness is a relative term and all steel has some hardness.

There are three general heat treatment operations, so considered; forging, hardening—with which this article will deal—and tempering. In all of these the object sought is to change in some manner the existing properties of the steel; in other words, to produce in it certain permanent conditions.

The controlling factor in all heat treatment is temperature. Whether the operation is forging, hardening or tempering, there is for any certain steel and particular use thereof a definite temperature point that alone gives the best results in working it. Insufficient temperatures do not produce the results sought. Excessive temperatures, either through ignorance of what the correct point is, or through inability to tell when it exists, cause "burned" steel; this is a common failing, resulting in great loss. Very slight variations from the proper temperature may do irreparable damage.

Due to temperature variation alone, carbon steel may be had in any of three conditions: first, in the unhardened or annealed state, when not heated to temperatures above 1,350 degrees F.; second, in the hardened state, by heating to temperatures between 1,350 and 1,500 degrees F.; third, in a state softer than the second though harder than the first, when heated to temperatures which exceed 1,500 degrees F.

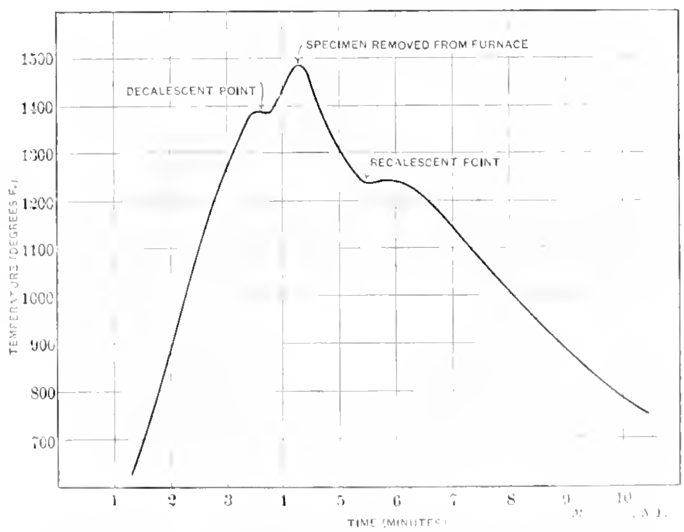

Fig. 2. Diagram showing the Relation between Time and Temperature when heating Steel, and the Critical Temperatures of One-point Carbon Steel

The Hardening Process

The hardening of a carbon steel is the result of a change of internal structure which takes place in the steel when heated properly to a correct temperature. In the different carbon steels this change, for practical purposes, is effective only in those in which the proportion of carbon is between 0.2 per

* For additional information on this and kindred subjects see the following articles previously published in MACHINERY: Steel and its Treatment, September, October, November and December, 1902, and January, 1903; Pyrometers with Special Reference to the Morse Heat Gage, February, 1904, engineering edition; A New Hardening Furnace, January, 1905, engineering edition; Hardening without Cracking, February, 1906; Method of Hardening Thin Milling Cutters, July, 1907; The Gaging of Heats for Hardening, April, 1908; Indicator for Ascertaining Hardening Temperatures, June, 1908, engineering edition; Local Hardening and Tempering, August, 1908; A Modern Steel Hardening Plant, November, 1908; Temper Colors and Temperatures and Colors for Hardening, December, 1908; Westmacott Hardening and Annealing Furnace, March, 1909; The Heat Treatment of Steel, April, 1909; Leeds and Northrup Hardening and Annealing Pyrometer, June, 1909; and Recalescence and its Relation to Hardening, October, 1909.

† Address: 26 Commonwealth Ave., Detroit, Mich.

cent and 2.0 per cent, that is, between "twenty-point" and "two" carbon steels, respectively.

When heated, ordinary carbon steels begin to soften at about 390 degrees F. and continue to soften throughout a range of 310 degrees F. At the point 700 degrees F. practically all of the hardness has disappeared. "Red hardness" in a steel is a property which enables it to remain hard at red heat. In a high-speed steel this property is of the first importance, 1,020 degrees F. being a minimum temperature at which softening may begin. This is some 630 degrees F. above the point at which softening commences in ordinary carbon steels.

The process of hardening a steel is best carried out in a closed furnace. Of the many sources of energy capable of producing the required heat, electricity offers the most attractive advantages. The electric resistance furnace, as now built in a variety of sizes of either muffle or tube chamber types, has one fundamental point of superiority over all coal, coke, gas, or oil-heated furnaces. It is entirely free from all products of combustion, the heat heing produced by electrical resistance. This is important. It does away with the chief cause of oxidation of the heated steel. Further, the temperature of the electric furnaces can be easily and accurately regulated to, and maintained uniform at, any desired point. When electric power is generated for other purposes, the increased cost of this form of energy for operating furnaces is not sufficient to argue against it. Even when the current is purchased, the superior quality of work performed by this kind of furnace frequently more than offsets the slightly higher cost of operation.

In the actual heating of a piece of steel, several requirements are essential to good hardening: first, that small projections or cutting edges are not heated more rapidly than is the body of the piece, that is, that all parts are heated at the same rate, and second, that all parts are heated to the same temperature. These conditions are facilitated by slow heating, especially when the heated piece is large. A uniform heat, as low in temperature as will give the required hardness, produces the best product. Lack of uniformity in heating causes irregular grain and internal strains, and may even produce surface cracks. Any temperature above the "critical point" of steel tends to open its grain—to make it coarse and to diminish its strength—though such a temperature may not be sufficient to lessen appreciably its hardness.

Critical Temperatures

The temperatures at which take place the previously mentioned internal changes in the structure of a steel are frequently spoken of as the "critical points." These are different in steels of different carbon contents. The higher the percentage of carbon present, the lower the temperature required to produce the internal change. In other words, the critical points of a high carbon steel are lower than those of a low carbon steel. In steels of the commonly used carbon contents, there are two of these critical temperatures, called the *decalescence* point and the *recalescence* point, respectively.

The decalescence point of any steel marks the correct hardening temperature of that particular steel. It occurs while the temperature of the steel is rising. The piece is ready to be removed from the source of heat directly after it has been heated uniformly to this temperature, for then the structural change necessary to produce hardness has been completed. Heating the piece slightly more may be desirable for either or both of the two following reasons. First, in case the piece has been heated too quickly, that is, not uniformly, this excess temperature will assure the structural change being complete throughout the piece. Second, any slight loss of heat which may take place in transferring the piece from the furnace to the quenching bath may thus be allowed for, leaving the piece at the proper temperature when quenched.

If a piece of steel which has been heated above its decalescence point be allowed to cool slowly, it will pass through a structural change, the reverse of that which takes place on a rising temperature. The point at which this takes place is the recalescence point and is lower than the rising critical temperature by some 85 to 215 degrees. The location of these points is made evident by the fact that while passing through them the temperature of the steel remains stationary for an appreciable length of time. It is well to observe that the lower of

Fig. 3. Micro-photograph (Magnified 45 Diameters) of Steel Quenched at 1900 Degrees F.

Fig. 4. Micro-photograph (Magnified 45 Diameters) of Steel Quenched at 1750 Degrees F.

Fig. 5. Micro-photograph (Magnified 45 Diameters) of Steel Quenched at 1600 Degrees F.

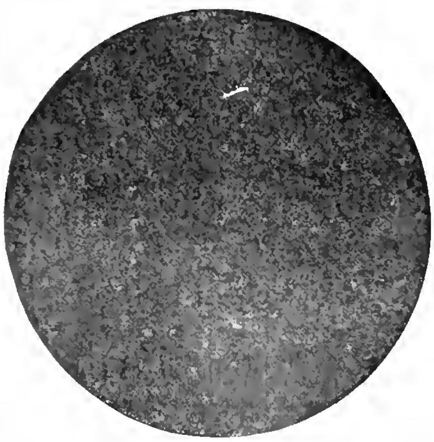

Fig. 6. Micro-photograph (Magnified 45 Diameters) of Steel Quenched at 1510 Degrees F.

Fig. 7. Micro-photograph (Magnified 45 Diameters) of Steel Quenched at 1425 Degrees F.

Fig. 8. Micro-photograph (Magnified 22 Diameters) of Steel Quenched at 1385 Degrees F., or 5 Degrees above the Decalescence Point

these points does not manifest itself unless the higher one has been first fully passed. As these critical points are different for different steels, they cannot be definitely known for any particular steel without an actual determination. While heating a piece of steel to its correct hardening temperature produces a change in its structure which makes possible an increase in its hardness, this condition is only temporary unless the piece is quenched.

Quenching

The quenching consists in plunging the heated steel into a bath, cooling it quickly. By this operation the structural change seems to be "trapped" and permanently set. Were it possible to make this cooling instantaneous and uniform throughout the piece, it would be perfectly and symmetrically hardened. This condition cannot, however, be realized, as the rate of cooling is affected both by the size and shape of the treated piece; the bulkier the piece, the larger the amount of heat that must be transferred to the surface and there dissipated through the cooling bath; the smaller the exposed surface in comparison with the bulk, the longer will be the time required for cooling. Remembering that the cooling should be as quickly accomplished as possible, the bath should be amply large to dissipate the heat rapidly and uniformly. Too small a quenching bath will cause much loss, due to the resulting irregular and slow cooling. To insure uniformly quenched products, the temperature of the bath should be kept constant, so that successive pieces immersed in it will be acted upon by the same quenching temperature. Running water is a satisfactory means of producing this condition.

Fig. 9. Micro-photograph of Steel Quenched at 1380 Degrees F. or when just reaching the Decalescence Point

The composition of the quenching bath may vary for different purposes, water, oil or brine being used. Greater hardness is obtained from quenching, at the same temperature, in salt brine and less in oil, than is obtained by quenching in water. This is due to a difference in the heat-dissipating power possessed by these substances. Quenching thin and complicated pieces in salt brine is unsafe as there is danger of the piece cracking, due to the extreme suddenness of cooling thus produced.

In actual shop work the steel to be hardened is generally of a variety of sizes, shapes and compositions. To obtain uniformity both of heating and of cooling, as well as the correct limiting temperature, the peculiarities of each piece must be given consideration in accordance with the points outlined above. In other words, to harden all pieces in a manner best adapted to but one piece would result in inferior quality and possible loss of all except this one. Each different piece must be treated individually in a way calculated to bring out the best results from it.

Theory of Critical Points

The presence of the critical points in the heating and cooling of a piece of steel is a phenomenon. The most reasonable explanation is as follows:

While heating, the steel uniformly absorbs heat. Up to the decalescence point all of the energy of this heat is exerted in raising the temperature of the piece. At this point, the heat taken on by the steel is expended, not in raising the temperature of the piece, but in work which produces the internal changes here taking place between the carbon and the iron. Hence, when the heat added is used in this manner, the temperature of the piece, having nothing to increase it, remains stationary, or, owing to surface radiation, may even fall slightly. After the change is complete, the added heat is again expended in raising the temperature of the piece, which increases proportionally.

When the piece has been heated above the decalescence point and allowed to cool slowly, the process is reversed. Heat is then radiated from the piece. Until the recalescence point is reached, the temperature falls uniformly. Here the internal relation of the carbon and iron is transformed to its original condition, the work required to do this being converted into heat. This heat, set free in the steel, supplies, for the moment, the equivalent of that being radiated from the surface, and the temperature of the piece ceases falling and remains stationary. Should the heat resulting from the internal changes be greater than that of surface radiation, the resulting temperature of the piece will not only cease falling but will obviously rise slightly at this point. In either event the condition exists only momentarily, but when the carbon and iron constituents have resumed their original relation, the internal heating ceases, and the temperature of the piece falls steadily, due to surface radiation.

Apparatus for Determining the Critical Point

From the foregoing sections it is evident, first, that there is a definite temperature at which any carbon steel should be hardened, and, second, that there results great loss, both of labor and material, unless the hardening is carried out at this temperature. The actual shop problem thus presented is to determine readily and accurately the correct hardening temperature for any carbon steel that may be in use. This can be done by the use of various types of pyrometers; the apparatus illustrated in Fig. 1, which is made by the Hoskins Mfg. Co., of Detroit, Mich., is well adapted for the purpose. This apparatus consists of a small electric furnace in which to heat a specimen of the steel to be tested, and a special thermo-couple pyrometer for indicating the temperature of this specimen throughout its range of heating. The specimen itself should be properly shaped for clamping to the thermo-couple.

The furnace may be operated on either alternating or direct current circuits. The furnace chamber is 2 1/16 inches in diameter and 2½ inches deep. Heat is produced by means of the resistance offered to the passage of an electric current through the "resistor" or heating element which in the form of wire is wound in close contact with the chamber lining. The furnace is designed so that it can be used on standard lighting circuits to which ready connection is made with a twin conductor cord and lamp plug. In operation, it consumes 3½ amperes at 110 volts, and is capable of producing a chamber temperature of 1,830 degrees F., which is considerably higher than required for a carbon steel.

The pyrometer consists of a thermo-couple, connecting leads and indicating meter. The thermo-couple is of small wire so as to respond quickly to any slight variation in temperature. The welded end of this couple is slightly flattened to enable a good contact between it and the steel specimen. The meter is portable and indicates temperatures up to 2,552 degrees F.

The specimen of the steel to be tested should be small, so as to heat quickly and uniformly. A well-formed specimen is made with two duplicate parts, each 1¼ inch long x ½ inch wide x ¼ inch thick. The pieces are clamped by means of two ¼-inch bolts, one on each side of the welded part of the extreme end of the thermo-couple. Care is taken to form a tight contact, though not to cause an undue strain on the couple. The dimensions here given for the test specimen are not essential, though convenient; any pieces which will permit of tight contact with the thermo-couple and of readily heating in furnace chamber, may be used.

With the specimen fastened to the couple as just described, the furnace is connected in circuit and the cover placed over the chamber opening. The temperature within the chamber rises steadily. When it becomes 1,700 degrees F. the end of the couple, with specimen attached, is inserted in the chamber. The steel specimen rapidly heats, its temperature being constantly the same as that of the welded junction of the thermo-couple, due to the intimate contact between them. This temperature, indicated by the meter, will rise uniformly until the decalescence point of the steel tested is reached. At

this temperature the indicating needle of the meter becomes stationary, the added heat being consumed by internal changes. These changes completed, the temperature again rises, the length of the elapsed period of time depending upon the speed of heating. With the furnace temperature kept nearly constant at the initial point, here given as 1,700 degrees F., this "speed of heating" will be such as to allow of readily observing the pause in motion of the needle. The temperature at which this occurs should be carefully noted.

To obtain the lower critical point, the temperature of the piece is first raised above the decalescence point by about 105 degrees F. In this condition it is removed from the furnace and rested on top to cool. The decrease of temperature is at once noticeable by the fall of the meter needle. At a temperature somewhat below the decalescence point, varying with the composition of the steel, as previously mentioned, there is again a noticeable lag in the movement of the needle. The temperature at which the movement ceases entirely is the recalescence point. Immediately following there may occur a slight rising movement of the needle, as previously explained.

During these intervals of temperature lag, both during the heating and cooling of the steel, there may occur a small fluctuation in the temperature. In order to get results that are comparable, a definite point in each of these intervals should be considered each time a test is made. Hence, both the decalescence and recalescence temperatures are taken as the points at which the needle first becomes stationary. As all operations of heat treatment of a steel center around its critical point, the importance of knowing these exactly is realized; to make certain, each test should be checked by a second reading. The time required for this is small. A close agreement of two succeeding readings will give assurance of the correctness of the determination.

Results Obtained from Sample Specimens

In order to show graphically the necessity of working carbon steels at the proper temperature points, a series of specimen pieces of the same steel were treated at different temperatures. The steel used contained exactly 1 per cent carbon, that is, it was a "one-point" steel. A number of test specimens were made of this from adjacent parts of the same bar.

First the critical points of this steel were determined. Temperatures were recorded throughout both the heating and cooling. In the diagram, Fig. 2, these values have been plotted. The curve shows grapically the location of the critical points, and also the slight fall or rise of temperature, as the case may be.

With this data obtained, seven specimens of the same steel were heated, in the electric furnace, each to a different temperature. As these pieces were removed from the furnace they were immediately quenched in water. The temperature of the quenching bath was held constant at 45 degrees F. The hardened pieces were then broken at right angles and the fractured surface of each was photographed under a microscope. These photographs are reproduced in Figs. 3 to 9 in the same size as the originals. Due to magnification, the first five of these engravings represent a circular area, the actual diameter of which is but 0.05 inch; while the piece illustrated in Fig. 8 is of 0.1 inch diameter.

An inspection of these shows at once the serious effects on its structure, and hence on its strength, of overheating a piece of steel. The micro-photograph of specimen No. 1, Fig. 3, shows a very badly "burned" steel, as is evidenced by the extreme coarseness of its grain. Specimen No. 2, Fig. 4, hardened at 150 degrees F. lower temperature, shows less coarseness, but is still badly "burned." The succeeding specimens, Figs. 5, 6 and 7, show a gradual improvement, as the temperature at which they were hardened approaches the decalescence point of the steel. Specimen No. 6, Fig. 8, was quenched just after the hardening change in its structure had become complete, at 5 degrees F. above the critical temperature. The very fine grain and closely woven texture of this fracture show a properly hardened steel, one which has both the desired hardness and the maximum tensile strength.

Specimen No. 7, Fig. 9, was hardened just as the temperature reached the decalescence point. This shows clearly the direction in which the hardening moves, namely, from the exterior toward the interior. This would naturally be expected as the temperature of the surface, which is exposed directly to the source of heat, reaches the critical point first. This illustration shows that the structural change has been completed only in the surface layer of the specimen. Here the grain is fine and the steel hardened, while the interior is still in the unhardened state. This condition indicates the necessity of heating the piece uniformly.

While 1,900 degrees F., the temperature at which the Specimen No. 1, Fig. 3, was hardened, represents, of course, a very excessive heat, yet it is not infrequent that carefully machined parts are ruined by overheating even to this degree. The practice of guessing at hardening temperatures can only result in uncertainty.

Conclusions

The hardening of carbon steels for highest quality and greatest saving entails, then, three things. First, a definite knowledge of what constitutes the correct temperature at which to harden the steel. The second point necessitates a positive means of accurately determining this hardening temperature for any carbon steel. The third consideration is that the correct hardening temperature, once determined, is actually carried out in the hardening work. A simple and effective way of doing this is by checking the temperature of the hardening furnace by means of a pyrometer. When there is a large quantity of work to be hardened, economy dictates a permanent installation of pyrometers. The convenience of such installations is manifest. A thermo-couple is placed in each furnace. A number of these, from three to sixteen, depending upon individual conditions, are connected by wire leads, through a selective switch to one meter. By a turn of the switch, the temperature of any furnace may be read at once from the meter. This makes it possible for the foreman to know definitely, at a single point, the temperatures of all of the hardening furnaces in use.

* * *

An aerial exhibition was opened in the Grand Palais, Paris, the last Saturday in September. Some thirty full-sized aeroplanes were exhibited in addition to a dirigible airship and several balloons. There was a striking likeness between all the heavier-than-air machines exhibited. Of course, two types were represented, the mono- and the bi-plane, but the Bleriot machine is the obvious prototype of nearly all the monoplanes, while all the biplanes show important features of either the Wright, Farman or Voisen branches of the biplane family. There were considerably more monoplanes than biplanes displayed, possibly because of the success of Bleriot's cross-channel trip, and, perhaps, also on account of the greater simplicity and cheapness of construction. Improvements are noted in the monoplanes, but no noteworthy improvements are visible over the already tested types of the biplanes.

* * *

The importance that engineering will play in the future in the destruction of harmful insects is, to some extent, indicated by the experiments which have been carried out with great success at Zittau, Germany. According to the *Scientific American*, the beam from a searchlight mounted on the roof of the municipal electric light plant was played upon a forest several miles distant, and the moths to be destroyed came fluttering up the beam in swarms to the light, behind which was the intake of a powerful suction blower. The moths were drawn in by the suction and exhausted into a wire net cage which was removed as often as filled. In one single night 140 pounds of moths representing, by numbers, some 400,000 were destroyed in this way.

* * *

A treaty has been made between the United States and Canada limiting the total amount of water that may be taken for power purposes at Niagara Falls. According to this treaty the power companies on the Canadian side are limited to 36,000 cubic feet per second, and those on the American side to 20,000 cubic feet. The average total discharge of the Niagara river is 250,000 cubic feet per second.

SOME INTERESTING CAM CONSTRUCTIONS*

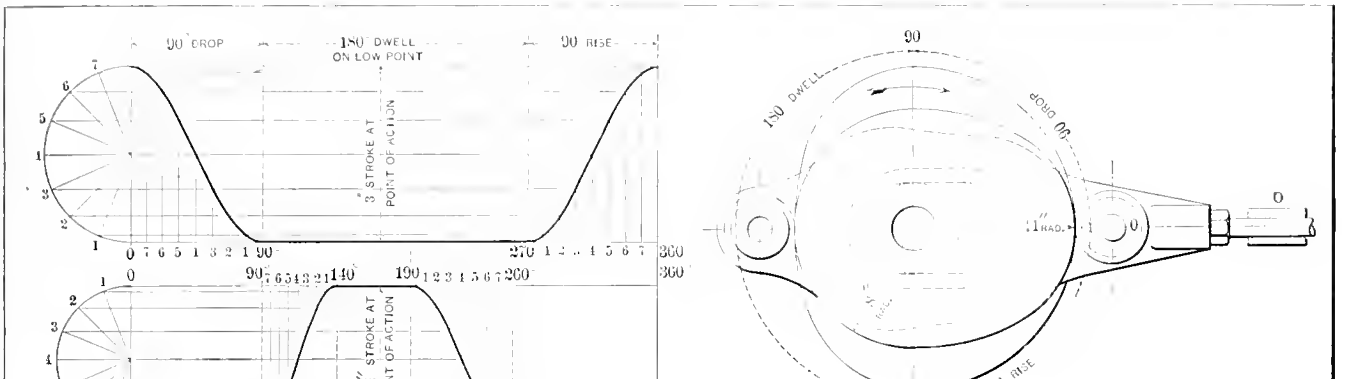
EDWARD PERSON†

When designing automatic machines that are more or less complicated, it is not always possible to avoid the use of cams in order to accomplish the work for which the machine is intended. When several cams are to be used on the same machine, it is necessary to make up a cam chart from which the designer works when laying out the cams. This chart should give the stroke required for the mechanism and indicate what part of the revolution of the cam shaft is required to produce the required stroke, as well as the period of rest. These quantities are given in degrees.

Fig. 1 shows a cam chart for two cams, the curves being crank-motion curves. The first cam, starting at zero, moves the mechanism operated three inches, while turning 90 degrees. There is then a rest or dwell for 180 degrees, and a return movement in the remaining 90 degrees. The mechanism operated by the second cam rests until the cam has turned 90 degrees; the cam then imparts a motion of 2½ inches from 90 to 140 degrees. There is then a dwell for 50 degrees, a return motion during 70 degrees, and finally a 100-degree dwell on the low point of the cam.

The crank-motion curves on the cam chart are constructed as follows: Set off the stroke of the mechanism, three inches in the first case, and two and a-half inches in the second. Construct a half-circle with the length of the stroke as diameter, and divide the half-circle into a certain number of equal parts. Also divide the length representing the drop and rise into the same number of equal parts as that into which the half-circle has been divided. Then draw lines from the dividing points as shown in Fig. 1. The intersecting points will be the points of the curve. It is of importance that these curves be correctly constructed, as this provides for a smooth movement of the mechanism at any point during the revolution of the cam. Of course, these curves do not need to be crank-motion curves, but can be changed to suit conditions.

Figs. 2 and 3 show the constructions of cams laid out from the first cam chart curve in Fig. 1. These cams are working positively in either direction. The construction in Fig. 2 consists of a grooved cam *A*, and a yoke *B* forked over the hub of the cam and carrying the roller *C*, placed in the groove. When revolving the shaft, the yoke, guided by a bushing at *D*, will move back and forth three inches in a straight line. For laying out the cam proceed as follows: Set off from the zero point on the cam in a direction opposite to that in which the cam revolves, 90 degrees, and from this point set off 180 degrees, and then another 90 degrees, which brings us back to the starting point. Determine the highest and lowest points on the cam, which in this case are located 8 and 11 inches from the center respectively. Set off at the lowest point (as shown at the top of the cam in Fig. 2) the radius of the roller and the stroke of the cam, which latter, of course, is the same as the difference between the highest and lowest points. Draw a half-circle having the stroke for its diameter, as shown, divide the circumference of the half-circle into the given number of equal parts, and draw perpendiculars from the division points to the diameter or base line. Then divide the angles for the rise and the drop into the same number of divisions as that of the half-circle, and draw radii to the division points from the center of the cam. From the points where the perpendiculars intersect the base line draw circular arcs with the center of the cam shaft as a center until the arcs intersect the corresponding angular division lines. Take the points of intersection for centers and draw circles having a diameter equal to the roller diameter. The line tangent to these circles is the true crank-motion curve.



Cam Charts and Different Methods of Laying Out Cams

* For additional information on this and kindred subjects, see "Method of Laying Out and Cutting Cams," MACHINERY, October, 1908, and other articles there referred to. See also MACHINERY'S Reference Series No. 9, "Designing and Cutting Cams."

† Address: 438 Fifty-eighth St., Brooklyn, N. Y.

The second cam construction, Fig. 3, consists of two cams A and C, one on each side of the yoke B, and two rollers E and F mounted on each side of the yoke. The yoke in this case is also forked over the hub of the cams and guided at D. The cam curve for the top cam is identical with the inner curve in Fig. 2, and is laid out in the same manner, as is also the rise and the drop for the bottom cam. The only difference is that when the top cam has a dwell on the high point the bottom cam has a dwell on the low point, and *vice versa*. This, of course, insures a positive movement both ways.

Fig. 4 shows another cam construction laid out from the second chart in Fig. 1. It consists of only one cam, a lever and a roller. This construction is positive only one way and must be actuated by a spring for returning, but it can be arranged to work positively by making a three-arm lever, a return cam and a return cam roller. The point illustrated in Fig. 4 is the variation of the angles of the cam, as compared with those of the cam charts, due to the rise and the drop of the roller on the end of its lever. Instead of turning the cam shaft in the direction indicated by the arrow, assume that we swing the center of the lever pivot in a circle around the center of the cam, but in the opposite direction to the cam motion. To lay out the cam, we must first assume the length of the lever, the stroke of the cam, and the highest and the lowest points on it. The center of the lever pivot, at the start, will be at zero on the cam chart, and the center of the roller will be at zero on the cam. From the zero of the lever pivot, Fig. 4, set off 90 degrees for the dwell on the low point, 50 degrees for the rise, 50 degrees for the dwell on the high point, 70 degrees for the drop, and then 100 degrees for another dwell on the low point. Draw radii from the center of the cam shaft to each of these divisions. Take the points where these radii intersect the circle along which the center of the lever pivot moves, as centers for circular arcs having the roller arm AA' for radius, as shown at BB', CC', DD' and EE'. Then set off, from the center of the cam shaft, a distance equal to the radius of the cam plus the radius of the cam roller at each of these places (at B' the distance set off would be $8+2\frac{1}{2}$; at C' $10\frac{1}{2}+2\frac{1}{2}$, etc.). The points of intersection between these distances and the arcs struck with radii BB', CC', etc., are used for centers for circles having a diameter equal to that of the cam roller. Now it will be seen by measuring with a protractor, that where the dwell occurs the angle of the cam will be the same as the angle on the cam chart, but where a rise or a drop takes place the angles will be different.* In the present case, the 50-degree rise on the cam chart and of the cam lever will be about 53 degrees on the cam, and the 70 degrees drop on the cam chart will be about 67 degrees on the cam. This is of importance when several movements are used, and one movement starts immediately after another in such a relation that one must come to rest before another starts. The curves for the cam can be laid out in a manner similar to that explained in Fig. 2.

* * *

"A full conception of infinity is impossible to the finite mind," said the learned professor to his class, "and it is doubtful if an approach to it even is possible, but to illustrate in terms that will convey to your minds something of its immensity, let us consider infinite time. Suppose that the highest peak in the Himalayas were a solid diamond mountain and that an eagle came to it to sharpen his beak once in a hundred years. In the lapse of untold billions of centuries that diamond mountain undoubtedly would be worn away to dust. That is an illustration of finite time of great duration, but great as it is we cannot use it as a 'time-stick' to gage eternity."

* * *

In a recent address on Business English at Tufts College, Walter B. Snow, publicity engineer, of Boston, chose the modern advertisement in its display of force, terseness, knowledge of subject and consideration of the person addressed, as typical of the elements to be embodied in commercial intercourse and in technical reports, articles, etc.

* For a more thorough explanation of this kind of cam construction see MACHINERY, October, 1908: Method of Laying Out and Cutting Cams.

THE McKINLEY MANUAL TRAINING SCHOOL, WASHINGTON, D. C.*

GEORGE W. SUNDERLAND†

The subject of industrial education is becoming more and more important throughout the United States. It is now recognized that the training of the hand and mind together confers far greater benefits than the training of either separately. The object of industrial education is not necessarily that a boy or girl who has passed through the manual training school must follow any of the trades or vocations of which

Fig. 1. View of Machine Shop, McKinley Manual Training School, Washington, D. C.

they have acquired some knowledge; but education of this kind gives them a broader view of the advantages of a trained hand in combination with a trained mind, and it aids them in determining for themselves what they are best adapted for. Nearly all of the largest cities in the United States now have manual training or technical high schools, where regularly prescribed courses are followed, while in small communities the idea is carried out to some extent, even if sometimes on a reduced scale.

Among the foremost manual training schools in the country is the McKinley Manual Training School of Washington, D. C. The school-building is strictly fireproof and contains seventeen class-rooms, besides three rooms devoted to chemistry, five

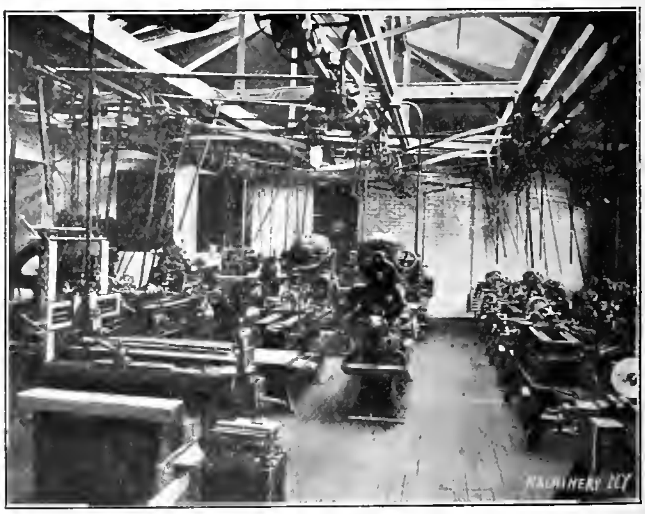


Fig. 2. Another Interior of the Machine Shop

rooms to physics, four rooms to free-hand drawing, two rooms to domestic art, four rooms to domestic science, four rooms to mechanical drawing, one library, one assembly hall with a seating capacity of 700, one art metal shop, one machine shop, one forge shop, two carpenter shops, one engineering laboratory, one shower bath-room, and the necessary lavatories, etc. The very names by which these rooms are designated suggest the purposes for which they are used, but a long and detailed

* For additional articles on this and kindred subjects previously published in MACHINERY, see issue of September, 1907, Education for Industrial Workers, and the articles there referred to.

† Head Instructor of machine shop work, McKinley Manual Training School, Washington, D. C.

description would be required to convey an adequate idea of their complete and substantial equipment.

Three courses of study are provided. A general scientific course, a technical preparatory course (both requiring four years), and a special technical course, requiring two years. In connection with the manual training work, there is given a thorough course in English, French, German, physics, chemistry and mathematics. The part of the course which is of especial interest to the readers of MACHINERY, is the machine shop course. This includes instruction in the use of measuring instruments and tools, and as thorough a course as possible in bench, vise and floor work, drill press, lathe, planer, shaper, milling machine and grinding machine work, as well as instruction in the first principles of gearing.

The school has its own plant for power, heat, light and ventilation. The equipment consists of four Heine safety boilers of 75 horse-power each; one Ames high-speed, direct connected engine of 150 horse-power with a Westinghouse direct-current 100 K. W. generator, 125 volts, 800 amperes, 200 R. P. M.; one American Ball engine and generator, 50 horse-power, 125 volts, 230 amperes, 323 R. P. M.; one General Electric engine and generator, 80 horse-power, 125 volts, 400 amperes, 400 R. P. M.; one Johnson temperature regulator; one Cochrane feed water heater and return tank; two steam pumps for the boilers; two Sturtevant fans connected direct to motors, each 16 horse-power, 110 volts, 114 amperes, 975 R. P. M.; one Westinghouse 15 horse-power steam turbine driving a centrifugal pump.

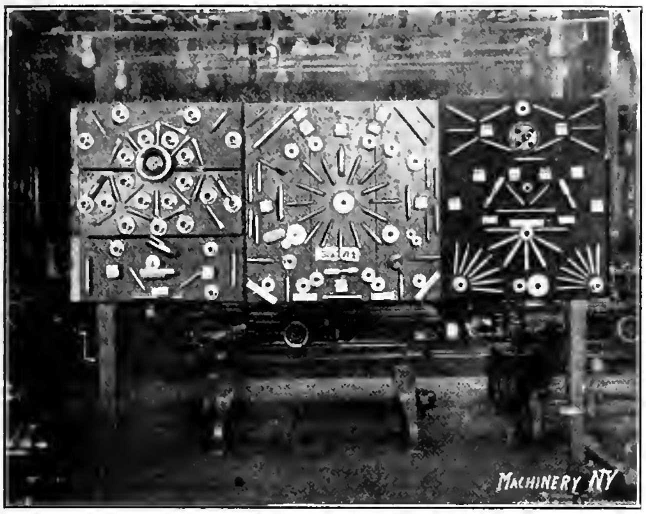

Fig. 3. An Exhibit of Work made by the Students in the McKinley Manual Training School

The equipment of the machine, forge and carpenter shops will no doubt be of interest and value to others interested in the equipment of manual training schools. The following is a list of the machinery in the machine shop:

One 16-inch—10-foot Pratt & Whitney new model engine lathe, motor-driven.

Two 14-inch—6-foot Pratt & Whitney tool-room engine lathes, motor-driven.

One 16-inch—6-foot Hendey geared head engine lathe, motor-driven.

Two 14-inch—6-foot F. E. Reed geared head engine lathes, motor-driven.

Four 14-inch—6-foot F. E. Reed engine lathes, belt-driven.

Six 12-inch—5-foot F. E. Reed engine lathes, belt-driven.

One 14-inch—6-foot Hendey engine lathe, belt-driven.

Four 12-inch—5-foot Hendey engine lathes, belt-driven.

One No. 1 Brown & Sharpe universal milling machine, belt-driven.

One No. 3 Brown & Sharpe universal milling machine, belt-driven, with all attachments.

Three 16-inch Stockbridge shapers, latest type, motor-driven.

Three No. $1\frac{1}{2}$ Brown & Sharpe universal milling machines, motor-driven, with all attachments.

One 16-inch Potter & Johnston shaper, belt-driven.

One 36-inch—6-foot Pease planer, belt-driven.

One 24-inch Prentice drill press, belt-driven.

One $22\frac{1}{2}$-inch Willey drill press, motor-driven.

One 12-inch Willey sensitive drill press, motor-driven.

One Wilmarth & Morman "Yankee" drill grinder, motor-driven.

One No. 3 Brown & Sharpe cutter and reamer grinder, motor-driven.

One No. 2A Landis universal grinding machine, motor-driven.

Two Willey tool grinding machines, motor-driven.

One Walker "Globe" grinding machine, belt-driven.

One Hisey center grinder, motor-driven.

One Willey center grinder, motor-driven.

One Pratt & Whitney centering machine, motor-driven.

One Higley metal saw, motor-driven.

One Chicago gas furnace.

One Greenerd arbor press.

One L. S. Starrett display cabinet.

One Brown & Sharpe display cabinet.

One "Pike" oilstone display cabinet.

The shop is equipped with the necessary benches and vises. The tool-room is stocked with a full line, from a hack-saw to a micrometer, including the Pratt & Whitney Co.'s small tools. The check system is used. The stock-room is furnished with "New Britain" metal racks and metal shelving. It makes the most complete and non-combustible arrangement that can be found. The Higley metal saw is placed in the stock-room to give greater convenience in handling material.

The carpenter shop has a stock- and tool-room and a full line of tools as follows:

Thirty-six Oliver lathes, motor-driven.

One Oliver band-saw, motor-driven.

One Oliver buzz-saw, motor-driven.

One No. 3 Oliver trimmer.

One Oliver jig-saw.

One Oliver band-saw, belt-driven.

Twenty F. E. Reed lathes, belt-driven.

One Brown & Sharpe grindstone, motor-driven.

Two Willey tool grinders, motor-driven.

One demonstration bench for molding.

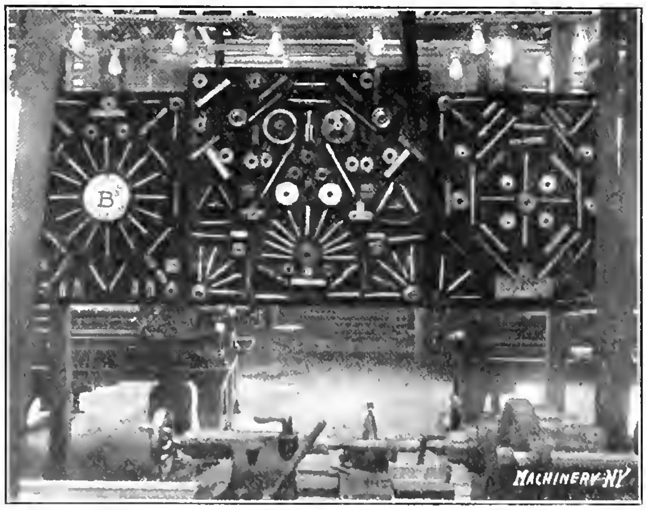

Fig. 4. Another Exhibit of Students' Work

A course in bench work is provided in connection with wood turning and pattern-making.

The forge-shop has the following equipment:

Twenty No. 02 Buffalo down-draft forges.

Ten B. F. Sturtevant ideal down-draft forges.

One No. E1 Dupont power hammer.

Thirty-one anvils.

One Buffalo $7\frac{1}{2}$ horse-power blower, motor-driven.

One Sturtevant, 15 horse-power exhaust fan, motor-driven.

One Norton floor grinder 18-inch, belt-driven.

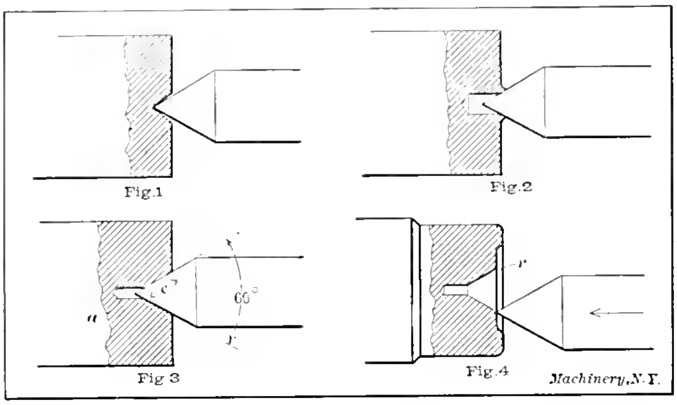
One "McKinley" drill press, belt-driven.

Two of the accompanying half-tones, Figs. 1 and 2, show interior views of the machine shop, and Figs. 3 and 4 illustrate some of the work done by the students. A great deal of the success of the school is due to the untiring efforts of Mr. J. A. Chamberlain, supervisor of manual training of the District of Columbia, who has been with the school since its infancy, and also to Dr. George E. Myers, the principal, who has shown great interest in all matters pertaining to shop work.

MACHINE SHOP PRACTICE*

CENTERING

While the importance of centering work properly, is appreciated by almost every machinist and most apprentices, still, in spite of this fact, inaccuracy in a turned part is often the result of haphazard centering. This is perhaps due more to the lack of care and thought than to anything else. When there are no special tools provided for centering, of course, too much cannot be expected in the way of accuracy; but even though the equipment consists only of a center-punch, there is no excuse for the form of center illustrated in Fig. 1. The center-punch should, however, never be used if it can be avoided. A better method is to locate and mark with a punch, centers in each end of the work and then drill and ream the ends with a combination drill and countersink, such as is illustrated on the Shop Operation Sheet accompanying this number. The center will then appear as shown in the sectional view, Fig. 3. The small straight hole *a* prevents the point of the lathe center from coming in contact with the work and insures that there will be a good bearing throughout the conical surface *c*, providing the angularity of both the lathe and work centers is the same and their axes coincide.



Figs. 1 to 4. Centers of Incorrect and Correct Form

Many shops are equipped with a regular centering machine. If such a tool is available, it is not necessary to locate centers in the ends of the work, as the chuck of the machine is so constructed that it automatically centers shafts of any diameter within its capacity, with reference to the drill. The center shown in Fig. 2, which is formed by simply drilling a straight hole in the end of the work, is, obviously, bad practice in more than one respect. Fig. 4 shows a form of center which is often found in the ends of lathe arbors. As the illustration shows, the mouth of the center is rounded at *r* and the end of the arbor is recessed. This is done to protect the center against bruises. The rounded corner is particularly desirable as the point of the lathe center is thereby prevented from catching on it when, at times, it is moved rapidly towards the work, which is not being held centrally by the workman.

When stock which is to be turned, is bent, it should be straightened before the centers are drilled and reamed. If

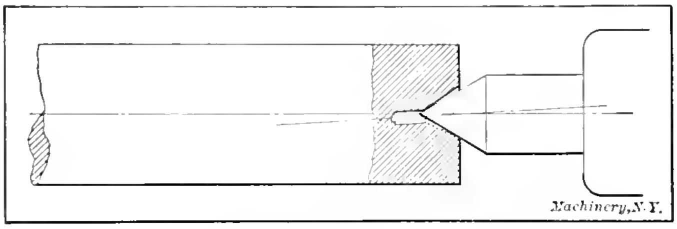


Fig. 5. The Poor Center Bearing shown is the Result of Centering before Straightening

the work is first centered and it is then bent considerably to make it straight, the bearing on the lathe center would be as shown in Fig. 5; consequently, the center would wear unevenly with the result that the surfaces last finished would not be concentric with those which were turned first.

Stock for tools such as reamers, mills, arbors, etc., which need to be hardened, should always be centered so that the rough stock runs approximately true. This is not merely to insure that the piece will be true when it is of the required size, as there is a more important consideration, the disregard of which often greatly affects the quality of the finished tool. As is well known, the degree of hardness of a piece of steel that has been heated sufficiently and then suddenly cooled, depends upon the amount of carbon that it contains, steel

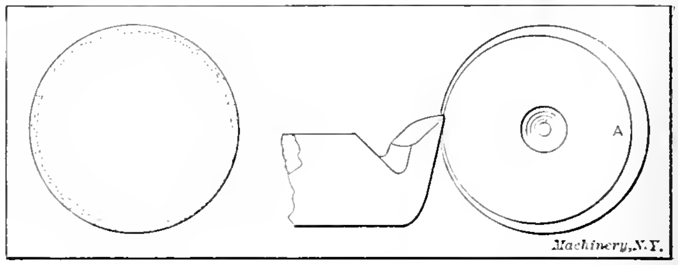

Fig. 6. Tool Steel should be centered Concentric, in order to remove the Decarbonized Outer Surface

that is high in carbon becoming much harder and more brittle than that which contains less carbon. Now the amount of carbon found at the surface, and to some little depth below the surface of a bar of steel, is much less than the carbon content of the rest of the bar, as illustrated diagrammatically in Fig. 6 by the shaded area of the view to the left. (This decarbonization is probably due to the action of the oxygen of the air on the bar during the process of manufacture.) Consequently, stock which is to be used for hardened tools should be enough larger than the finished diameter and so centered that this decarbonized surface will be entirely removed in turning. For example, if when making a reamer, the stock is so centered that the tool removes the decarbonized surface only on one side, as shown to the right in Fig. 6, obviously, when the reamer is finished and hardened, the teeth on the side *A* will be much harder than those on the opposite side. It will thus be seen that stock for such tools should not be too near to the finished size, in order that the decarbonized part will be entirely turned away. The depth to which the carbon is burned out increases with the size of the stock, and also varies somewhat with different pieces of steel. Generally speaking, about 1/16 or 3/32 inch should be removed for diameters near 1 inch, while for sizes of 2 and 3 inches, as much as 1/8 to 3/16 inch in one case and 1/4 inch in the other should be removed, respectively.

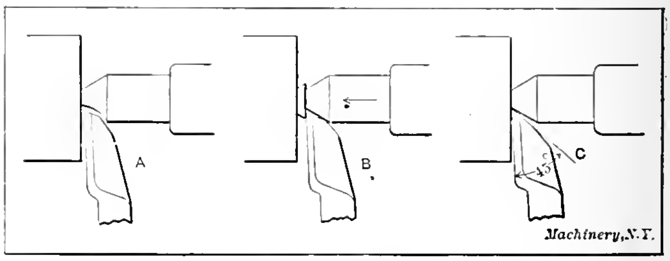

Fig. 7. Three Methods of Facing the End Square

As a piece of work would hardly be properly centered until the ends are faced square, we shall consider this operation, which, though simple, seems to be the cause for considerable comment. Some advocate the use of centers that are cut away, as shown at *A*, Fig. 7, so that the point of the tool may be fed in far enough to face the end up to the center. Others instead of using a special center simply loosen the regular one slightly, and then with the tool in the position shown at *B*, face the projecting teat by moving both tool and center simultaneously as shown by the arrow. This last method hardly represents good practice, but whenever it is employed, care should be taken to remove any chips from the center hole which may have entered. A method which is better than loosening the regular center or employing a special one, is to provide clearance for the tool point by grinding it to an angle of approximately 45 degrees, as shown at *C*. Providing the tool is not set too high, it may then be fed right up to the lathe center and the end squared without difficulty. As for the special center, the use of special tools and appliances in a shop should always be avoided unless they are essential to economical production, or their use makes it possible to accomplish the same end with an expenditure of less energy.

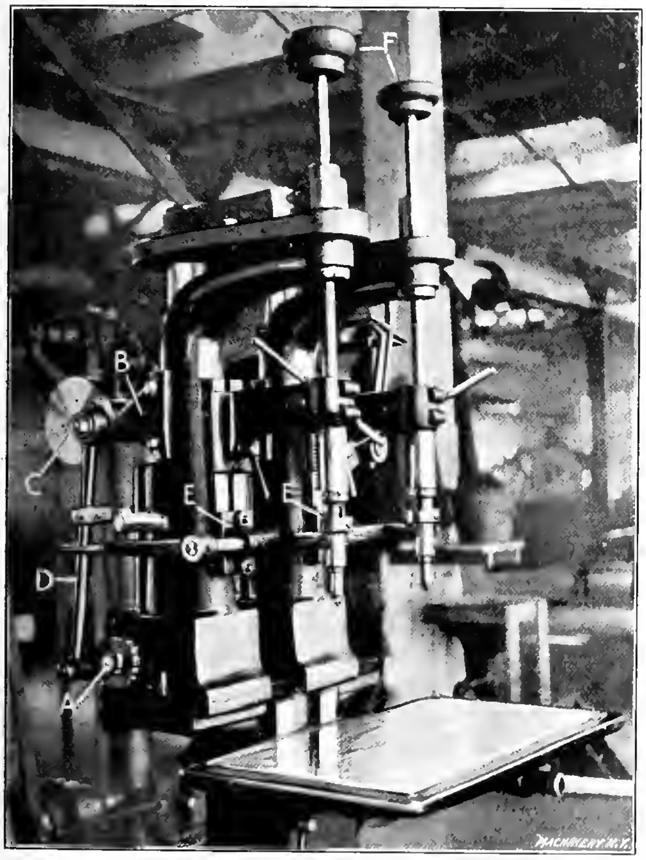
* With Shop Operation Sheet Supplement.

DRILL PRESS VALVE GRINDING ATTACHMENT

A. G. KENYON*

The attachment described in the following was made for the purpose of grinding in the valves of automobile cylinders in a drill press instead of by hand, as has been the practice for some time past. This operation has always been a source of some little annoyance and a time consumer, ever since manufacturers began to build engines in large quantities. A minute saved here and there very often means many more engines built in a month and many dollars saved on the month's expenses. The device shown in the accompanying engraving has proved itself well worth the amount it cost, although it was not at all expensive.

This attachment was designed for and placed on a two-spindle drill press made by the Fenn Machine Co. of Hartford, Conn. The machine is of the type in which the spindles are adjustable for center distance and it has a cross driving shaft *A* through the bases of the upright arms. This shaft is ordinarily driven by a pinion on the driving pulley which,



Drill Press equipped with a Special Attachment for Grinding Valves

together with the loose pulley, is carried on a stud set into the main stand casting. The cross shaft drives vertical shafts which are connected to the spindles of the machine by chains and sprockets. In order to make the attachment, the stud carrying the loose and driving pulleys was removed and also the gear on the end of the cross shaft. Castings *B* were made to fit the upright arms of the press and were cored out to allow for babbitting with the countershaft in place. The same two pulleys that were on the machine originally were placed on this shaft at one end. On the other end there is a disk, *C*, about six inches in diameter, which has a hub on one side to allow for set-screwing to the shaft. In this disk at the proper radius there is a shoulder-stud or crank-pin as shown. On the lower cross shaft *A* two ratchets are mounted, one made right- and the other left-hand. These ratchets are pinned to the shaft and in between them is placed a link or lever which carries two pawls to engage with the ratchet teeth. This lever also has a pin at its outer end and is connected to the upper shaft crank-pin by a connecting-rod *D*. The stroke of this connecting-rod is of the proper length to give the cross-shaft enough turn to move the spindles just half way around and then back again, the same as a workman does when he grinds valves by hand. One ratchet has twice as many teeth on its circumference as the other, and this one is placed on the inside. The pawl that drives this inside ratchet has a hardened pin on its side that trips over a block cut to the proper shape to cause it to disengage at nearly the bottom of the stroke. In this way the spindles of the machine make a full half revolution in one direction and then reverse and make almost a half revolution in the other. The result is that the valve, in the course of grinding, is advanced around its seat every other move, so that the seating is absolutely perfect. The reason for having one ratchet with twice as many teeth as the other, is to provide for the movement due to the momentum of the driven parts at the end of a stroke, so that the pawl will engage at almost any point on the circumference. In this way lost motion is largely eliminated, and consequently, there is no knocking or vibration while the machine is running.

As it is common practice with mechanics to place a spring under the valve head, while grinding, to raise it occasionally in order to let the grinding-in compound settle and change in the seat, this is done in this case. Two castings *E* were made to fit the front T-slot, and these support a rod three-quarters of an inch in diameter on which is placed three forgings, two of which are forked at the end and straddle the spindles of the machine as shown. The other is forked at the end and straddles the connecting-rod. Collars were made to fit the spindles and a clip was also made to fit the connecting-rod. This clip is so adjusted that when the connecting-rod is at the bottom of the stroke, it strikes the forked lever and causes it to move down. This brings the forked levers at the spindles in contact with the collars on the spindles and, consequently, raises them slightly. As the pressure is then removed from the valve, it rises just the same as it would if it were being ground by hand. These levers are so located with reference to the collars on the spindles, that none of the grinding pressure is removed from the valves except at the time of lifting. The grinding pressure is obtained from two cast-iron weights *F* on the spindle shafts. The drivers are like a screw-driver, except that in the center of the blade a center is left projecting so that it will settle in the countersunk lathe center usually left in the heads of valves. These drivers are placed in old drill shanks that fit the sockets of the spindles. These drill shanks are bored out a little larger than the shank diameter on the driver and a pin is placed through them that fits loosely in the driver shank. This gives the driver a sort of floating action and allows the valve to find its own seat and center, which it would not do if the valve center was not quite in line with the spindle center and a rigid driver were used.

The cylinders, the valves of which are ground with this fixture, have four cylinders cast "*en bloc*" with the valves all on one side. As the distance between the spindle centers is adjustable, they are set to the first and fifth valves so that it only takes four moves to complete the grinding of one set of valves. Either spindle can be raised independently of the other at the will of the operator by the ordinary means for raising a drill press spindle, which was not interfered with in the least in attaching the device. Either spindle can be stopped also by simply shifting a lever on the back of the machine to a neutral point. This is also a part of the regular equipment of the press that was not interfered with.

This device has been in use now for some time and has repeatedly ground all eight valves in a cylinder, perfectly, in seven minutes. It positively does not ring the valve, nor does it chatter the seat in the least, and in every way it has proved successful beyond our expectations. The engraving shows how comparatively simple the device is to make and attach, if a shop has a drill press of this make or style. This fixture has solved the valve grinding troubles in our own shop for some time and we hope that if anyone else builds one, it will be as successful as ours has been.

The Prussian state railways have specified that 214, or about 35 per cent, out of 611 locomotives ordered to be delivered between October, 1909, and March, 1910, are to be provided with Schmidt superheaters.

SOME ECONOMIES IN MAKING DRAWINGS

W. E. WILKINSON*

The engineering staff connected with a manufacturing establishment is usually regarded as a necessary evil because it is not directly remunerative, and it is tolerated only because it cannot well be dispensed with; this is because drawings and designs are not an end in themselves, but a means to an end—a graphical representation of ideas, more or less thoroughly depicted, for the conveyance of the same to others to be wrought out; concrete thoughts in a universal language, if one chooses to put it that way. Whatever ways and means of shortening processes and eliminating unnecessary expense, that can be emplóyed without depreciating either the quality or quantity of work produced is of interest to all concerned with such offices. With these objects in view the following suggestions are made, which are thought to be generally applicable in any engineering office or drawing room, whatever the size may be.

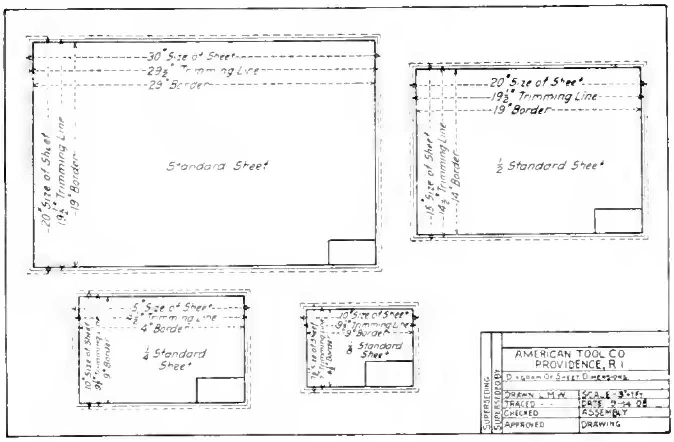

Fig. 1. Dimensions of Standard Drawings

The best general practice seems to be to have competent designers for making general plans who will pencil the work only; detail draftsmen and tracers to complete the work; efficient checking and inspection of each part; all drawings to be made to scale and on standard-sized sheets invariably; each detail made separately with as many views on the sheet as may be needed to make the subject clear. The advantages of small size sheets are that they are more convenient in the shops and if subsequently changed—as most are—the changes do not affect other detail sheets. The smaller sheets should be subdivisions of the larger, as shown in Fig. 1, so that if desired the entire construction, including the details, may be blueprinted on large sheets and the whole suitably bound into uniform-sized folios or booklets.

The first suggestion is that each sheet of tracing cloth be given to the tracer with the border and title stamp printed on it. The advantages are that the sheet will be smooth and flat at the start, absolutely uniform in size, appearance, title and all that pertains to it, and only the blanks in the title will need to be filled in by the detailer. The prime advantage is the saving in time, which will range from 10 to 25 per cent in average cases, and even more on small sheets, where the work detailed is comparatively quickly executed. Hand-written titles are an abomination unless done by an expert, whose time should be better employed. Rubber stamp work is seldom satisfactory and no good substitute for a properly printed title is thought to exist. The first expense may seem heavy, as it means the purchase of a considerable amount of cloth at one time, but there is no waste or time lost in cutting, which will more than counterbalance the slightly increased cost of having the material cut and printed in quantities.

A second economy lies in the use of properly prepared lists of every possible small part, such as screws, bolts, nuts, washers, pins, etc., using a symbol for the same in place of making detail drawings. In fact, this list system is capable of almost indefinite expansion, limited only by the special requirements of the particular factory in which the work is to be done; besides serving as economizers of time, they materially prevent errors and mistakes and also serve to avoid the drawing of a multiplicity of small parts, which are almost duplicates. Such lists may have at their head a drawing representing the object and a symbol, as a letter, used exclusively for it. In place of dimensions on the object, let the same be given symbolically and the list so arranged that all of its proportions beginning with the smaller sizes, preferably, can be determined and a distinguishing mark, as a numeral, be united to the subject symbol so that its relative size may be known at a glance.

Another suggestion, perhaps more applicable to larger objects having a greater number of dimensions, is to have printed sheets bearing a representation of the object, the dimensions being left blank to be filled in by the draftsman as may be required. In place of printed objects, which would be expensive if but few of a kind were required, the same results may be attained by well executed tracings, filling in the blank dimensions on the prints, the same as would be done on original drawings (see Fig. 2). Don't forget to file a duplicate, however, for future reference.

Where mere sketches are required, cross-section paper, a sheet of carbon and a hard copying pencil may be utilized, but this will not do very well for permanent records and is a make-shift at best.

A further economy in any engineering department may be effected by the use of a record file, kept carefully and fully up to date. The time lost in hunting for some mislaid drawing is not productive of profit or pleasure to any concerned, yet it is the too common experience. Possibly if less cheap (?) labor were employed and this work more generally in the hands of competent persons, made responsible for the instant production of any drawing, the results would justify the expense.

Of course a blueprint machine is installed if the office is of any considerable size, but how about the facilities for washing and drying prints? A sloppy sink may answer for the first, but on a dull or rainy day, wet paper dries slowly and a delayed print often means direct loss by reason of holding up the mail, a customer or a machine. A steam coil or electric heater can generally be readily arranged and will save its cost many times over in a short time.

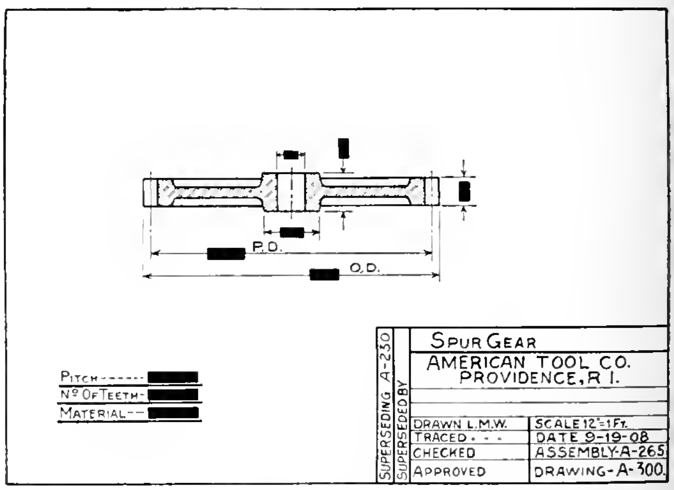

Fig. 2. Printed Sheet with Representation of Commonly used Part and Blank Spaces to be filled in by the Draftsman

A mistake frequently made is to change tracings, involving erasures and re-inking; generally the tracing is spoiled and in any case is lost as a record. It is far better to retrace wholly, making such changes as are desired, as less time is likely to be required and better results attained, while both the old and new tracings may be preserved.

The use of tracing paper is also thought to be a mistake, as it is so easily crumpled, torn and rendered useless for permanent records; the practice can only be condoned on the possible score of extreme urgency.

In conclusion, as time is the most important factor in drawing-room expenses, it should be the duty of some one constantly within reach to see to it that supplies are immediately available to such as require them, and that sufficient data be given so that workmen do not have the common excuse of waiting for this or that, when idle, be it an article of use or a word of explanation or information.

FORMERS FOR CUTTING BEVEL GEARS*

The most common method of making bevel gears at the present time is, perhaps, that of using formers for shaping the gear tooth. The pin or roller, controlling the part in which the cutting tool is held, guides this so that a tooth of the same shape as that of the former will be cut by the tool. It would seem at first that a great many different formers would be required in order to make possible the cutting of bevel gears of different pitch diameters, pitch and pitch cone angles. It is the object of the following analysis to show that correct bevel gear teeth may be planed by the use of a comparatively small number of formers.

In Fig. 1 a bevel gear is shown, and at the left is indicated the former, the path of the cutting tool being guided by a pin moving over same. The gear here shown has a comparatively wide face. Imagine this gear cut up into a number of gears with narrow tooth face. These gears would then have the same number of teeth, but they would have different pitch diameters, and consequently would be of different pitch; yet all being a part of and identical with a single gear which can be cut by a single former, it is clear that a single former is sufficient for cutting all bevel gears within the capacity of the machine without regard to the pitch, provided the gears have the same number of teeth and the same pitch cone angle.

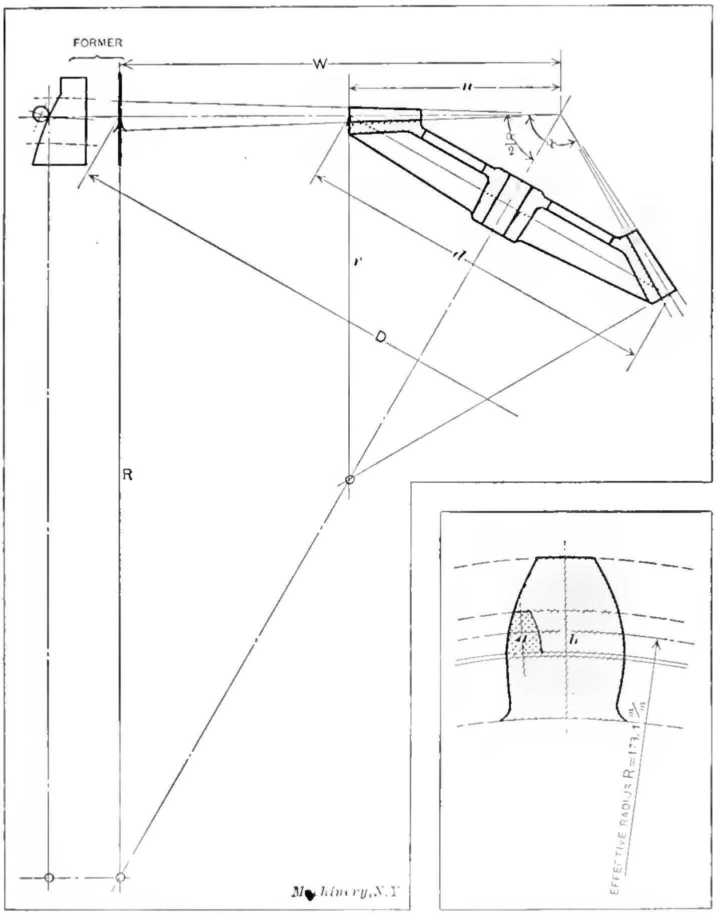

Fig. 1. Diagram for Proving that the Shape of the Former is Independent of the Pitch of the Bevel Gear

Fig 2. Diagram showing that the Same Former can be used for Planing Different Numbers of Teeth

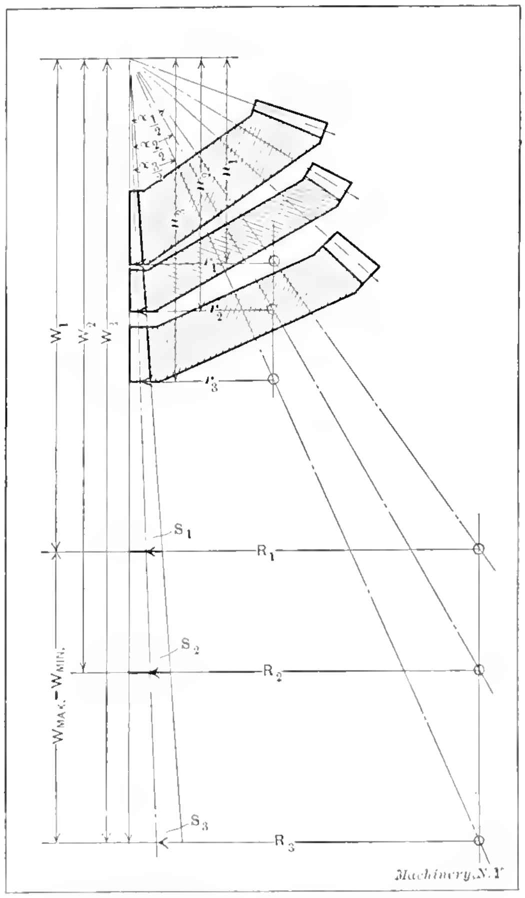

Fig 3. Diagram showing how Correct Bevel Gear Teeth can be cut with a Limited Number of Adjustable Formers

On account of its simplicity, the involute form of tooth is almost exclusively used for bevel gears, and the following investigation will cover this form of tooth only. The form of the involute curve depends entirely on the length of the radius r (Fig. 1). This radius equals $\frac{d}{2}$ divided by cosine $\frac{a}{2}$. In the following this radius r will be known as the *effective radius*.

In Fig. 2 are shown two teeth from gears having widely different pitch. The illustration indicates how the same former can be used for both teeth provided the former is large enough so that the full length of the tooth flank of the larger tooth can be formed from it. It is clear that if the bevel gear planing machine is so constructed that the former can be adjusted for planing the opposite side of the tooth, then the same former will be suitable for cutting all gears having the same effective radius, irrespective of the number of teeth in the gear; therefore the conclusion previously arrived at may be further extended by saying that within the capacity of the machine, all bevel gears having an equal pitch cone angle can be cut with the same former irrespective of the pitch or the number of teeth. In other words, the shape of the former depends on the angle of the pitch cone only.

The question of the angular limits of the pitch cone angle between which each former can be employed without serious inaccuracy in the tooth form is a highly important one. In other words, it is necessary to determine how many formers will be required for the full capacity of the machine, assuming, for instance, that it will commence to cut gears with a pitch cone angle of about 10 degrees up to 160 degrees. Certain (German) makers of milling cutters for spur gear teeth make these in sets of 15, this giving a very close degree of accuracy for all numbers of teeth. It would be reasonable to base calculations for limits of tolerance for bevel gear formers on the same basis as has been used for determining the number of teeth for the 15 cutters in a set of spur gear cutters. An example may illustrate this more clearly. Assume that the bevel gear planing machine has a capacity for cutting all bevel gears up to a modulus of 20 and with pitch cone angles of from 10 to 160 degrees. Assume that the smallest number of teeth is 12. Then we have the required circular pitch for the former (see Fig. 1):

$$\text{Circular pitch} = \frac{W \sin \frac{a}{2} \times 2\pi}{\text{Number of teeth}}$$

and the modulus is

$$\text{Modulus} = \frac{\text{Circular pitch}}{\pi} = \frac{2W \sin \frac{a}{2}}{\text{Number of teeth}}$$

In this case then the modulus equals 61.5, W being equal to 1,500 millimeters and a being assumed as 30 degrees, this

* Abstract of an article by H. Becker, *Werkstatts Technik*, September, 1909. See also an article entitled Adjustable Former for Bevel Gear Planing, MACHINERY, December, 1906.

being the greatest angle that ought to be used when the number of teeth equals 12. The modulus found is the greatest one for any former for the machine, and from this one the other formers must be determined.

We have previously said that the involute form depends only on the pitch cone angle, or on the length of the effective radius r. The number of teeth in the present case corresponding to the largest pitch cone angle $a = 160$ degrees would be

$$\text{Number of teeth} = \frac{2W \sin \frac{a}{2}}{\text{Modulus}} = \frac{2 \times 1{,}500 \times \sin 80^\circ}{20} = 148.$$

TABLE GIVING PITCH CONE ANGLES FOR DIFFERENT FORMERS

No. of Spur Gear Cutter (or Corresponding Bevel Gear Former)	No. of Teeth for which Spur Gear Cutter is intended	Pitch Cone Angles for which Former can be Used	Exact Angle to which Former Corresponds
1	12	98° 48'— 10° 35'	10°
1½	13	10° 36'— 11° 25'	10° 55'
2	14	11° 26'— 12° 13'	11° 55'
2½	15— 16	12° 14'— 14° 1'	13°
3	17— 18	14° 2'— 15° 27'	14° 30'
3½	19— 20	15° 28'— 17° 3'	16°
4	21— 22	17° 4'— 18° 37'	17° 30'
4½	23— 25	18° 38'— 21° 1'	19° 30'
5	26— 29	21° 2'— 24° 9'	22° 20'
5½	30— 34	24° 10'— 28° 3'	26°
6	35— 41	28° 4'— 33° 23'	30° 30'
6½	42— 54	33° 24'— 42° 53'	37°
7	55— 79	42° 54'— 59° 27'	49°
7½	80—134	59° 28'— 87° 53'	70° 30'
8	135— 00	87° 54'—180°	122°

From this equation, solved for $\frac{a}{2}$ we can easily determine the angles which correspond to the numbers of teeth for which the spur gear cutters are made; and in this manner, by comparing with a list of cutters for spur gears and seeing the number of teeth for which each cutter is intended, we can determine the limits of the pitch cone angles for which each former should be used. The accompanying table shows the results obtained from these calculations, and also gives the angle for which each former should be made.

While a machine provided with formers made with the limits indicated will cut gears which are practically correct, it would be advisable to have special formers made for such ratios as 1 to 1, 1 to 2, 2 to 2, 2 to 3, etc., so that in these cases absolutely correct teeth can be cut.

One of the most interesting considerations in connection with this subject is yet to be mentioned. While the formers are made for a certain pitch cone angle, and it therefore would appear that it would not be possible to make a bevel gear with perfectly correct teeth, except if it had a pitch cone angle corresponding to the angle for which the former had, in particular, been made, it is possible by a method now to be described, to produce theoretically correct teeth for all pitch cone angles with the formers mentioned. In Fig. 3 are shown three bevel gears with different pitch cone angles; the effective radii r_1, r_2, r_3, however, are equal for the three bevel gears. Therefore,

$$n_1 \tan \frac{a_1}{2} = n_2 \tan \frac{a_2}{2} = n_3 \tan \frac{a_3}{2}$$

From what has previously been said, it is clear that for producing the teeth in these gears one can use the same former, provided the distances W from the former to the apices of the pitch cones be made to correspond. If, for instance, on a certain machine W equals 1,000 millimeters, and an adjustment of 300 millimeters is possible, then $W_{max.}$ equals 1,300 millimeters. If the former corresponds to a pitch cone angle of 90 degrees when W equals 1,000 millimeters, then it will correspond to a pitch cone angle of 75 degrees 20 minutes when W equals 1,300 millimeters. It is also clear that when passing from 1,000 to 1,300 millimeters the former comes into intermediate positions corresponding to all angles between 90 degrees and 75 degrees 20 minutes. This arrangement has the advantage that a very few formers make it possible to cut theoretically correct teeth for every angle within the limits of 10 to 160 degrees, even when the limits of the adjustment of the former on the machine are small. If the limit of adjustment of the former on the machine increases, it is evident that the required number of formers will decrease correspondingly, and a very few formers will be required for cutting correctly all bevel gears, whatever the pitch, pitch cone angle, or number of teeth.

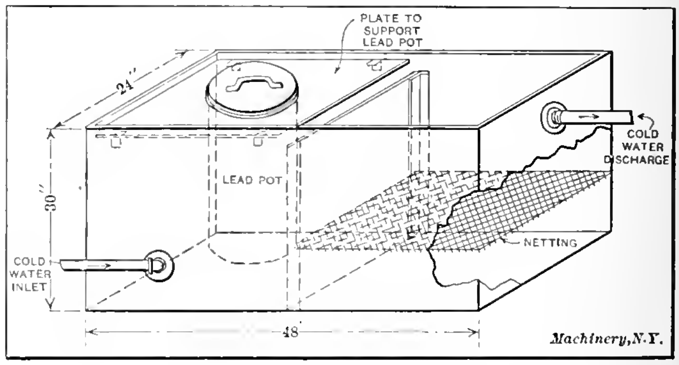
* * *

PROCESS FOR HARDENING CAST IRON

R. F. WILLIAMS

An improved process whereby cast iron in the rough or in the finished state may be hardened or tempered, the hardness extending completely through articles of comparatively large dimensions, is described in the following. One of the principal objects of this process is to provide a cheap and simple method of rendering iron castings so hard that they may be used for many purposes in the place of steel, thus reducing the manufacturing cost of a large number of articles. The various steps of the process and the manner of carrying it out are here described. The castings which are to be treated by this process may be completely finished as regards machine work before they are hardened, and it will thus be seen that the wear on the machine is greatly reduced and the necessary labor is also less than where similar articles are made from hardened steel.

The casting is first heated in any suitable or convenient heating device, until it reaches a temperature sufficient to cause the casting to glow, or, in other words, to what is known as a cherry red heat. It is then dipped in a bath which consists of practically anhydrous acid, of high heat-conducting power, preferably sulphuric acid of a specific gravity of from 1.8 to 1.9, to which is added a suitable quantity of arsenic. The ingredients of the bath are sulphuric acid of a specific gravity of about 1.84 and red-arsenic (As_2S_2) in the proportions of ¾ of a pound of red-arsenic crystals to one gallon of sulphuric acid. The castings may be either suddenly dipped in this mixture and then taken out and cooled in water, or they may be left



Cooling Tank and Hardening Bath for Cast Iron

in the bath until cooled. It has been found, however, that dipping the castings in the bath and holding them there for some time, which varies according to the size of the casting, and then completely cooling in water, is quite as satisfactory, and produces a material which is just as hard as if the castings were allowed to remain in the bath until cooled, and this method is preferable if a large number of castings are to be hardened, as the bath is thus prevented from becoming overheated. In preparing the bath, when sulphuric acid and red-arsenic are used, we find that better results are obtained when the crystals are added to the sulphuric acid and the bath is allowed to stand for about a week before using, the reason probably being that the bath becomes more saturated with the arsenious compound when the dissolved red-arsenic has been long in the sulphuric acid.

It is not necessary that the casting be machined completely before hardening, as rough finished castings may be hardened equally well. The change which takes place in the metal is in the nature of a molecular re-arrangement or re-crystallization coincident with an increase in the combined carbon at the expense of graphitic carbon, and in this change

Address: 444 St. James St., Montreal, Canada.

lies the difference between the results obtained by this bath and ordinary case-hardening processes, in which a certain portion of the carbon contained in the material of the bath is actually given up to the metal.

It is found that the more rapid the cooling of the metal, the harder it will become. For this reason the bath must be of high heat-conducting power, and this requirement is obtained by the use of the ingredients referred to. Furthermore, the bath must be practically free from water, as it is found that when the acid contains water in any considerable quantity, a steam cushion is formed between the acid and the metal which prevents their coming in contact, with the result that the cooling is less rapid, and, consequently, the iron is not so hard.

A cylindrical jar made of lead should contain the bath, the size varying according to the work to be done. A jar about 10 inches in diameter by 18 inches deep, will be about right for ordinary small work. This lead jar should be enclosed in an outer vessel through which water is caused to continuously circulate in order to keep it cool. It might be further pointed out that if it is desired to harden one portion of a casting and leave the remaining portion soft, this may be accomplished very readily by immersing only the part to be hardened.

Such a hardening equipment has proved very satisfactory in locomotive work for hardening bushings, etc., and many other uses could no doubt be found for it. The whole equipment can be homemade, consisting as it does simply of a steel tank divided into two compartments, and the lead jar for the bath, as shown in the illustration. The water circulates in the first chamber around the lead vessel, keeping it cool, and then passes to the second chamber, into which the castings are dropped, when taken from the bath, to cool off. The water then passes into the sewer or other suitable containing device. There is a screen placed in the second compartment to keep the castings from falling to the bottom. A lead cover should be made for the bath to keep the acid solution from evaporating, and a little care exercised by the workman so as to prevent the solution from splashing on him.

* * *

TIME OF EXPOSURE FOR DRY-PLATE PHOTOGRAPHY

In the January, 1909, issue of MACHINERY, engineering edition, an abstract was published of a paper on "Industrial Photography," by Mr. S. Ashton Hand, read before the American Society of Mechanical Engineers at the December, 1908, meeting. A contribution to the discussion on this subject was made by Mr. Charles W. Hunt, who submitted some interesting records of experiments made by himself for the purpose of estimating the proper time of exposure for dry-plate photography. The accompanying tables are based on this series of experiments. As a preliminary step, the altitude of the sun was calculated for each hour of the day from sunrise to sunset on the first day of each month of the year and the results plotted.

In June, 1905, a series of exposures was made with a Watkins exposure meter at each hour of the day, and a tentative table of the relative exposure time for each hour from sunrise to sunset was made. Using this tentative table, a series of similar exposures was made with dry plates. The plates were each developed the same length of time and in the same strength of developer. From these tests the tabular time was corrected. A table was then made giving the estimated time of exposure for each hour of the first day in each month in the year, basing the time of exposure largely upon the tests and the altitude of the sun in the different months. During the ensuing year this table was tested from month to month, and revised as experience indicated, in order to get the best attainable negative at any hour of the day in any month of the year. Table I is derived from the results of the above tests, with the formulas corrected to correspond with exposures made on Eastman films of 1908.

The time for a theoretically perfect exposure that will result in the best printing negative that the subject will give, cannot be expected from any formula that takes into consideration only the most prominent factors affecting the problem. These rules may, however, be expected to give a reasonably close approximation to a perfect exposure. In making exposures where it is unusually important to secure a good negative, and the exposure cannot be repeated, make three exposures as follows: The first exposure with time as computed; the second, with one-half the computed time; the third, with double the computed time.

For less important cases, but where great uncertainty exists as to the proper time of exposure, proceed as above, but make only two exposures, the slowest and the fastest, omitting the computed time exposure. The latitude of the plate will give a satisfactory negative if the theoretically perfect time of exposure lies within very wide limits.

An exposure should not be made in a fog, and in hazy weather only of nearby subjects. Good negatives may be made during a shower if the weather is otherwise clear. Generally, if contrast in the negative is desired, underexpose; if definition in the shadows is wanted, overexpose. When in doubt, it is safer to overexpose. Stops number 64 or 128 are excellent for general outdoor exposure; number 32 or 16, for indoor work. If it is desirable to emphasize a specific part of a machine, focus carefully with a large stop, and shorten the exposure to correspond with the stop.

TABLE I. COEFFICIENTS "A" FOR PHOTOGRAPHIC EXPOSURES IN THE LATITUDE OF NEW YORK

Month	Hour of the Day				
	7 to 8 or 5 to 6	8 to 9 or 4 to 5	9 to 10 or 3 to 4	10 to 11 or 2 to 3	11 A. M. 12 M. 10 P. M.

May-August..	5	8	12	18	28
June-July...........	7	10	16	24	32

The following formulas and tables are based on normal light conditions and ordinary subjects. If either or both are abnormal, the operator must make allowance in the duration of exposure as computed by coefficients from Tables I, II and III:

TABLE II. WEATHER COEFFICIENTS B

Clear, sunshiny weather..............................	1.0
Floating, white fleecy clouds.........................	1.0
Overcast, but a light day...........................	1.5
Cloudy, dull day	2.0
Lowery, heavy clouds...............................	4.0

TABLE III. SUBJECT COEFFICIENTS T

Shop interior, dark and poorly lighted................	1000.0
Shop machinery fairly well lighted..................	400.0
Shop machinery placed near a good window light......	150.0
Machinery under sheds with one side open, or covered areas	15.0
Machinery outdoors to give details in the shadows....	2.0
Machinery outdoors, general views....................	1.5
Groups or portraits outdoors.........................	1.0
Buildings and nearby landscape......................	1.0
Distant structures or landscape views................	0.5

Time Exposure

Assume a stop suitable for the subject and call it H; then the seconds to expose will be

$$\frac{H \times B \times T}{32 \times A} = \text{seconds exposure for an } H \text{ stop.}$$

Bulb Exposure

A "quick" bulb exposure is a time exposure of about 1/5 to 1/4 second. To compute the number of the lens stop, use the formula:

$$\frac{8 \times A}{B \times T} = \text{stop for a "quick" bulb exposure.}$$

* * *

A non-shrinking alloy can, according to the *Scientific American*, be made by melting together equal weights of tin and zinc. The alloy is hard when a good grade of zinc is used. Two parts of bismuth by weight to 50 parts of tin and 50 parts of zinc, will render the alloy very fluid and make it possible to pour it at a lower temperature.

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively

MILLING INDEX DIALS

The charts shown in the accompanying illustrations, together with the following explanation, show how a rather complicated job of indexing was simplified to enable an operator who was familiar with only plain milling operation, to carry on the work.

It will be observed by referring to the drawing of the dial, Fig. 1, that the index lines, notches and set-screw must be in a fixed relative position. An index plate with a 54-hole circle was selected, and the degrees between the notches and lines on the dial were reduced to turns and holes for each movement as follows: As it requires forty turns of the crank to make one complete turn of the work, there is, in this case, $40 \times 54 = 2{,}160$ holes to one turn of the work, and a movement of one degree equals $2{,}160 \div 360 = 6$ holes. It is now only necessary to multiply the number of degrees given on the charts by six, to get the number of holes for each movement, and then divide by 54 to reduce the movement to turns

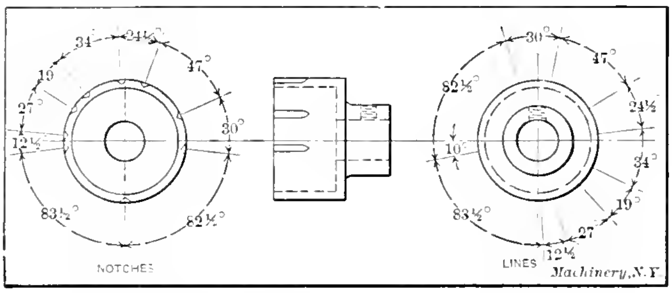

Fig. 1. Index Dial in which Notches and Lines are to be milled

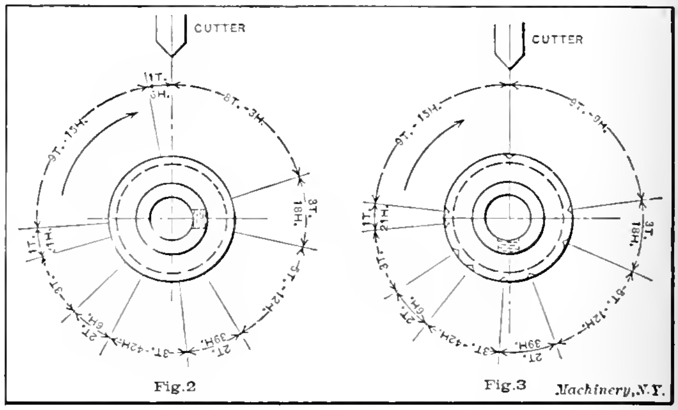
of the crank and additional holes in the plate. For example, 10 degrees $\times$ 6 $=$ 60 holes, or 1 turn and 6 holes.

The work of milling the index lines and the index notches was divided into two operations to avoid confusion, and two charts were made as shown in Figs. 2 and 3. The lines were milled first, and in starting great care was exercised to get the center of the set-screw exactly on the horizontal center line, and to the right, as viewed from the hub end. Now by indexing ten degrees, or one turn and six holes, we are in position to mill the first line, the cutter having been previously set central. Then by indexing, in the direction of the arrow, the required number of turns and holes for each successive cut as indicated on the chart for milling lines, it is a simple



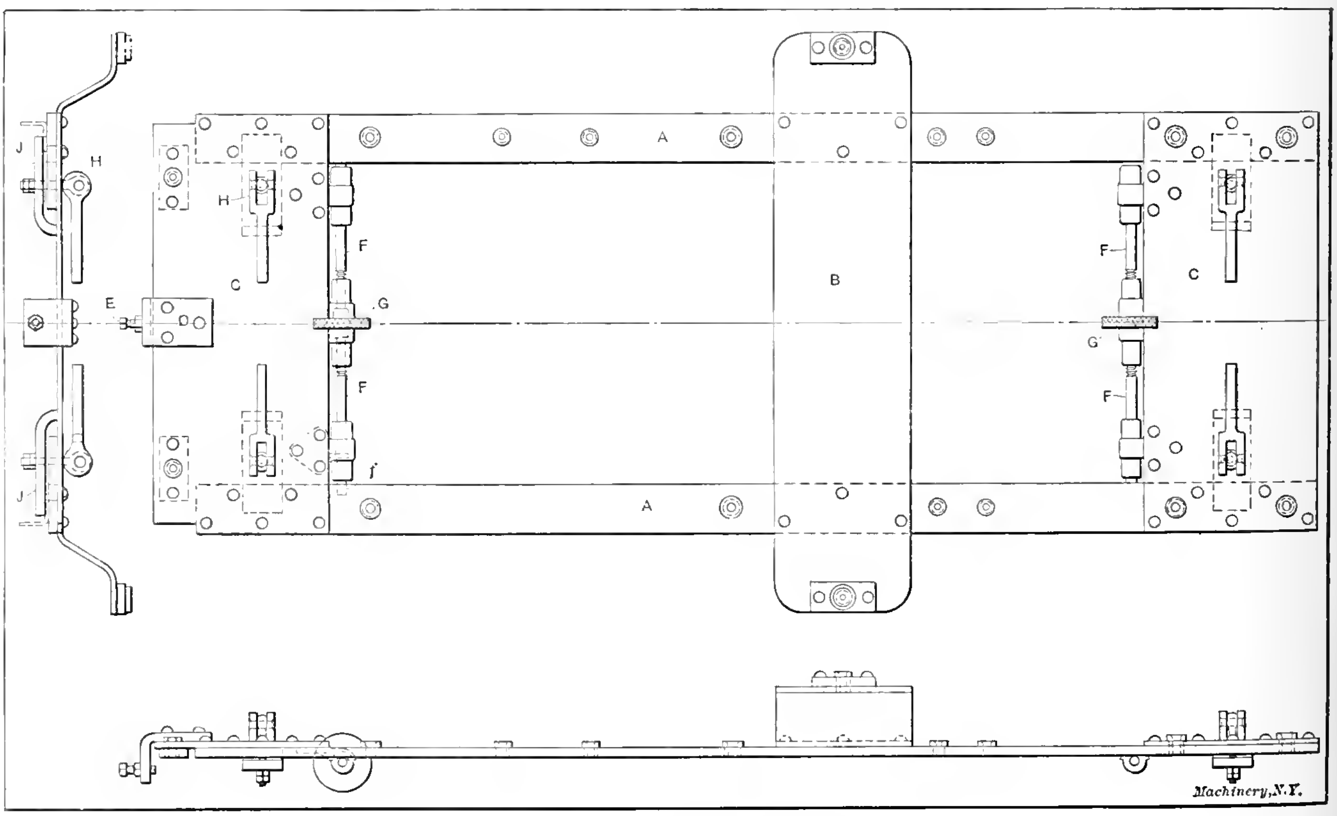
Figs. 2 and 3. Charts for Milling the Lines and Notches

matter to finish that operation. The work will then be in the original position. By referring to the chart for indexing the notches, it is found that one of them is in line with the set-screw hole. As this point makes a convenient starting place for the second operation, the work is indexed one-quarter turn or 90 degrees by ten turns of the crank. This brings the work in the proper position for starting the first cut. Then, by indexing in the direction of the arrow, as shown by the chart in Fig. 3 for milling the notches, the second operation is finished.

C. G. H.

JIG FOR DRILLING AUTOMOBILE FRAMES

A jig for drilling automobile frames is shown in the accompanying engraving. This jig is designed for drilling the holes for the motor and transmission feet, dash anchor plate, radiator, clutch, and shifting yoke holes, all at one setting. The frames, when received, are riveted and have all the holes drilled, except the ones mentioned.



Adjustable Jig for Drilling Automobile Frames

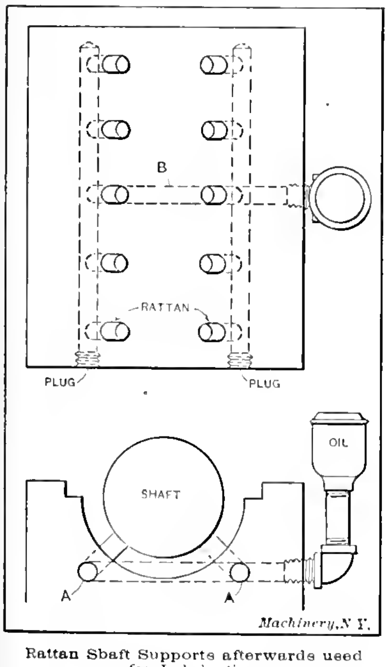
The jig consists, principally, of two side members, *A*, made of ½ x 2½ inch machinery steel; one cross member *B*, made of ¾ x 7-inch machinery steel; and two cross members *C*, made of ¼ x 9-inch machinery steel. The parts are put together with 5/16-inch rivets. The bracket *D* is riveted to the front cross member *C* and it holds the jig in the proper position lengthwise. The screw *E* allows for adjustment. Bracket *D* is made of 1½ x 2½-inch machinery steel and it is riveted to the cross member *C*. The jig is centered by the four adjusting rods shown at *F*; the points *f* bear against the inside of the sub-frame. Adjustment is made by hand-nuts *G*, right- and left-hand threads being employed. Four eccentric levers *H*, in conjunction with the clamps shown at *J*, are used for securing the jig to the frame. After the various members were riveted together, the holes were laid out, drilled and fitted with hardened bushings. This jig proved to be light and accurate.

After experimenting with various styles of drilling machinery, the writer found an elbow bracket drill to be the most convenient and rapid.

Detroit, Mich. J. F. RICHMAN.

SUPPORT FOR SHAFT WHEN BABBITTING

An excellent support for a shaft when babbitting, which may be used afterward for lubricating purposes, is made by inserting pieces of rattan in two rows of holes drilled in the casting, as shown in the accompanying illustration. The holes should be about ¼ inch in diameter, and the rattan cut long enough to support the shaft in the proper position. Two holes *A* should also be drilled lengthwise of the bearing to connect the bottoms of the holes in which the rattan pieces are inserted. The ends of these holes *A* are plugged as shown. After the babbitting is finished, a hole *B* should be drilled across the bearing to connect the oil cup with the supply channels *A*. When the shaft is in place and in motion, it draws the oil through the rattan pieces which wear eventually and which are always in contact with both the shaft and the oil in the supply channel below. This feeding action is due to capillary attraction combined with gravity.



Rattan Shaft Supports afterwards used for Lubricating

S. C. SMITH.

BORING MILL INTERNAL GEAR REPAIR

A 10-foot boring mill table with a broken internal gear is shown inverted in Fig. 1. This table is of cast iron, and the gear was cast integral with it. The breaking of this gear was caused by a broken tooth which jammed in the pinion, causing it to break out a section of the large gear at each revolution. As a new table would cost $385 in addition to a probable delay of several weeks, it was decided to repair the old one, and this was done in the following manner: A locomotive tire was found that would finish approximately to the correct size, and there was also stock enough for an inner flange for bolting the finished gear to the faceplate. A 15-inch Dill slotter with a table graduated into 360 degrees, was used to cut the teeth. As there were 120 teeth in the gear, the table was moved three degrees for each indexing. While the teeth were being cut, the tire was fastened to an old driving wheel center, to which it had been fitted in the same manner as it was to be held in position on the boring mill table. A recess about ½ inch deep was turned in the wheel center,

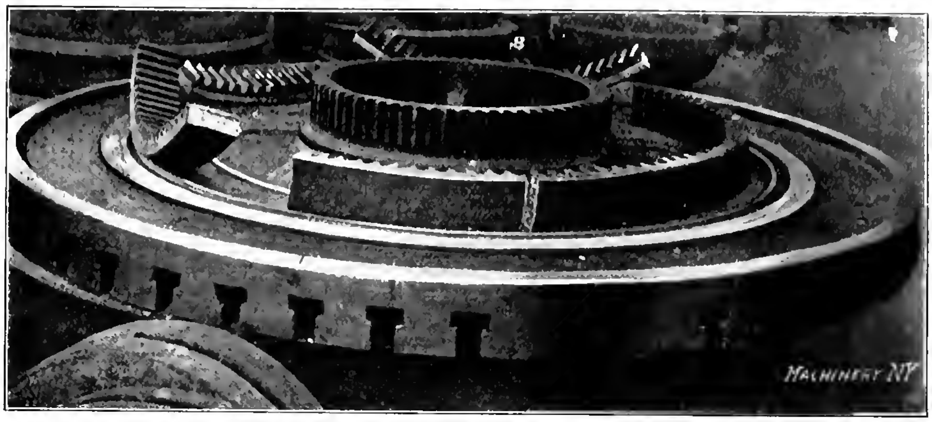


Fig. 1. The Boring Mill Table with its Broken Gear

and cap-screws were used to hold the work in place. The wheel center was also turned out on the under side to fit down over the outside of the slotter table. A roughing and finishing tool of the proper shape for the teeth was made to fit the slotter tool-bar, and the whole job was completed at a labor cost of less than $35. While this gear would probably **not** suit our friends, Mr. Grant or Mr. Bilgram, still it is doing the work for which it was intended, and is a fairly good job.

Battle Creek, Mich. M. H. WESTBROOK.

SUGGESTION DEPARTMENT IN THE SHOP

I would like to learn what the opinions of some of the readers of MACHINERY are on the merits and demerits of a suggestion department in shops, such as many stores and manufacturing concerns have, where prize money is paid to employes for suggestions submitted by them and adopted by the concern, that will be of value. I think that it is a good thing if good sense and judgment are exercised in submitting the suggestions; and if conducted properly, it is an important factor toward the goal of commercial supremacy. I know of a number of highly prosperous concerns who acknowledge that much of their success is due to the suggestions submitted by their employes through the suggestion department.

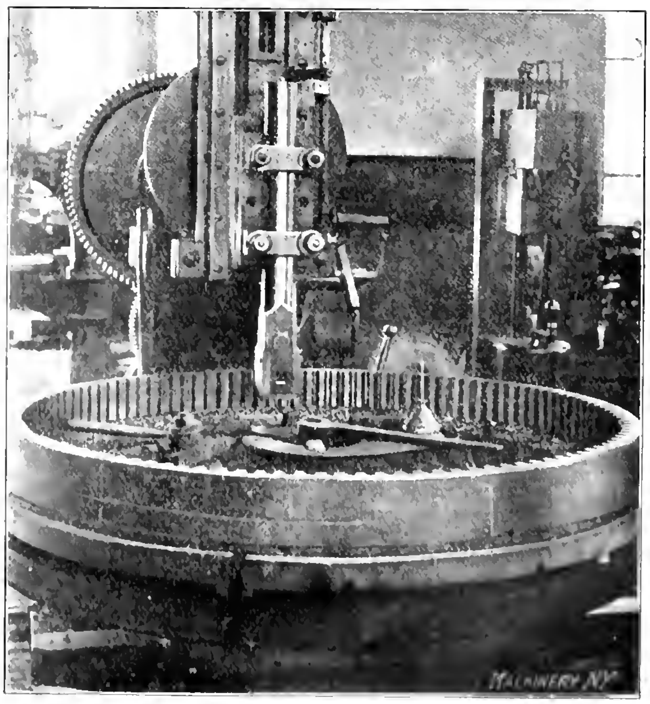

Fig. 2. New Gear being made from Old Locomotive Tire

Encouragement to employes from a concern for suggestions induces men to take an interest in their work and in the welfare of their employer. The ability of each man whose support is enlisted is also developed. Men engaged in a line of work day in and day out are often more likely to see the need of an improvement, than the foreman or superintendent.

When a suggestion is submitted by an employe through the suggestion department, he and not the foreman receives the credit for any improvement. A superintendent or foreman who is opposed to and refuses to accept or encourage suggestions from his men for improvements on a method or process, whether the suggestions come through a department or not, is, more than likely, impelled by jealousy and conceit and is burdened with an exaggerated sense of his own importance and ability. Obviously, such men should not be entrusted with important positions, as they are not qualified for the handling of men and the affairs of a concern. If a superintendent or foreman does not like to have it known that men under him can improve on his methods or system, it should spur him to so improve them that there will be no chance or room for suggestions.

Peoria, Ill. ARTHUR Z. WOLGAMOT.

LOCATING WORK WHEN BORING IN THE MILLING MACHINE

It often happens that accurate boring, drilling and reaming must be done on jigs, dies, fixtures, etc., in a milling machine, that cannot be relied on as to the accuracy of the measurement indicated by the adjusting screw dials because of lost motion between the screw and the nut. By the following method, the most run-down milling machine can be used for such work, and accurate results secured.

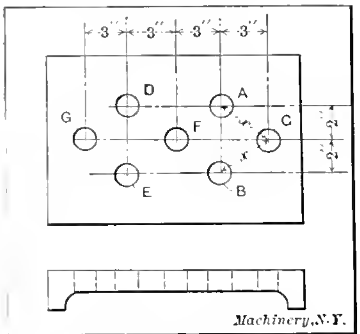

Fig. 1. Jig-plate to be bored as indicated

A jig-plate is represented in Fig. 1 that is to be drilled and bored for jig bushings as indicated. This will serve to illustrate the method of setting work on a milling machine that cannot be relied on. It is assumed that the plate is finished on the edges, and that it is fastened to an angle-plate, which is secured to the table and set square with the spindle. A piece of cold rolled steel or brass is first fastened in the chuck (which is mounted on the spindle) and turned off to any diameter. This diameter should preferably be an even number of thousandths to make the calculations which are to follow, easier. The turning can be done either by holding the tool in the milling machine vise, as shown in Fig. 2, or by securing it to the carriage with clamps. In either case, the tool should be located near the end of the table, so as to be out of the way when not in use.

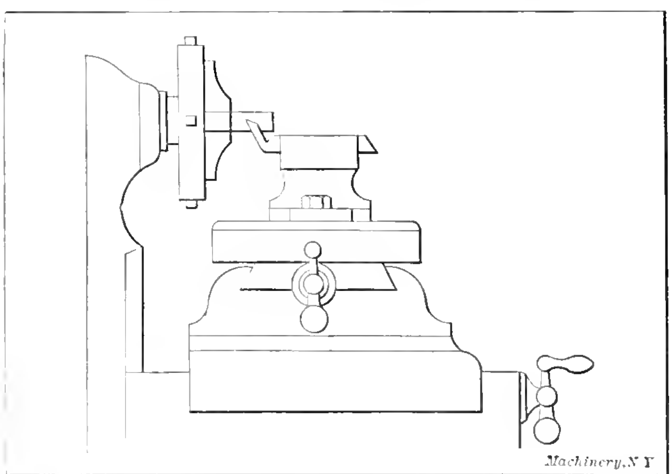

Fig 2. Turning Plug used for Setting Jig-plate

After the piece in the chuck is trued, the table and knee is adjusted until the center of the spindle is in alignment with the center of the first hole to be machined. This setting of the jig-plate is accomplished by measuring with a micrometer depth gage from the top and sides of the work to the turned plug as illustrated in Fig. 3. When taking these measurements, one-half the diameter of the plug in the chuck is, of course, deducted. When the plug is properly set, it is removed from the chuck and the first hole A is drilled and bored or reamed to its proper size. The plug is then again inserted in the chuck and trued with the tool. After which it is placed in alignment with the second hole B; this is done by inserting an accurately fitting plug-gage in hole A and measuring from this gage to the turned piece in the chuck with an outside micrometer as in Fig. 4. Allowance is, of course, again made for the radii of the two plugs. The horizontal measurement can be taken from the side of the work with a depth gage as before. The plug is then removed and the hole drilled and bored to the proper size. Without changing the adjustment, the plug is again inserted in the chuck and turned true; the table is then moved vertically to a position midway between A and B, and then horizontally to the proper position for hole C as indicated by the depth gage from the side of the work. The location can be verified by measuring the center distances x with the micrometer. In a similar manner holes D, E, F and G are accurately located.

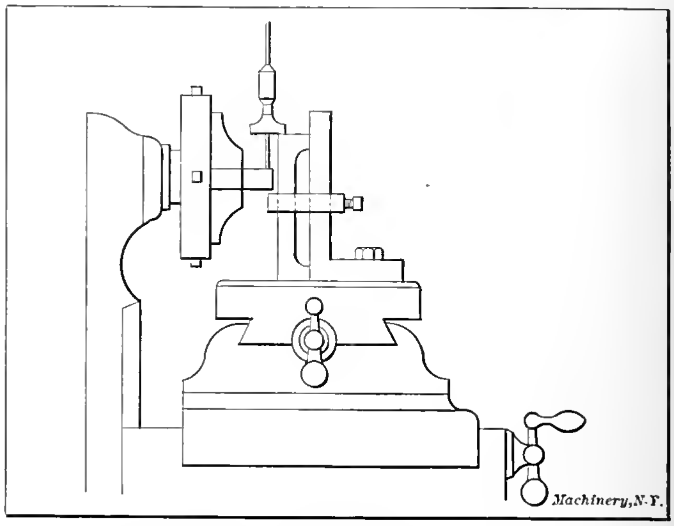

Fig. 3. Setting Jig-plate by measuring to Turned Plug with Depth Gage

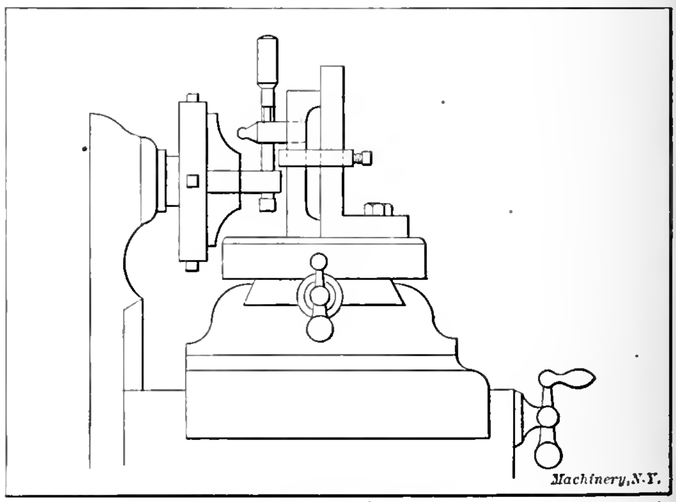

Fig. 4. Obtaining Accurate Center-to-center Distance by the Use of Plugs and Micrometer

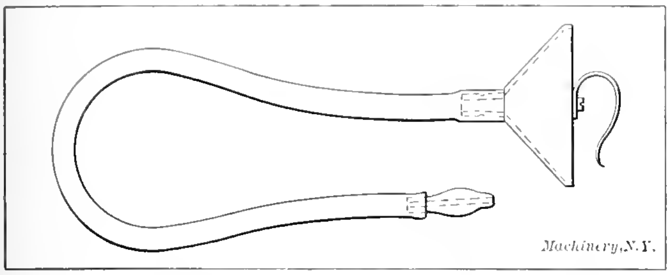
If the proper allowances are made for the variation in the size of the plug, which, of course, is made smaller each time it is trued, and if no mistakes are made in the calculations, this method is very accurate. Care should be taken to have the gibs on all sides fairly tight at the beginning, and these should not be tightened after each consecutive alignment as this generally throws the work out a few thousandths. If the reductions in the size of the plug, each time it is turned,

are confusing, separate pieces can be cut off and trued up to one side. If the center distances x are not given, it is, of course, far more convenient to make all the geometric calculations before starting to work. L. E. KRAMER.

Newark, N. J.

MECHANICS' STETHOSCOPE OR SOUND TRANSMITTER

The engraving shows how a simple stethoscope or sound transmitter is made. Its use is adapted to small work and particularly to bench lathe boring, grinding or lapping. It is composed of a piece of ¼-inch rubber tubing with a hard rubber ear-piece and a conical brass cup with a thin steel disk for a diaphragm soldered to the large end. In addition, there is a spring clip fastened to the diaphragm with a screw. Suppose a small hole 0.015 inch in diameter is to be lapped;



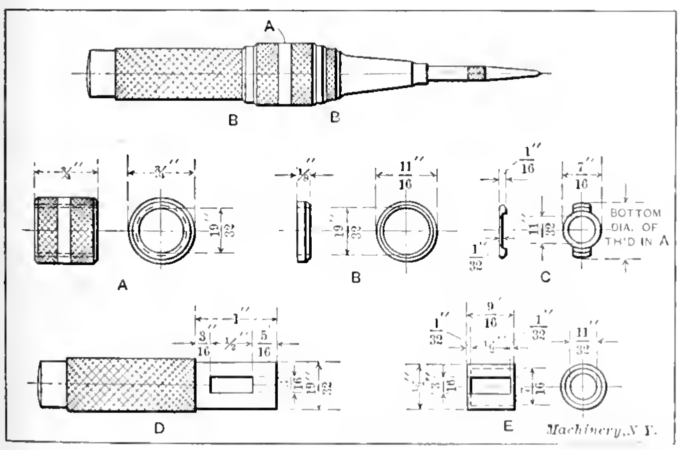
Simple Instrument for Transmitting Sound

then the spring clip on the diaphragm is slipped on the outside of the spindle bearing in which the lap is being used, and as soon as the lap is set in motion and adjusted, the finest touch can be detected with this instrument. I have seen many mechanics use the cover of a round tin box with a wire rod soldered to it. This transmits the sound fairly well, but the operator must hold his head in one position to listen, whereas the instrument shown in the sketch, because of the rubber tube, allows the operator to hear and also move so he can see what he is doing. A. J. DELILLE.

Elgin, Ill.

ADJUSTMENT FOR AUTOMATIC CENTER PUNCH

The following article describes an adjustment which may be fitted to a Brown & Sharpe plain automatic center punch. The advantages claimed for it are, a wider range of adjustment and the absence of projecting nuts on the ends of the



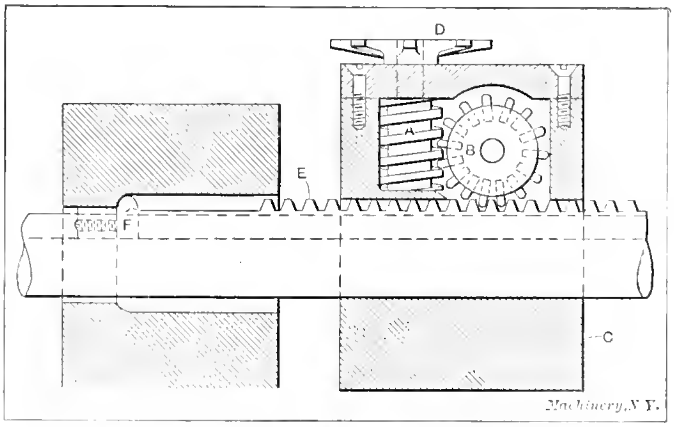
Parts for Making a Plain Automatic Center Punch Adjustable

punch. Its range of adjustment is from the full stroke of the punch down to no movement at all, as the release of the striking block is made adjustable, instead of the compression, on the spring.

At the top of the accompanying engraving the punch is shown assembled, and I do not think that it loses any of its neatness by the addition made to it. Parts A, B, and C are the extra parts required. The handle D is turned down on the end as shown, and two slots are cut through. Two slots of the same size are also cut in thimble E, so that when it is in position inside the handle, these slots are in line. Knurled sleeve A is bored to fit over the end of handle D, and it is threaded inside, 16 threads per inch, V thread. A nice smooth thread is required. Collars B, of which two are needed, are merely to keep sleeve A from screwing up on the knurled handle, as the shoulder is so small. Part C is made a nice sliding fit inside of thimble E, and the two projections pass through the slots in E and D. The ends of these projections are bevelled to fit the thread inside of A, so that, when the parts are assembled, and the sleeve A, which is fixed endways, is revolved, the part C moves up or down inside of E. The bore of part C is the same as the bore of the inside flange on thimble E, this flange releasing the striking block. It is obvious that by revolving sleeve A until part C is at the bottom, the center punch is practically solid. When part C is at the top, the stroke is practically the same as in the plain center punch, and any stroke between these limits can be obtained. T. H. N.

SPECIAL BORING TOOL

We ran up against a snag at one time which made it necessary to design a special boring head and tool, and as the tool worked so satisfactorily I consider it entitled to a brief description in MACHINERY. This special tool was made necessary by a cored bearing which had to be bored, as there was no room around the shaft for babbitt. This shaft was fixed so that we could not get an end movement (or feed), and the bearing was also fixed, but we could drive the shaft by power when it was applied.



Special Boring Head and Tool

The accompanying illustration shows the construction of the special boring head used. It was made as cheaply as possible, and the parts were obtained from every available source. The worm A was taken from an old S-wrench, and the body C was made from a piece of scrap shafting. The cavity in which the worm A and wormwheel B were inserted, was cut with an end mill of practically the same diameter as the worm. This wormwheel was also made from a piece of scrap shaft, cut the right length to fit into the chamber. The teeth were formed by driving pieces of drill rod into holes drilled for the purpose. The part D is an eight-pointed star wheel, which was used for feeding the bar at each revolution of the shaft. The rack E was made from a piece of common key stock, of a size to fill the spline which happened to be in the shaft. The boring tool F was inserted in a hole in the end of the rack, and secured with a headless set-screw which allowed for adjustment. After the job was finished, it was found that by making two sets of brackets to support the ends of a permanent bar which was made to suit the head C, this tool could be used in many an out-of-the-way place, especially on repair work. H. E. WOOD.

Newark, N. J.

MAKING ACCURATE AUTOMOBILE ENGINE PISTONS

In a large shop that was turning out a great number of automobile parts on contract, they had trouble in setting accurately finished pistons, and after trying several different plans, the following was found to be most satisfactory.

Fig. 1 represents a chuck which is made of two gray iron parts; namely, the body A and the closing ring B. The body

was screwed on the spindle of an engine lathe by a spanner wrench which engaged the holes *C*. Fig 2 represents the finished piston. These pistons after having been entirely machined, except grinding, were placed in this chuck and a fine finish cut was taken in the mouth. When the piston was placed in the chuck, closing ring *B* was screwed tight by a spanner wrench which engaged holes *D*. The ring being a good fit at *H*, remained true when drawn back by the threads; and as the chuck body *A* was beveled to match the

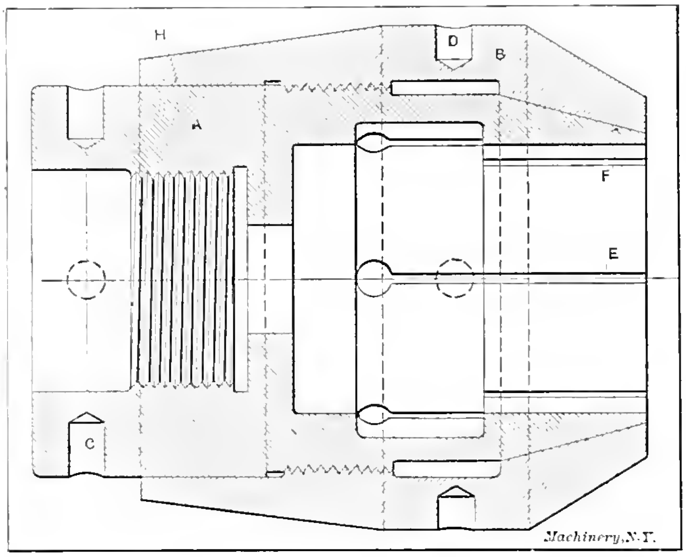


Fig. 1. Chuck for Holding Pistons while Boring Mouth

closing ring and saw-divided at *E* into three equal parts, it closed tightly on the piston and held it true so that the finish cut was true to the outside of the piston.

The cross bore in pistons which had previously been machined in a jig that fitted the outside diameter of the piston was, therefore, at right angles to the finished outside. Thus the cross bore, the mouth bore, and the outside diameter were made exactly true to each other. This much being accom-

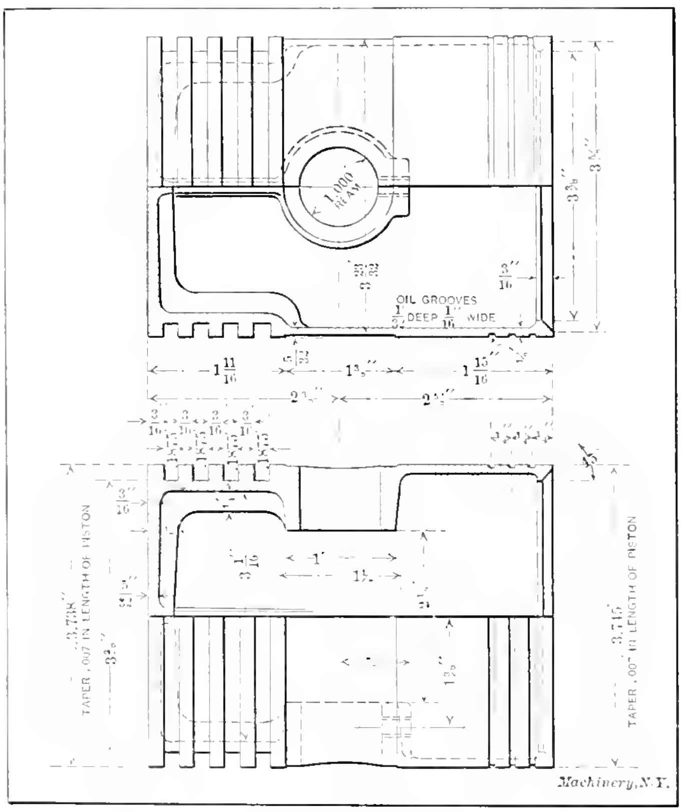

Fig. 2. Automobile Engine Piston

plished, the finish grinding was made perfect by the mandrel shown in Fig. 3. This consists of a finished forging *J*, a pin *K*, that is a close fit in the cross bore of the piston and in forging *J*, and a cylindrical part *L* that is fitted accurately to the forging *J* and that also is a close fit at *O* in the finished mouth of the piston. By tightening nut *M*, shoulder *P* is brought square against the end of the piston. It is now evident that with the piston center on one center of the grinder, and the centered end of forging *J* on the other grinder center, with pin *N* acting as a driver, that an accurately ground pis-

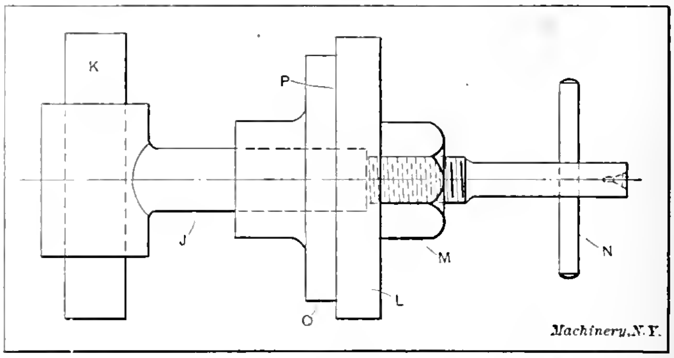

Fig. 3. Mandrel on which Pistons are held while being ground

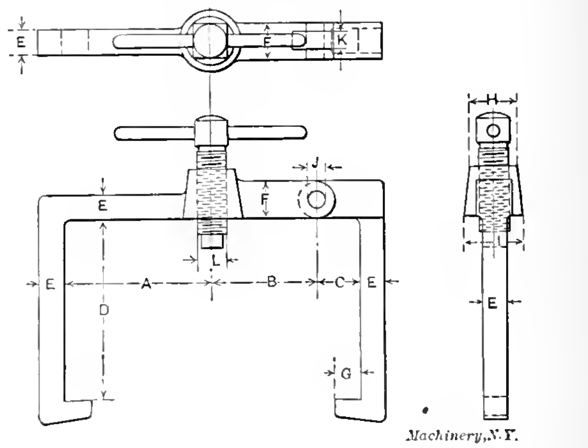
ton would be the result. We found this method a little slower than some others, but the extreme accuracy obtained and the small number of pistons rejected by the inspectors, made the gain all in favor of the fixture.

JIG AND TOOL DESIGNER.

HANDY SET OF CLAMPS

We had some work to clamp in a drill jig, and as the ordinary C-clamp required too much time to operate, the type of clamp shown in the accompanying illustration was designed. A common squared-head cap-screw with a dog point is used to



Size No.	A	B	C	D	E	F	G	H	I	J	K	L
1	3	2 1/8	7/8	2 1/4	1/2	3/4	9/16	1	1 1/4	3/8	3/8	5/8
2	3	2 1/8	7/8	2 1/8	1/2	3/4	9/16	1	1 1/4	3/8	3/8	5/8
3	1 7/8	1 1/4	5/8	1 3/4	1/2	3/4	9/16	1	1 1/4	3/8	3/8	1/2
4	2 1/4	1 1/2	3/4	2 1/4	1/2	3/4	9/16	1	1 1/4	3/8	3/8	5/8

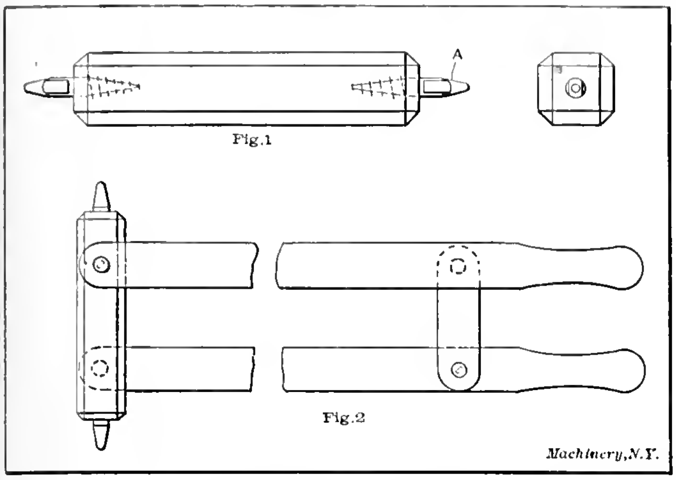
tighten the clamp after the movable side is swung into place. A 1/4-inch pin, 3 inches long, passes through the head of the clamping screw, which makes it unnecessary to use a wrench for tightening. The swinging side of the clamp is pivoted to the main part by a pin which passes through a hinge fitting, as shown. Dimensions for four different sizes of clamps of this type are given in the table below the engraving. These clamps are very convenient, quick-acting, and they may be used for many purposes.

E. H. PRATT.

DEEP HOLE CALIPERS

In response to the editor's request, in the December number, for descriptions of deep hole calipers, I submit the following and the accompanying sketch, as a possible solution of "J. W. M.'s" problem. Fig. 1 represents a point or inside caliper similar to those used in the U. S. arsenals on large gun work. The body of the caliper or "stick," as it is called in the shop, is made of a piece of wood, and the points *A* are made from wood screws, the heads being cut off and the body

turned down as shown. Two flat places are filed on each point so that a wrench may be applied to adjust the points in or out for any required size within its limits. These sticks have many advantages over the usual methods of obtaining inside measurements: They are easily adjusted to outside micrometers or verniers and it is only a few minutes' work to make one of any desired length; the wood acts as an insu-



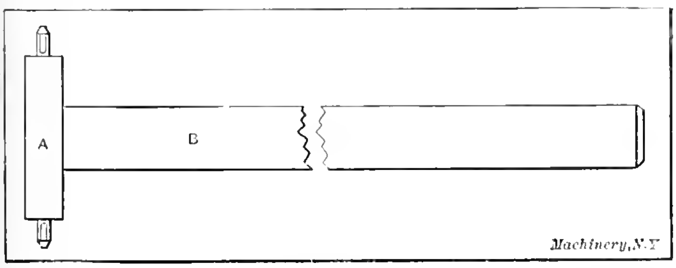
Figs. 1 and 2. Inside Caliper and Same Tool with Handles for Deep-hole Work

lation from the heat of the hand and furnishes a convenient place on which to mark the size to which it has been or is to be set in the inspection department. Fig. 2 shows how I would rig up one of these sticks to caliper the size at the bottom of a deep hole such as J. W. M. mentions, and with it I believe it would be an easy matter to ascertain the size within 0.00025 providing, of course, an outside micrometer of the required size is convenient. However, if the pieces are to be measured in large quantities, a star gage would be much quicker.

T. Covey.

DEEP HOLE CALIPERS

Through the "How and Why" page of the December, 1909, number of Machinery, J. W. M. asks for the best means of accurately determining the size at the bottom of a bore approximately 4 inches in diameter and 12 feet long. The best and cheapest way of measuring the diameter that I know of, is to take two wood screws, cut off the heads, point them,



Improved Deep-hole Caliper

file a flat on each side of the body so that they can be turned with a wrench, and screw one in each end of a piece of wood *A* about ¾ inch square by 3 inches long. A wooden handle *B* of the required length should be attached to the center of the cross-piece *A*, thus forming a T. The flats on the screws make it easy to adjust them in or out until they are set to the diameter of the work. Of course, the caliper must be withdrawn each time an adjustment is made.

Poughkeepsie, N. Y. George H. Desrochers.

CENTERING A SHAFT WITH A MILLING CUTTER

The method of centering a shaft with a milling cutter when key-seating, described by Mr. H. E. Wood in the October number, is a very good one, and one that I have used many times. It is also a good way of centering work with the cutter when milling spirals. By this method the centers can be set central with the cutter before swinging the table to the angle of the spiral. Another good method of centering the cutter when milling spirals, is to set the pointer of a surface gage to the height of the center, and then scribe a line across the end of the work, which is then indexed a quarter turn so as to bring the scribed line in a vertical position. The cutter may then be set with reference to this line. Still another method I often use when key-seating is as follows: The shaft is first adjusted so as to bring it within a few thousandths of being against the side of the cutter; then, if the cutter runs out laterally, it can easily be detected by sighting down over it while it is revolving. With the cross feed, the shaft is then set so that it just touches the side of the cutter. If the latter runs out of true, that part which is midway between the two points that run out the most should be set against the shaft. The dial on the screw is then set to zero; the table is locked, and the shaft is moved in a distance equal to one-half its diameter. The side of the cutter will then be in the same vertical plane as the center of the shaft. The dial may then be again set to zero so that the work may be moved a distance equal to one-half the cutter width. The shaft will then be exactly central with the cutter.

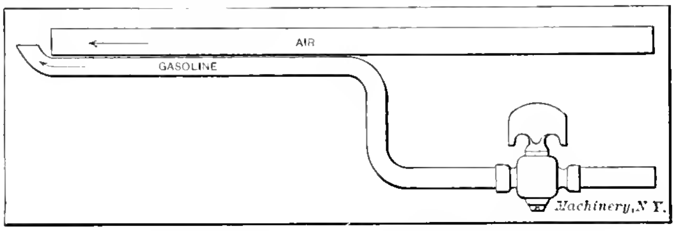
Peoria, Ill.

CLEANING AUTOMOBILES

As a foreman and mechanic in the automobile industry, I have been called upon many times to repair very dirty machines, a job which is sometimes annoying to the men. The device shown in the accompanying illustration has been found very effective for removing the dirt from automobiles, and it doubt-



Air and Gasoline Nozzle used for Cleaning Automobiles

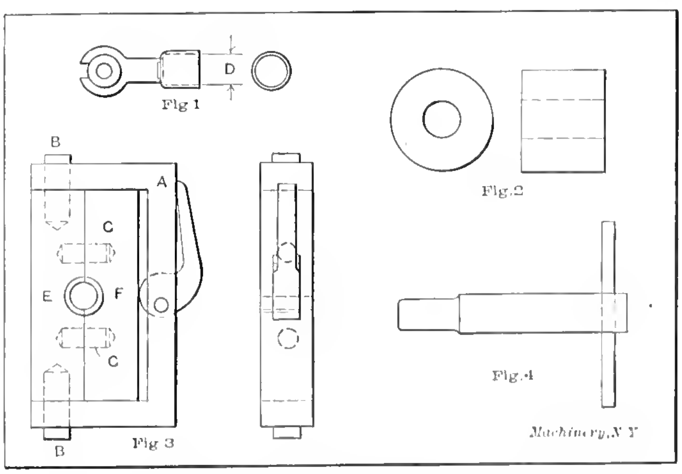
less would prove useful in connection with other work. This device consists of an air and gasoline nozzle, which is made of two pieces of tubing about fifteen inches in length. The sizes of these tubes are ⅜ and ¼ inch for the air and gasoline, respectively. Care should be taken to make the end of the gasoline pipe come exactly central with the air outlet, as shown in the illustration. By means of hose, one nozzle is connected with the compressed air and the other to a gasoline can. A valve can be placed on the gasoline pipe to regulate the amount of gasoline to be used. With a heavy air pressure, one gallon of gasoline will clean an entire automobile very effectively in an hour or so, and better than by any other method known to the writer.

J. B. Kemp.

Indianapolis, Ind.

DIE FOR REDUCING MAGNETO CABLE ENDS

A handy fixture is shown below, which the writer had occasion to use for re-forming the spark-plug end of magneto cables used on automobile engines. Magnetos with cables were bought from one company, and after some time a change



Figs. 1 to 4. Die for Reducing Spark-plug End of Magneto Cable and Sample of Work

was made in the cables and it was found that the new cables were 1/16 inch smaller in diameter. As a result, the terminal for the spark-plug end of the cable was too large and scraping this piece was out of the question, as this would involve considerable delay, which at the time could not be tolerated. In Fig. 1 is shown the cable end, the diameter *D*, being, as before stated, 1/16 inch larger than required. Fig. 3 shows the die for reducing the diameter. This die was split in order to be able to place the work into it. The part *A* of the die was pivoted on the pins *B* which were fastened into the half of the die marked *E*. The other half of the die was held by the eccentric which pivoted in *A*, the pins *C* locating this half. Fig. 4 shows the punch, and Fig. 2, a guide for the punch. This work was done by a boy, in a small hand press. After the piece was forced through the die and reduced, it was trimmed on the end, this being necessary because of the redrawing of the metal.

St. Louis, Mo. C. T. Schaefer.

EFFICIENT TYPES OF MILLING FIXTURES

With reference to W. A. Sawyer's "Efficient Type of Milling Fixture," illustrated and described in the October number of Machinery, in the Letters Upon Practical Subjects department, I would like to offer a little friendly criticism. I consider that there are at least three weak points in the design, *viz.*, (1) Work is not properly clamped. (2) Fixture is hard to keep clean. (3) Fixture is slow to operate.

To prove the claims—First, the work is clamped on one side of the cutter only and there is nothing to prevent the cutter from lifting the unsupported side at the beginning of the cut, unless the operator is very careful in advancing the work to the cutter. Again, if the work is not of a uniform thickness, one piece will be clamped close to the cutter while the other is clamped at some distance from it. The engraving Fig. 1 will serve to illustrate this.

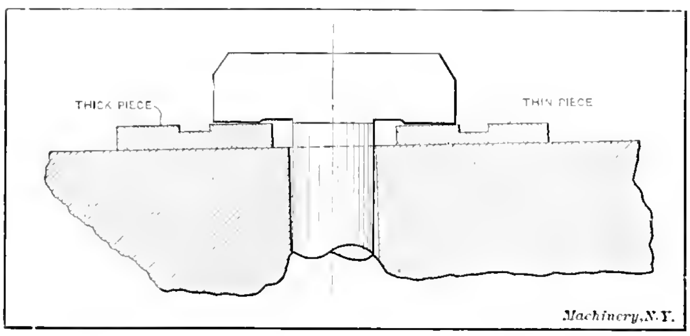


Fig. 1. Pieces of Different Thicknesses held by a T-clamp

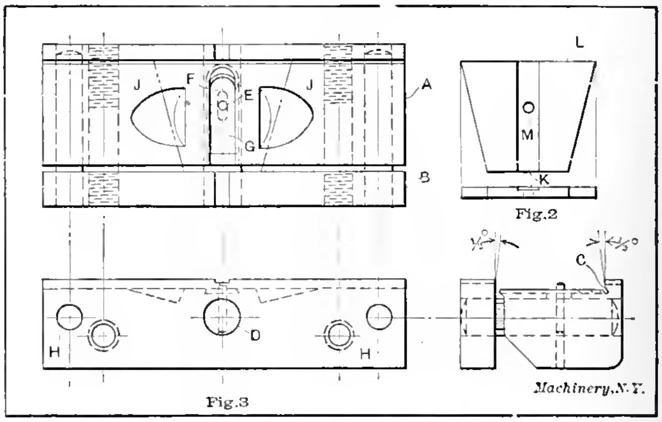
Second, to clean the fixture it must be taken apart, and this the writer considers a bad feature in fixture design, unless the construction is very simple. Any one studying Mr. Sawyer's design and noting the number of moves required to clean the fixture, will admit that the time required for cleaning is long compared with the time required to perform the cutting operation. I am, of course, assuming that Mr. Sawyer's sketch is proportional. The clearance slot for the pin *C* is unprotected from chips during the cleaning operation, and, in time, would become choked up. The foregoing objections would also apply to the third weak point, since it cuts down the output. It would be interesting to know what the latter would be per hour.

If a reliable vise is available, a pair of vise jaws could be made similar to Fig. 3 which would perform the operation satisfactorily. Jaw *A*, which is stationary, supports the work to within 1/32 of an inch of its width. *B* is a plain jaw. A slight angle of about ½ degree is given to the faces of both jaws to insure the work being held securely at the upper edge. A slight clearance check or groove is cut at *C*. *D* is a sliding pin which is an easy fit in both jaws. Into this pin is inserted pin *E* which locates the work. This pin is free to slide in jaw *A*, while slot *F* is protected from chips by means of a sheet metal piece *G*, which is dovetailed into *A* and slides with pin *E*. Clearance cuts *J* assist in lifting the work from the jaw. Lining pins *H*, which are driven into jaw *B* and slide in jaw *A*, prevent any lifting effect when tightening the vise.

It will readily be seen that a design of this type will embody what the writer considers the five most important features in fixture design, *viz*: Simplicity, efficiency of clamping device, ease with which it is cleaned, quickness of operation, and durability. A design such as is suggested would not cost more than 25 per cent of the cost of Mr. Sawyer's fixture, and while it is only a single fixture, there is very little time saved in making it multiple, as the cut is comparatively short and shallow and the time saved by being able to remove work and brush away chips quickly will more than counterbalance the advantage of milling two pieces at once; thus the output would be greater than with a fixture of Mr. Sawyer's design.



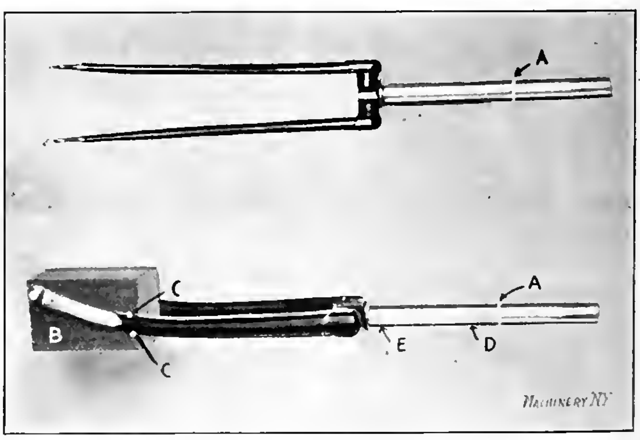
Figs. 2 and 3. Work and Fixture for Holding it while Groove "K" is being milled Square with Edge "L" and Central with Hole "M"

If a suitable vise is not available, a special vise with cam movement could be made at small cost to take a pair of jaws of the above type. The jaws can also be case-hardened and ground, thus adding greatly to their life. Where conditions will warrant the expense, and the output is increased, special fixtures are often advisable. Nevertheless there are many cases like the foregoing, where vise jaws will not only be cheaper but better in other ways.

Montreal, Canada. Irwin Jenkinson.

TURNING A BICYCLE FORK

As the fork of my bicycle was broken, I tried one from an old wheel to see how it would fit, and found that it was suitable in every respect except the length of the stem, which needed to be cut off at *A* and be re-threaded. This work was done without difficulty by the following method: A block of wood *B* was fitted in between the tines of the fork and was held rigidly by a bolt which passed through the tines and block. It was further secured by wire nails driven in at *C*. The fork was then placed in the lathe, the block of wood giving a good center for the live center of the lathe. After the steady-rest was placed at *D* the stem was easily cut off. The steady-rest was then changed to position *E*, the end of the work was supported by the dead center, and the thread cut, thus completing the job. Stephen Courter.



Bicycle Fork with Block fitted between Tines to permit turning in the Lathe

Paterson, N. J.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

COLBURN "NEW MODEL" BORING AND TURNING MILLS

The Colburn Machine Tool Co., of Franklin, Pa., has developed a line of boring and turning mills, which we herewith

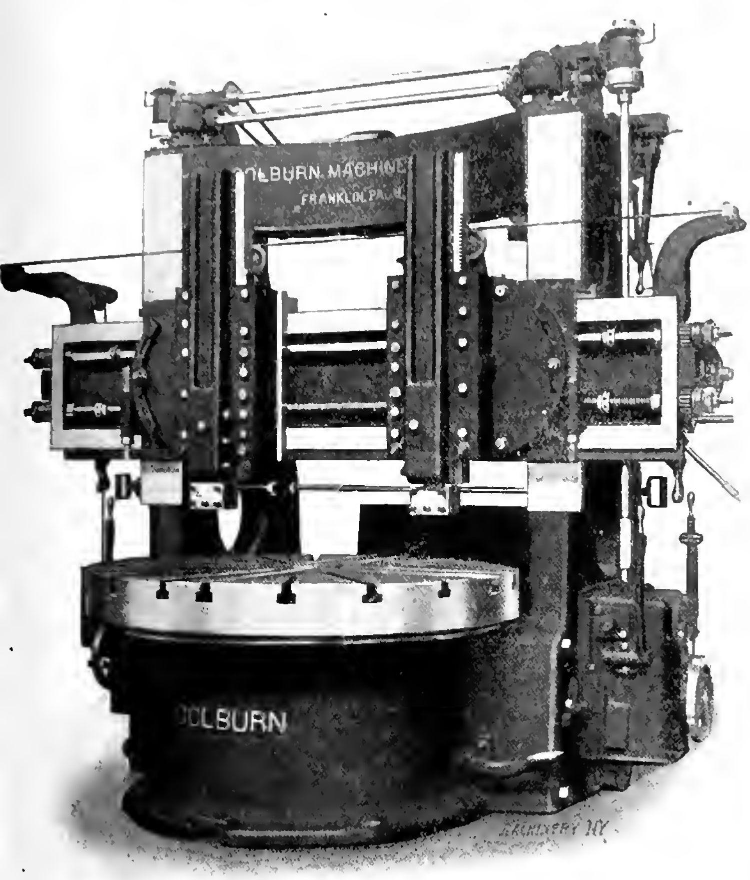


Fig. 1. "New Model" 60-inch Colburn Boring Mill

illustrate and describe. The name "New Model" is used to designate this design. In its general lines it does not differ from the older designs of the same builders but there have been important improvements in detail made throughout which materially increase its convenience and capacity. There are five sizes in the entire line, these being 42-, 48-, 50-, 60 and 72-inch swing, respectively. Practically the same features are incorporated in all the sizes, and a description of any one size applies to the rest. The illustrations here shown are mostly taken from the 60-inch machine.

The main framework of the machine is of standard construction as may be seen from the illustrations. The parts have been carefully designed to permit the taking of heavy cuts without vibration or deflections. The cross-rail, in particular, has been strengthened, having been given a heavy arched box section which is exceedingly rigid. The saddles have unusually liberal bearing surfaces on the cross-rail, with adjustable taper gibs to compensate for wear. The swivels, which are of large diameter and ample bearing area, are provided with an angular adjustment by means of a worm and gear, which also acts as a positive locking device making it impossible for the heads to accidentally fall over sideways when the clamping bolts are released. The ram (see *A*, Fig. 9) is very massive and has a steel rack set into its side. The cored opening is extended all the way to the top so that extra long boring-bars can be used. Clearance is provided to permit the rams to be raised within the guides.

The Main Spindle and Drive

Figs. 3 and 4 show clearly the construction of the spindle and the table drive. The spindle *A* has a massive angular thrust bearing which makes it self-centering. This, in conjunction with the two large cylindrical bearings *D*, effectually resists vertical, angular and horizontal strains. All these surfaces are lubricated from a common supply, this being the oil bath in which the angular bearing revolves. The lubricant is kept at the proper height by the oil gage and filler at the side of the base, connected to the spindle bearing by piping as shown in Fig. 3. The constant flow of oil along the conical thrust surface of *A* is maintained by the motion of the spindle. The lower part of the bearing is immersed in the reservoir of oil *B*, which is carried upward to the outer edge of the bearing and into the annular channel there, from which it is returned through suitable grooves to *B* again. By this means the bearing is automatically flushed, and the oil flows over into the cylindrical bearings. A circular safety pad of felt *E* contains enough oil to keep the cylindrical bearings *D* from becoming dry, even if the supplying of the reservoir is neglected for a long time.

The table is driven by a spur gear *F* of large diameter, attached directly to it. No lifting tendency is possible with this style of drive. As shown in Fig. 3, an internal gear is used on the 60- and 72-inch mills, while an external gear, as shown in Fig. 4, is used on the three smaller sizes. The table pinion *G* is mounted on a vertical shaft, which is oiled by a suitable reservoir and wicking as shown. In this case, as in the other important bearings, care is taken to provide a design which will give satisfactory lubrication, even though the oiler neglects the machine for continued periods.

The Speed Changing and Controlling Mechanism

The drive is by means of 5-step cone pulleys of large dimensions connected through a speed or back-gear box with the horizontal shaft carrying bevel gears

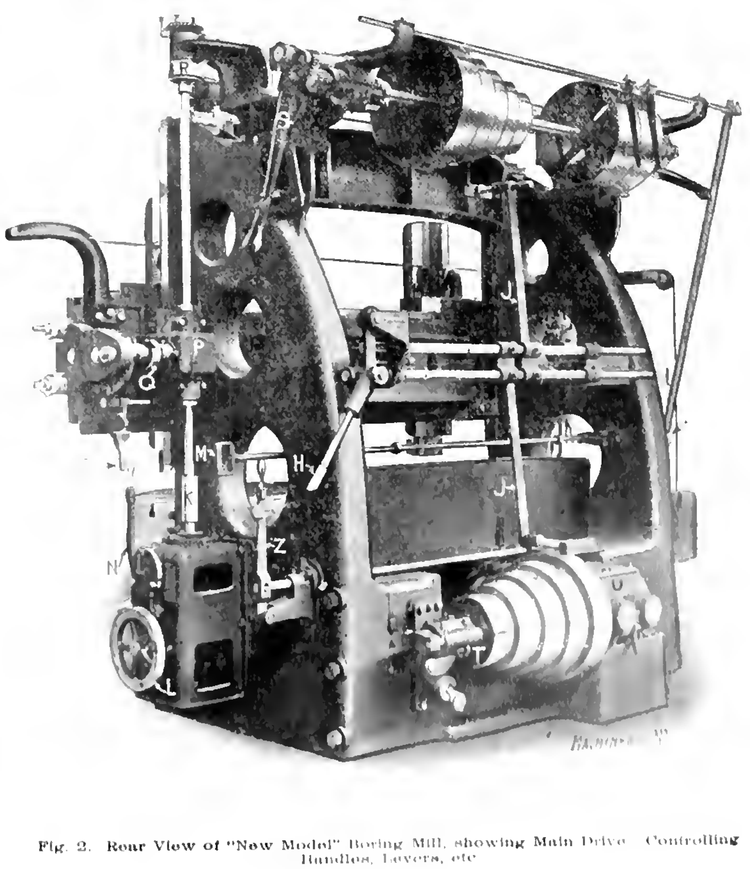

Fig. 2. Rear View of "New Model" Boring Mill, showing Main Drive, Controlling Handles, Levers, etc.

meshing with the vertical table pinion shaft shown in Fig. 4. The driving arrangement is best shown in Fig. 2, while details of the back-gear mechanism and the speed box are shown in Fig. 5. A belt shifter is shown which is simple, effective and easily operated, and avoids the necessity of the complicated mechanism and multiplicity of parts used on many geared speed-changing arrangements. By means of lever *H* (see Fig. 2) controlling belt shifters *J*, *J*, the belt can be changed from one step of the cone pulley to another with great rapidity and without any injury to the belt. In actual operation the change for the entire range of speeds given by the 5 steps in the cone pulleys has been obtained in eight seconds, going from the slowest to the fastest step and back again, and stopping momentarily at each speed.

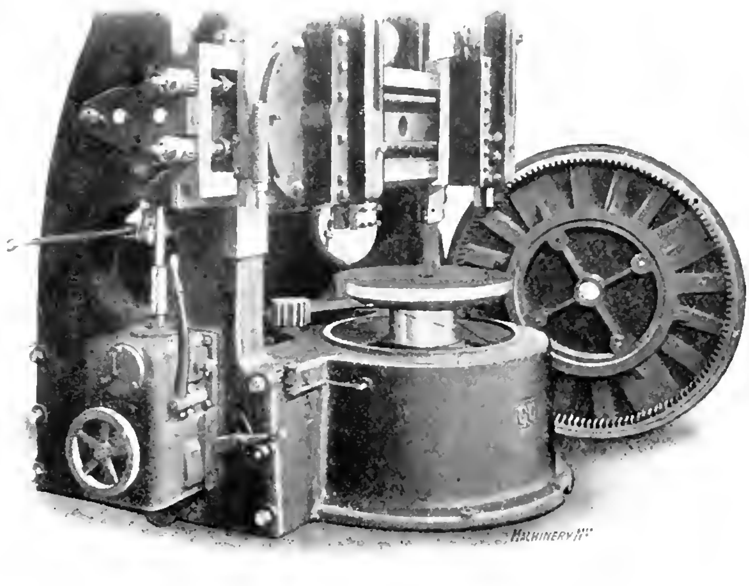

Fig. 3. Details, showing Construction of the Spindle Bearing and Internal Gear Drive used on the 60- and 72-inch Mills

The countershaft is attached directly to the upper parts of the housings by means of brackets having ring oiled bearings. It thus becomes a part of the machine itself. It carries the upper cone pulley and tight and loose pulleys. The loose pulley is provided with bronze bushings and is made smaller than the tight pulley, so that the strain of the belt is removed when the machine is not running. The machine may be controlled from either side of the mill by means of a horizontal rod connected with the shifter, having a spade handle at each end. One of these handles is shown at *M* in Fig. 2.

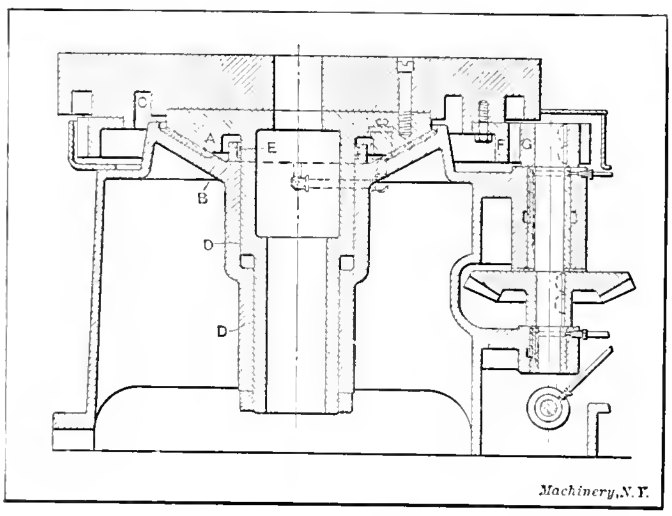

Fig. 4 Construction of the Taper Spindle Bearing and Provision for Oiling

The cone pulley is mounted on the driving shaft of the gear box, as shown in Fig. 2. This mechanism takes the place of the back-gearing ordinarily used. The speed change is made by gears and clutches which are constantly immersed in a bath of oil. The slow speed is thrown out and in by means of lever *Z*, conveniently located at the side of the machine. This, with the five-step cone pulley, gives 10 speeds, all in geometrical progression.

The speed box, when assembled, is oil-tight, and the proper height of oil is shown at all times by the glass gage and oil filler on the outside. All the bearings are bushed with phosphor-bronze and are provided with ring oilers for additional protection. The oil runs into the oil box from the main reservoir. By removing the single plug under the oil feed cup, the entire box can be drained dry. At any time it is necessary to make repairs the mechanism can be removed from the machine in its entirety, so that every part is accessible.

A brake is furnished which enables the operator to stop the machine with the table in any desired position. It is operated by a foot-treadle placed within easy reach on the working side of the machine. This brake, as shown at *B* in Fig. 9, is provided with taper friction surfaces, formed with hard maple shoes and wedges. It is applied to the inside of the cone pulley, as seen at *T* in Fig. 2. The conical type of friction prevents any distortion of the bearings; since it is operated directly on the prime mover, all shock and jar is eliminated and the braking effect is practically instantaneous.

The Feed Mechanism

The feeding mechanism for each head is contained in a separate case, one on each side of the mill, permitting each to work independently of the other. By turning the hand-wheel *L* one revolution, five changes of feed are obtained. The further movement of the multiplying lever, projecting from the front of the gear-box in Figs. 1 and 3, permits hand-wheel *L* to be revolved and gives five more changes, making ten in all. The vertical feed shaft *K*, extending upward to the feed case, engages the mechanism on each end of the rail, which conveys motion to the horizontal rods and screws in the cross-rail operating the heads horizontally, and vertically. The usual slip gears on the ends of the rods and screws are eliminated, and quick-adjusting positive clutches are substituted (see *D* in Fig. 9). This enables the operator to instantly change the feed from vertical to horizontal and *vice versa*.

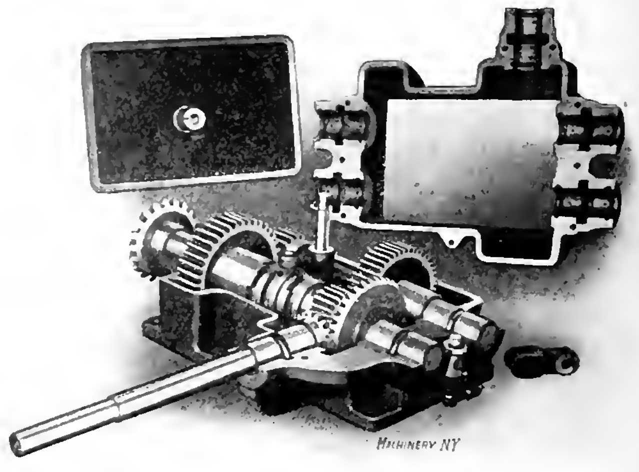

Fig. 5. Speed Box, showing Enclosed Mechanism and Ring Oiling Bearings

Either feed can be reversed by lever *O* at each end of the rail which controls a clutch playing between a set of reversing bevel gears in box *P*. These gears are connected with the feed shafts through a safety shear pin device shown at *Q* in Fig. 2, and in detail in Fig. 6. At the left of the latter engraving it is shown in position, while at the right it is shown taken apart. The connecting shaft is made in two sections with little couplings on their ends, adjoining each other. The motion is transmitted from the driving member to the driven one by a small pin passing through each flange of the coupling. Any abnormal strain on the feeding mechanism in excess of that necessary on the heaviest cuts will

shear this pin off, and thus protect the mechanism from breakage.

When a pin shears, one-half of the coupling is turned half around until the slots are opposite the broken pins, which are then readily removed as shown at the right of Fig. 6. The couplings are then turned until the holes are in line again, when a new pin is inserted and the mill is ready to run. The whole operation of taking out the old pin and putting in a new one only takes a few seconds. There is nothing to adjust or to get out of order in the device. A supply of pins is sent out with each machine, but in case these are exhausted, new ones can be readily obtained, as they are made from the ordinary wire nails found around any shop.

Power Rapid Traverse

An important feature of this machine relates to the construction of the power rapid traverse. This is provided for all the movements of the tools, whether in a horizontal, vertical or angular direction. It is obtained from the same vertical

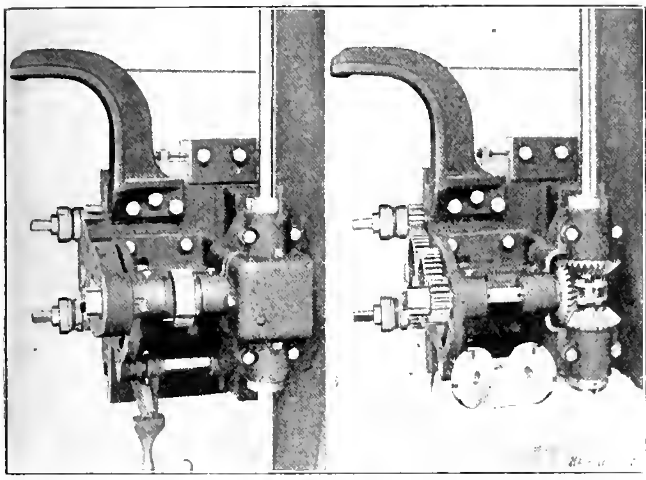

Fig. 6. The Safety Shear Pin Device for Protecting the Feed Mechanism, showing Ease of Replacing Shearing Pin

shaft K as the feed, and is controlled by the vertical lever N (see Fig. 2) at the side of the feed-box. This lever has two operating positions—either pulled in or pushed back. The regular gear feed is always engaged when the lever is in the back position, and if the feed is thrown in, the tool will then move in the direction determined by the position of the feed reverse lever O at the end of the cross-rail. On the other hand, the rapid traverse is always engaged and the gear feed is thrown out when the lever is in the forward position, and the tool will then travel rapidly in the opposite direction from that given by the gear feed.

It may take a word or two of explanation to show the advantage of this construction. It makes it impossible for

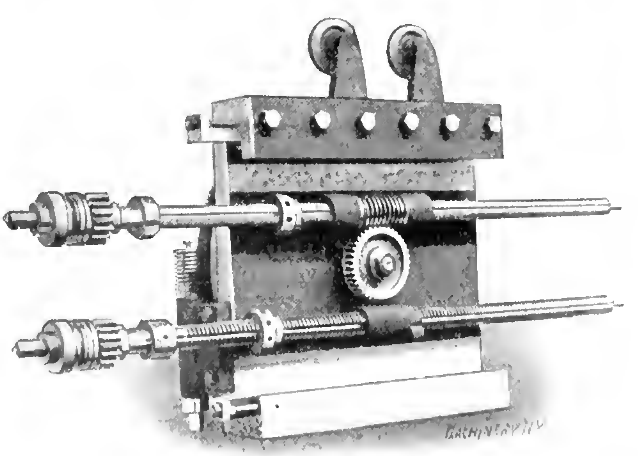

Fig. 7. Rear View of Saddle for Swivel Head, showing Large Diameter of Rods and Screws and the Fine Adjusting Collars for the Tool Movements

the operator to throw in the rapid traverse the wrong way, and thus avoids all chance of accident. For illustration, suppose the tool is feeding horizontally along the rail, taking a facing cut on a piece of work. Having reached the end of the cut, say with the tool up against the shoulder, the operator desires to disengage the feed and return the tool to the starting point again for a finishing cut. He simply pulls the rapid traverse lever forward. No mental effort is required, and he does not have to stop to think for a second which way to pull it, as there is only one direction in which it can be moved. It makes no difference whether the tool

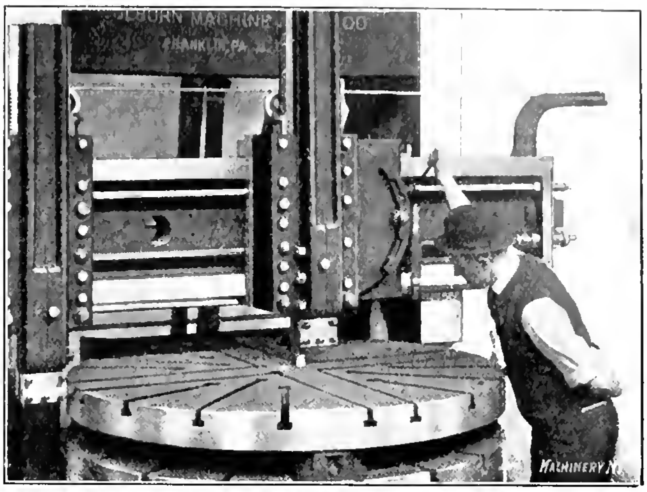

Fig. 8. Method of Making Minute Adjustments, which permits Close Observation of the Tool at the Same Time

is feeding to the right or to the left horizontally, or up and down vertically, the same lever controls the feed and rapid traverse in every case, and pulling the lever always throws the gear feed out and the rapid traverse in, at the same time reversing the direction of the travel of the tool. The rapid movement is obtained from the shaft at the top of the machine through vertical cones having cork inserts, of which one is shown at R in Fig. 2, and in detail at C in Fig. 9. This con-

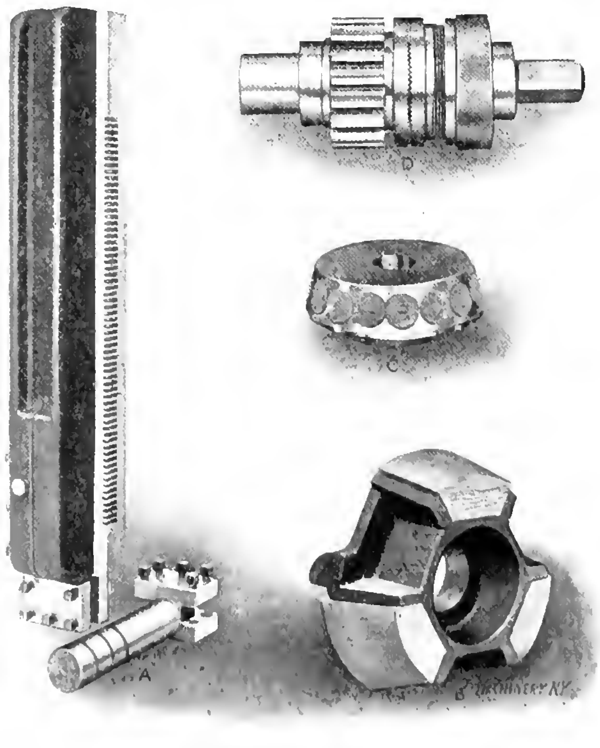

Fig. 9. Various Details. A—Ram. B—Brake Cone with Maple Shoes Treated with Paraffine. C—Cork Insert Clutch Member for Rapid Traverse. D—Quick-adjusting Clutch for Controlling Cross and Down Feeds

struction, which has proved its value in automobile design, does away with the necessity for flooded lubrication at this point.

The fine adjusting collar construction illustrated in Figs. 7 and 8, in connection with the rapid traverse just described, does away with the necessity for hand-cranking, although, of course, the ends of the shafts and screws in the cross-rail are squared so that a crank can be used in an emergency, or whenever the operator prefers. To permit the fine adjustment which the rapid traverse does not give, it has usually been necessary to go to the end of the cross rail and use the

crank-handle. In this design, however, both the feed-screws and the rods in the cross-rail are splined and each has a capstan collar fitted thereto with keys, and free to slide on them. By turning the capstan collars with a small lever furnished for this purpose, the rods and screws are turned also.

The operator can stand close to his work, as shown in Fig. 8, and by placing the capstan collars in the most convenient position, he can make fine adjustments of the tools in any direction without having to go to the end of the rail where he could not readily observe the movement of the tool point. When the heads are moved to the extreme outer position on the cross-rail, these collars do not in any way interfere, as is apparent in Fig. 1, so that it is not necessary to make the rails any longer for the sake of having the fine adjustment.

Attachments and Extra Equipment

Another attachment not shown here, is provided for thread cutting. When this is used, the feed change wheel L is set to a predetermined point at which the table and vertical feed shaft revolve in unison. A single tooth clutch, connected with the rapid traverse lever N, is used for returning the tool quickly to its starting point: and when this is again thrown in to connect the mechanism for threading, the tool must always catch the thread. This is the familiar construction used on certain types of engine lathes in which the lead-screw and not the work is reversed for thread cutting. While the gear connection for threading is not furnished regularly it can be put on at any time. It is attached to the bracket at the end of the cross-rail, always on the right-hand head. The change gears provided allow all threads to be cut between 2 and 14 per inch. For drum scoring, special arrangements are made which allow leads as coarse as one turn in 2 inches to be cut with the same facility as for the finer pitches.

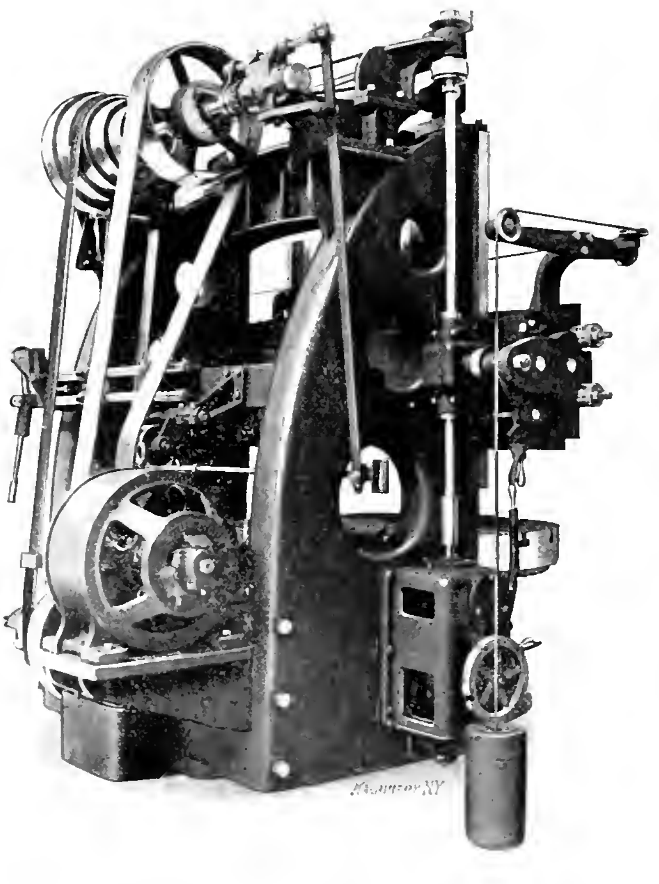

Fig. 10. Constant-speed Motor-drive for Colburn "New Model" Boring Mills

The self-contained countershaft construction described in the beginning of the article particularly adapts the machine to motor-drive. The 5-step cone, mechanical belt shifter and the speed box, furnish a wide range of speed changes so that a constant speed motor is recommended. The motor is mounted, as shown in Fig. 10, on a bracket in the rear, and is belted to a pulley on the countershaft. In order to enable the operator to stop or start the mill without stopping the motor, a clutch pulley replaces the regular tight and loose pulleys, and is operated by the same levers, with handles M (see Fig. 2) on both sides of the mill.

All the various features of design thus described apply to the whole line from the 42-inch to the 72-inch swing. There are some slight changes in the smaller sizes. As explained in connection with Figs. 3 and 4, for instance, an external spur gear is used for the table drive on the smaller sizes in place of an internal gear. Besides this the feed box is of different design on the 42-inch mill, as shown in Fig. 11. This change was made for the sake of securing compactness and to prevent the gear-box from extending out beyond the ends of the cross-rail where it would interfere with the movements of the operator. Turrets will be provided for the right-hand head, in the three smaller sizes if required by the purchaser. One of these is also shown in Fig. 11.

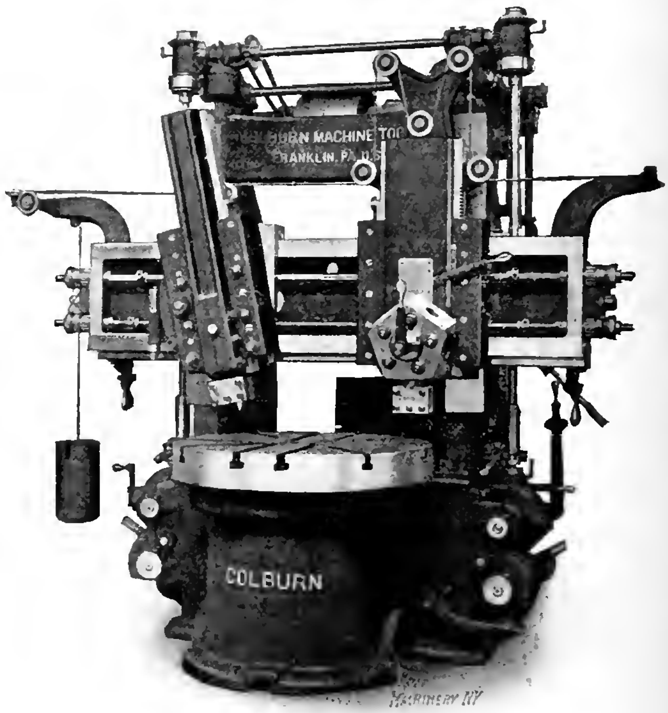

Fig. 11. The 42-inch Machine, showing Alternative Form of Feed Box and Turret on the Right-hand Head

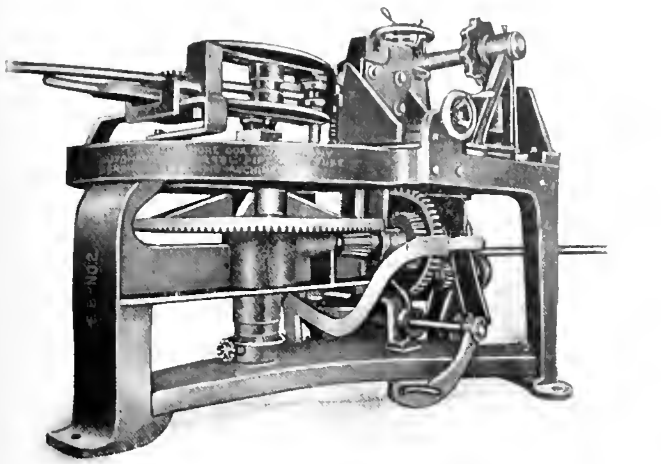
COX PIPE AND TUBE BENDING MACHINES

A series of pipe and tube bending machines is being brought out by J. Fillmore Cox & Co., Bayonne, N. J. These machines, of which one known as "Gem—Type B-No. 2" pipe and tube bending machine is shown in the illustration, embodying several interesting features, of which the most important is that the machine is capable of bending pipe and tubing cold, without the use of an inner filling, to any desired shape without injury to the metal in the pipe. Machines are being built that will take sizes from ⅛-inch tube up to the largest size which is likely to be required to be bent. The machine is, in many respects, a radical departure from previous designs of pipe bending machines, and in view of the rather crude and expensive methods and devices used in many places for bending pipe, it will undoubtedly prove of value to manufacturers who have a great deal of pipe bending to do. When bending pipes, a special collapsible plug is used in connection with a patented flexible chain operating the mandrel. The pipe is bent around rollers with specially shaped grooves, and levers are provided for certain operations with graduated adjustment for setting the bending rollers, so that certain predetermined bends will be produced.

The machine is gear-driven, and a "twin pinion" system of gearing has been incorporated which prevents any possible chance of backlash or lost motion, so that at all times a steady power is obtained, which is not generally possible with

other methods. An automatic stop arrangement is provided by means of which it is possible to obtain exact duplications of bends. A safety stop is also provided for the power mechanism. The main vertical shaft has been made of heavy dimensions so as to be able to easily withstand the heavy stresses to which it is subjected when in operation. In cases where a great number of pipes are to be bent in the same way, they may be cut to the same length and placed in a



Pipe Bending Machine, built by J. Fillmore Cox & Co., Bayonne, N. J.

magazine attachment from which they are fed gradually to the working mechanism. Radial bends, for instance, may be automatically made when the magazine attachment is provided. Such bends as a conical helix and regular helical coils may be performed on this machine by the use of special attachments. Outside of its application to the bending of pipes, the machine may also be used for other kinds of bending, such as the bending of steel rails, angle irons and other structural shapes.

ROCKFORD MULTIPLE SPINDLE DRILLS

We have previously described the sensitive drills both of the floor and bench types made by the Rockford Lathe & Drill

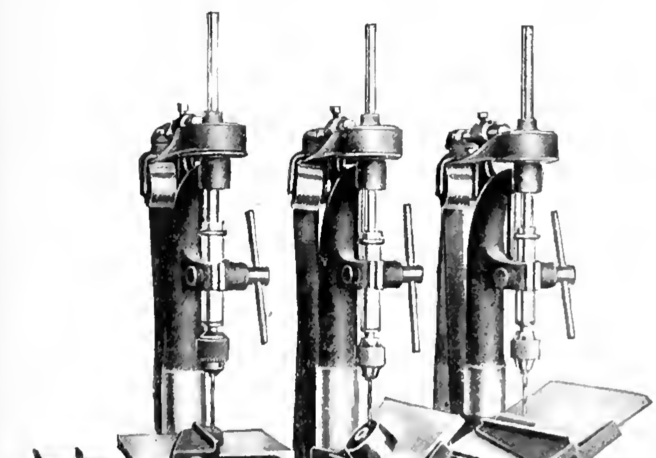


Fig. 1. Rockford Three-spindle Bench Drill, showing Use of Tilting Table and Adjustable Gage

Co., of Rockford, Ill. Both of these machines can now be furnished in the multiple spindle type as shown herewith. All the advantages of the single spindle machines are retained and a number of new features of design are added.

Fig. 2 shows the floor type of multiple spindle drill. The single spindle machine was first illustrated and described in the June, 1908, number of MACHINERY, under the old firm name of "Rockford Machine & Shuttle Co. As may be seen, the tool is provided with a substantial base and column, carrying, in the case shown, four spindle heads. It will be furnished as a two- or three-spindle machine when desired. Among the points that should be noticed is the self-contained countershaft with tight and loose pulley and convenient belt shifter. The work-table is adjustable for height, being counterbalanced inside the column. Another important improvement consists in mounting this table on a three-point adjustable bearing, making it possible to keep its surface in alignment with the spindle under all conditions. The two outer supports are adjustable by the threaded studs and nuts shown. Belt guards are provided for the spindle-driving pulley. The stop collars for the depth of the drilling are mounted on the upper ends of the spindle as shown.

The bench machine shown in Fig. 1 was illustrated as a single spindle machine in the New Tools department of the

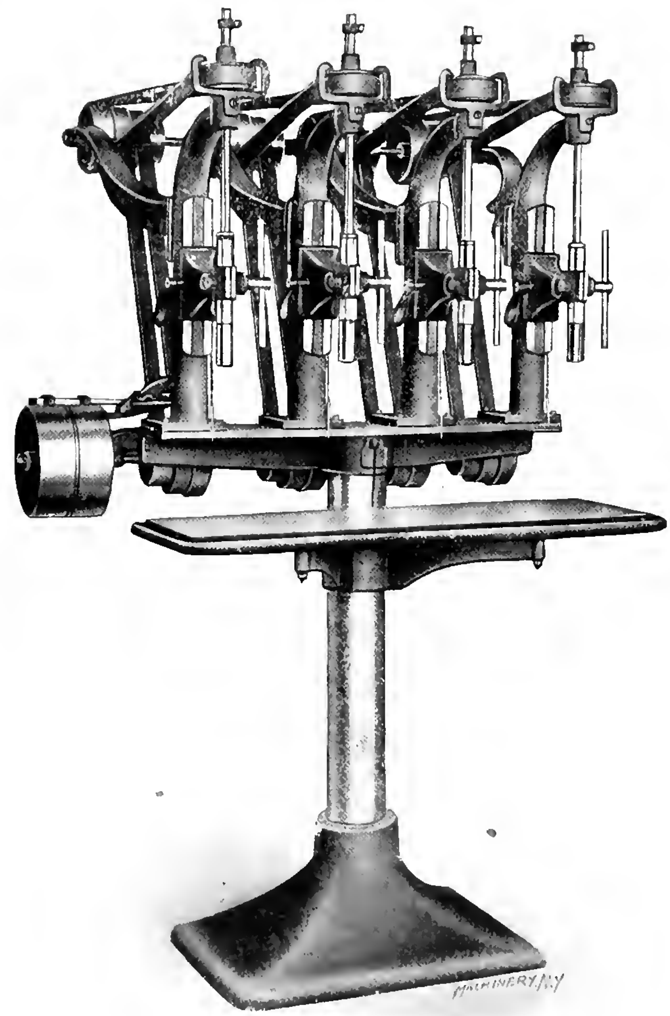

Fig. 2. Four-spindle Floor Type of Drill

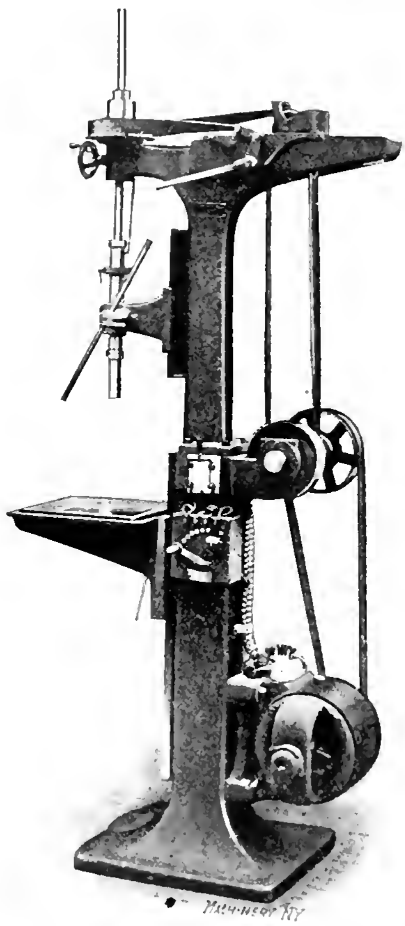
November, 1909, issue of MACHINERY. In this case, also, a self-contained countershaft with a convenient belt-shifter is provided. A two-step cone for each spindle is mounted on the countershaft from which the belt is led over the tightener pulleys to the spindle driving pulley above, permitting the separate spindles to be given speeds appropriate to the diameter of hole drilled. The machine will work to the center of a 10-inch circle. The stop for depth is located in this case on the spindle sleeve.

Fig. 1 illustrates very plainly the usefulness of one of the special features of this make of drills. The work-table can be swung around the column to any point desired, or can be turned, as shown in the case of the central and right-hand heads, to any desired angle about a horizontal axis. The usefulness of this adjustment is increased by the provision of a squared block or gage, which may be adjustably clamped to the table as shown. Reading from the left, in the first case

this is being used simply to locate a block so that the hole will be drilled at the desired distance from the edge. In the second case this gage is used to support a pulley while an oil or set-screw hole is drilled at an angle, the table being tilted for this purpose. In the third case the gage, in conjunction with the surface of the table, provides a V-block for drilling holes into round work. The use of this device makes it unnecessary to rig up temporary holding contrivances out of blocking, bolts, clamps, etc., and greatly increases the range of the machine.

MOTOR-DRIVEN AVEY SENSITIVE DRILL PRESS

A sensitive drill press made by the Cincinnati Pulley Machinery Co., Cincinnati, Ohio, was illustrated and described in the February, 1909, issue of MACHINERY. The machine then illustrated was provided with loose and fast pulleys and was intended to be driven from a countershaft. In the accompanying engraving the same machine is shown provided with individual motor drive, the motor being mounted on a bracket on the lower part of the column and driving the intermediate cone pulley shaft by means of belting. The starting box is placed on the side of the column, as shown. This arrangement is very simple and compact, and makes it possible to apply motor drives to these drill presses when required without making any change in the general design of the machine. The bracket on which the motor is mounted has vertical adjustment on the column so that proper belt tension can be secured at all times. The motor shown in the illustration is a General Electric ½-horse-power motor.

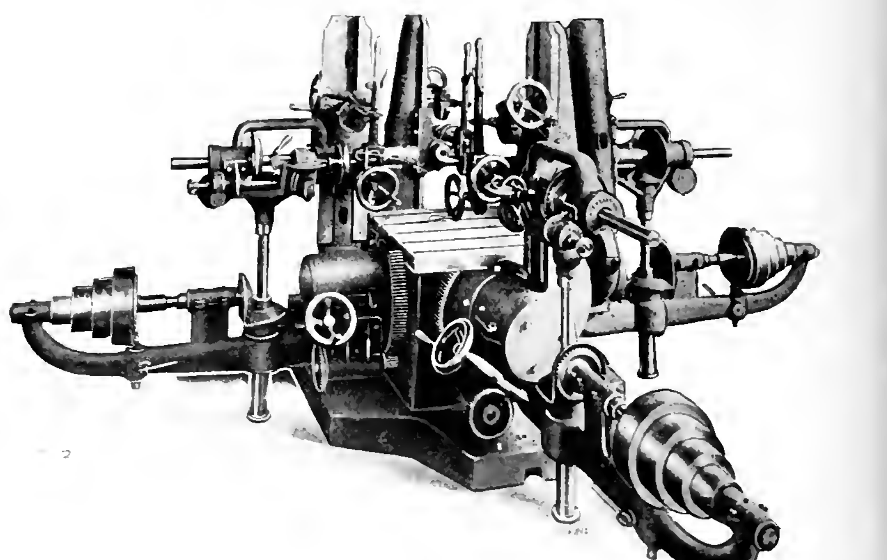


Avey Motor-driven Sensitive Drill Press, built by the Cincinnati Pulley Machinery Co.

It will be recalled from the previous description of this machine that the particular feature of it is the driving arrangement. Of additional features may be mentioned that it runs on ball bearings throughout, and has a graduated spindle sleeve with a stop collet having a clamp screw which requires no wrench or screw-driver; the graduated spindle sleeve makes scale measurements for depth of holes unnecessary. The spindle has a motion of 13½ inches, and a rack feed of 6 inches. The maximum distance of the spindle from the table is 35½ inches. While the drill is shown in the illustration as a single spindle machine, it may be provided with two, three and four spindles on the same base column, if required. The machine has a capacity for using drills provided with a No. 2 Morse taper, the largest diameter of drills with this taper being 29/32 inch.

BARNES HORIZONTAL RADIAL DRILL WITH FOUR HEADS

A horizontal radial drill built by the W. F. & John Barnes Co., 231 Ruby Street, Rockford, Ill., was illustrated and described in the December, 1908, issue of MACHINERY. This type of drilling machine has been found especially valuable for boring jigs, as the horizontal table is much better adapted for holding large irregular castings than is the vertical angle plate. The accompanying illustration shows a special machine of this type recently brought out by the company. This machine is provided with four heads, as shown, one on each side of the table. Each of the heads is of the same design and construction as the head used with the regular No. 3 horizontal radial drill, the special part being the table which has a top 30 inches square. The machine was built especially for boring, tapping, and other operations on a casting containing two different sized holes on each of its four sides. By having four heads working at once, the casting can be strapped to the table and left in this position while the heads which are adjustable both vertically and radially can be set so that the spindles come into proper positions to perform the operations required on the casting. It is readily seen that a large range of work can in this way be taken care of by machines designed with two or more heads mounted on the same table. The manufacturers often furnish the heads only, the customers making their own base or table to suit various requirements. The total weight of the machine shown in the accompanying illustration is 9,000 pounds.



Horizontal Radial Drill, made by the W. F. & John Barnes Co, Rockford, Ill.

As will be recalled from the previous description of the regular machine, the spindle is capable of all the movements and adjustments of a regular radial drill, but it has its spindle horizontal instead of vertical. The only adjustment which is not provided is that corresponding to the raising and lowering of the radial arm which, however, is not required, owing to the fact that the horizontal table allows the work to be clamped in any position relative to the spindle so that in this way the vertical adjustment of the arm in the ordinary radial drill is taken care of. The maximum distance from the table to the centers of the spindles is 29½ inches, the minimum being 2⅜ inches. The spindle which is provided with a No. 5 Morse taper hole has a horizontal travel of 18 inches. The drilling capacity is up to 3-inch holes in cast iron and 2-inch holes in steel, with a tapping capacity of 3-inch regular, and 2½-inch pipe taps.

The increasing tendency to use special machinery for operations which can be more rapidly handled in machines especially adapted for the purpose, will doubtless make machines of this type popular with manufacturers of interchangeable machine parts.

TOLEDO PRESSES OF UNUSUAL SIZES

The accompanying illustrations, Figs. 1 and 2, show two powerful presses of unusual dimensions recently designed and built by the Toledo Machine & Tool Co., Toledo, Ohio. These presses are constructed for cutting and forming the steel bodies and frames for automobiles. The press in Fig. 1 is intended for pressing up or forming the side and cross channels for the lower or under frame. This work has formerly been done on hydraulic presses, but the best results obtainable may be produced by the use of the press illustrated.

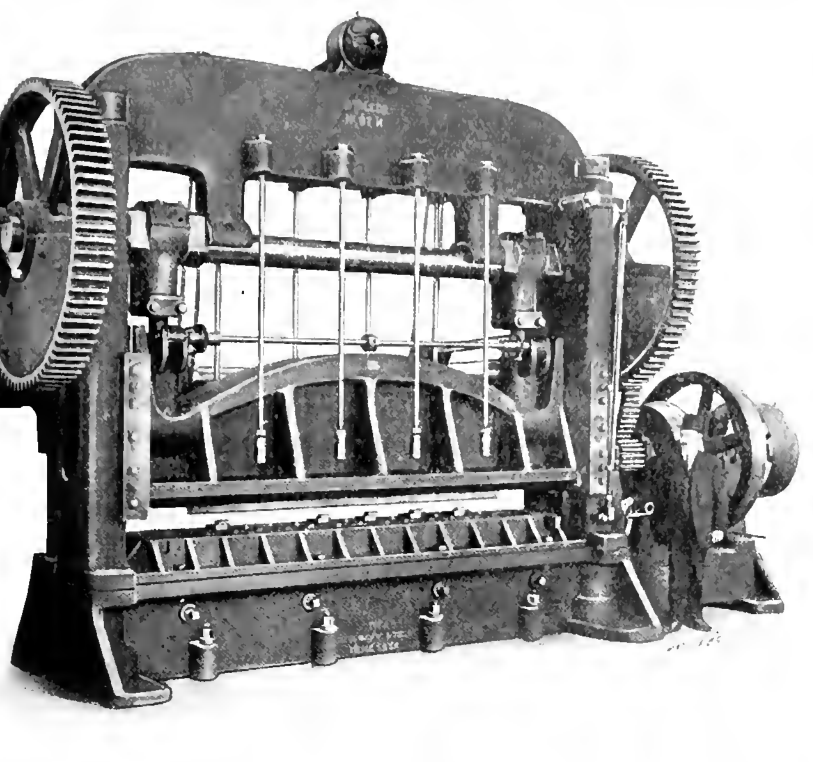


Fig. 1. Large Press for Automobile Frame Work, built by the Toledo Machine & Tool Co., Toledo, O.

In the illustration, the dies are shown in position for performing the work. The lower die is fitted with a pressure attachment, having a capacity for exerting a pressure of about 500 tons. This prevents the distortion of the strip while being formed. The press itself has a capacity or ram pressure of nearly 900 tons. It operates at the rate of eight strokes per minute.

As shown in the illustration, the press is fitted with twin gears on the crankshaft. Engaging with these gears are two pinions on the heavy pinion shaft driven through gearing from the main driving shaft. A powerful friction clutch with hand lever control is provided between the driving pulleys and the gearing, giving the operator complete control of the press stroke at all points. An interesting feature in connection with the press is the motor-driven elevating attachment for adjusting the slide, this being required on account of the size and weight of the sliding parts. This attachment is operated by a four horse-power motor mounted on the top of the frame arch, as shown in the engraving. The power is transmitted down to a rear shaft, by means of sprockets and link belts, and from there is carried over to the worm shafts, on which are mounted worms engaging with worm-wheels on each of the right- and left-hand pitman screws. This arrangement is plainly shown in the engraving. A reversible friction clutch is provided for this attachment, just below the motor, and is attached to the rear of the arch. As the illustration shows a front view of the machine, this clutch is, therefore, not in view. The lever and segment by means of which it is controlled, however, is shown to the right in the illustration, directly beneath the man's hand.

Some of the more important dimensions and weight of the machine are as follows: The stroke or slide motion is 8 inches; the ratio of the gearing is 40 to 1; the size of the main gears is 86 inches diameter by 10 inches face. The width between the housings is 14 feet 4 inches, and the height from the floor line to the top, 15 feet, the bed extending 2 feet below the floor line. The floor space required over all is 9 feet 4 inches by 25 feet 10 inches. The power required for operating the press is 40 horse-power, and the total weight of the press as illustrated is 185,000 pounds.

In Fig. 2 is shown a machine designed for pressing the parts for automobile bodies, including the seats and panels for touring car bodies. An unusual distance from the bed to the slide is consequently provided, in order to accommodate the dies necessary for pressing up large steel backs and seats. A stroke of 24 inches is necessary for this purpose. An additional sub-base or bed is attached to the top of the main bed of the machine. This sub-base is not shown in the illustration. It is 40 inches high, and when in position reduces the height or distance between the bed and the slide to what would ordinarily be required for regular work. The bed-plate or bolster which is used on the main bed of the press will fit on the sub-base also. The same applies to the drawing attachment which is used in connection with the bed for operating the drawing and forming dies necessary for this class of work. These attachments are made removable and may be changed from one bed to the other, in a reasonably short length of time. The machine is provided with clutch arrangement and gearing similar to the press previously described.

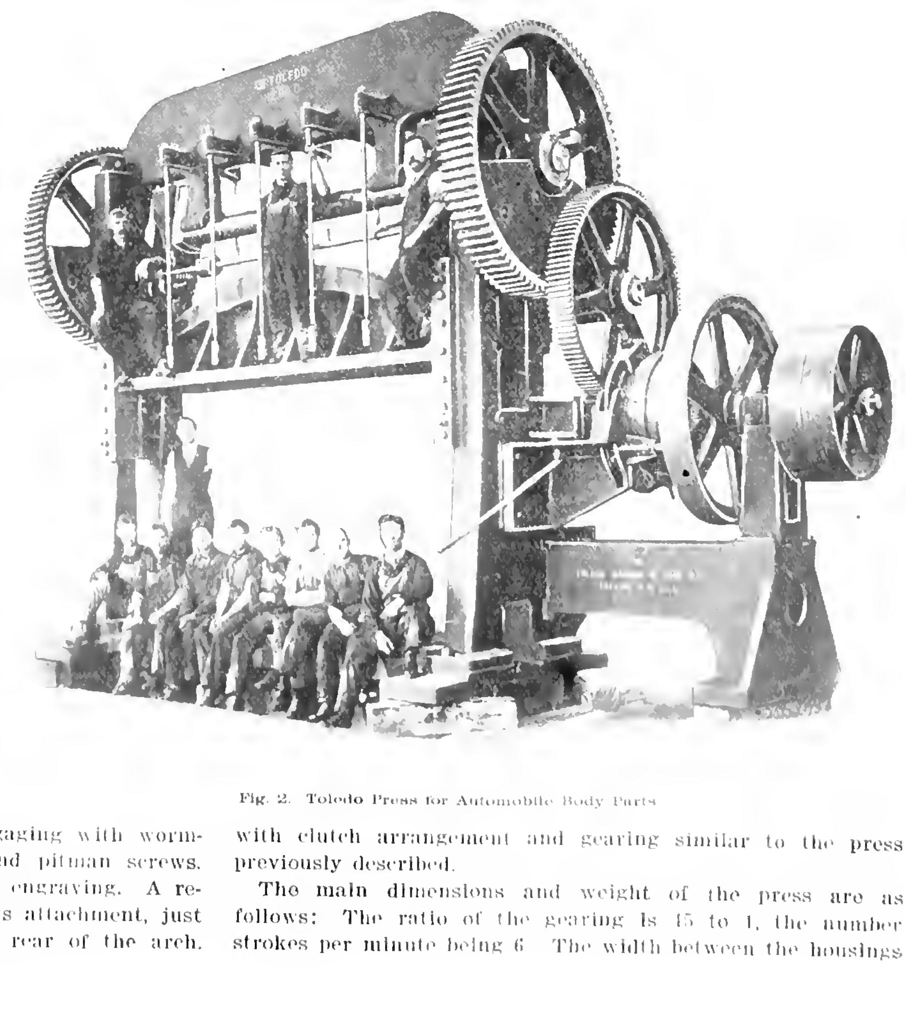

Fig. 2. Toledo Press for Automobile Body Parts

The main dimensions and weight of the press are as follows: The ratio of the gearing is 15 to 1, the number strokes per minute being 6. The width between the housings

is 12 feet 4 inches and the total height above the floor line is 16 feet. The bed extends 40 inches below the floor line. The floor space required is 8 feet 4 inches by 23 feet 4 inches. The total weight of the press is 165,000 pounds.

ROWBOTTOM CAM CUTTING MACHINE

The Rowbottom Machine Co., of Waterville, Conn., is building the cam cutting machine shown herewith. Among other interesting features this machine has the advantage of being universal—that is to say, it will cut plate and face cams, or barrel cams, without requiring the use of attachments or separate heads. It is also provided with unusually convenient adjustments which increase its adaptability for difficult work, as will be explained.

The machine comprises, primarily, a rigid bed on which are mounted a head for the master cam H, a swiveling work-head F for the cam K being cut, and a slide on which is mounted the cutter spindle and its driving mechanism and the adjustable bracket J for the master cam roll. The master cam spindle and the work-spindle are fixed in place in the bed and revolve together with the feed mechanism. The master cam roll and the cutter spindle, being mounted on the same slide, receive motion from the master cam, which thus gives an appropriate form to the cut taken in the work. The weight D connected to the slide holds the follower roll against the master cam.

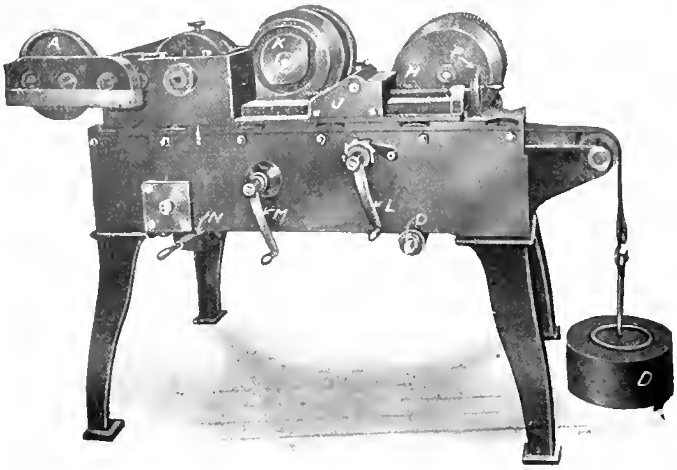

Fig. 1. The Rowbottom Universal Cam Cutting Machine

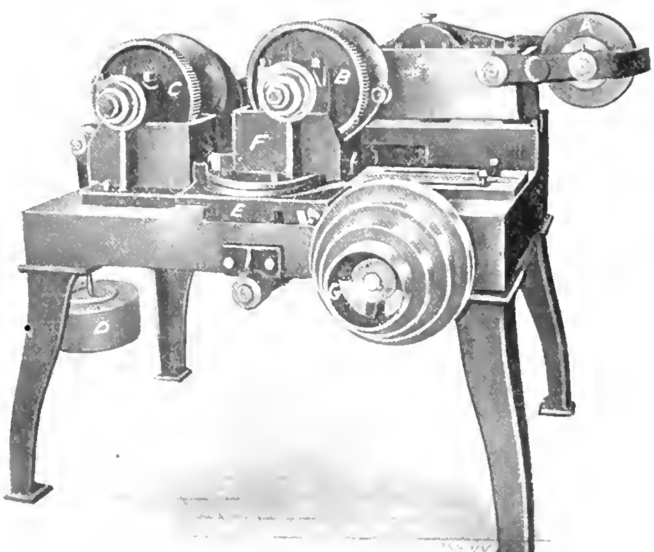

Fig. 2. Driving Side of Machine, showing Adjustment of Follow Roll Bracket on Cutter Slide

The spindle is driven by pulley A, which is mounted on a pivoted yoke. The pulley and the gearing contained in this yoke are heavy enough so as to keep the driving belt tightened to the proper degree throughout the movement of the slide, under the influence of the master cam. The gear-box, which is shown with cover removed, provides two changes of speed. This with the two on the double driving pulley A, gives four in all. All the gearing in the gear-box runs in an oil bath.

The rotation of the master cam and work-spindles is effected through cone pulley G, which is connected by gearing with

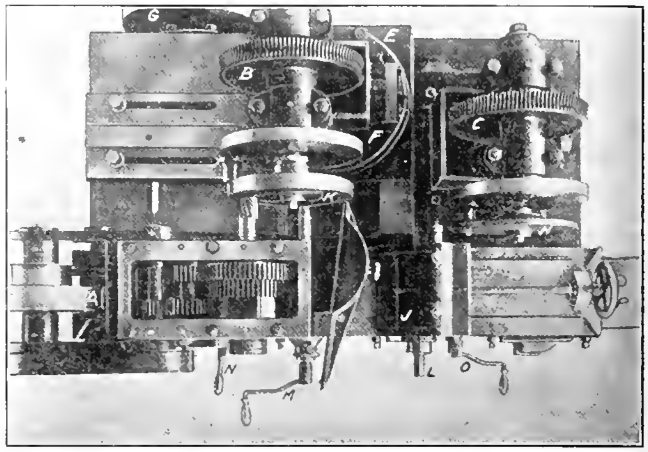

Fig. 3. Machine set up for Cutting Face and Plate Cams

worms meshing with worm-wheels B and C. Lever N controls this automatic feed, throwing it in or out. When it is thrown out, it may be operated by hand by placing the crank on feed shaft O. The handle on M operates the cross-slide screw by means of which the work-slide E, carrying the swivel work-head F, is fed in toward the cutter to give the required depth of cut. This adjustment is provided with a micrometer dial. By placing a crank on shaft L the slide carrying the former roll and the cutter spindle can be rapidly

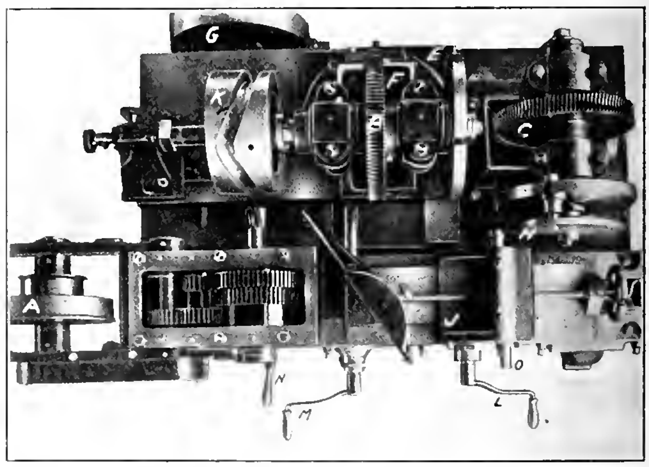

Fig. 4. Machine set up for Cutting Barrel Cams

drawn back against the tension of weight D for the purpose of inspection, removal of work, etc.; this movement is effected by a pinion on the shaft engaging the rack on the under side of the cutter slide. The ratchet shown on shaft L serves to support the slide in this position against the pressure of the weight. This ratchet has, of course, to be raised to allow the former roll to come back to its bearing on the cam. When ready to start, the pawl is thrown back from the ratchet, allowing the weight to be brought back into contact with the former roll and the periphery of the cam.

The particular construction of the machine, as described, offers certain advantages which are best seen from an inspection of Figs. 3 and 4. The master cam is always of the plate variety. This means that it is made in the least expensive way and in the way which permits the greatest accuracy. It is only the work-head F which is altered to permit the cutting of plate, face and barrel cams as may be required. This change from face to barrel cams, as has been explained, is done without the use of attachments of any kind, it being only necessary to swivel the head around at right angles. It is shown in the two positions in Figs. 3 and 4. This construction also fits the machine for cams cut on conical surfaces—a construction met with once in a great while. For

this work the head is simply swiveled to the angle required by the cone on which the cam is to be cut.

Another exceedingly useful adjustment is that of the former roll bracket *J* along the cutter-slide. This is controlled by a screw operated by handwheel *P*. It serves two purposes: For one thing, it may be used in connection with the quick traverse shaft *L* to adjust the forming roll and cutter to such a distance apart that the latter will center with a roughly cast groove in a barrel cam. By rapidly turning shaft *O* by hand, it can be found whether or not the cutter is centered with the rough cast groove, and if any adjustment is required, this is easily effected by handwheel *P*. Another advantage of this adjustment is that it permits the cutting of cams of very steep pitch. The master-plate made for the contour is cut on a much larger diameter than that desired for the finished work. This larger diameter will give easier rises, permitting the cutter-slide to be moved back against the weight with a smoothness and precision impossible where the pitch is too steep. Graduations are provided for the movement of bracket *J* on the slide, which show how much wider the distance between the cutter-slide and the roll is than the distance between the two spindles as set up in Fig. 3. When the master cam is made to a radius larger by a given amount than that desired for the finished cam, the setting of bracket *J* to this dimension on the cutter-slide brings the work to the desired diameter.

Fig. 5. Cams Cut on the Rowbottom Machine

The machine, as may be seen, is very rigidly constructed. For large work, slide *E* may be locked to the base after each feeding in to depth, so that heavy cuts can be taken. It will be seen that the machine is universal in its adaptability within the limits of size for which it is designed. In Fig. 5 is shown a variety of examples of its work.

IMPROVEMENTS IN CINCINNATI LATHE

The Cincinnati 16-inch engine lathe, built by the Cincinnati Lathe & Tool Co., Cincinnati, O., was illustrated and described in the September, 1908, issue of MACHINERY. Several improvements have now been introduced on this type of lathe, including a double-walled apron, as illustrated in Figs. 1 and 2, and a new arrangement of carriage and taper attachment, illustrated in Fig. 3.

The apron is of the box type, which gives a double and an especially rigid support to all shafts and studs mounted in it, and provides for accuracy as well as long life of all the working parts in the apron. The gears are of ten diametral pitch, thus having ample strength. The motion to the rack pinion is transmitted by compound gearing, as indicated in Fig. 2. The longitudinal and the cross friction feeds can be started, stopped or reversed while the lathe is running, but they cannot be engaged when cutting screws; this latter provision is an important safeguard when the machine is in the hands of inexperienced operators. The handwheel is provided with a thread chasing dial which permits the half-nuts to be opened, the carriage to be run back by hand, and the thread to be caught or picked up at any point. An automatic stop is also provided for throwing out the feeds.

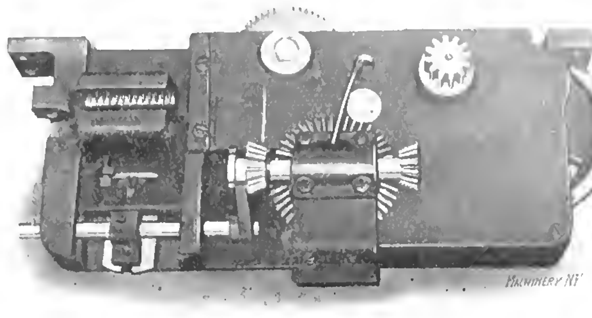

Fig. 1 Rear View of Apron of Cincinnati Lathe & Tool Co.'s 16-inch Engine Lathe

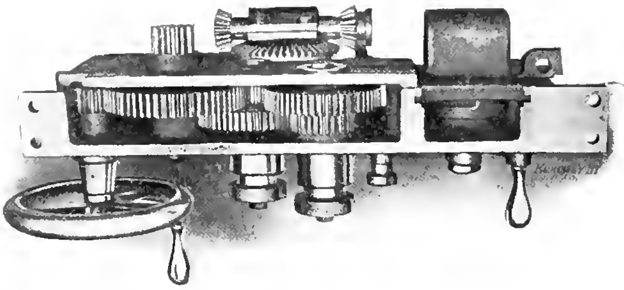

Fig. 2. View from the Top of the Apron of Lathe, showing Arrangement of Gearing

The taper attachment shown in Fig. 3 is provided with graduations at both ends, and can be firmly clamped in any position desired within its range by two heavy clamping bolts, one at each end. The carriage is gibbed both in the front and at the back and bears for its entire length of 22 inches on the V's of the bed. Both plain and compound rests are provided. Due to the heavy construction of the machine in general, as well as to the correct proportioning of the carriage details, very accurate work can be carried out on the machine. As an example, it may be mentioned that it is possible to bore holes on these lathes within 0.00025-inch in 8 inches of feed. As regards the cutting capacity of the lathe, it may be mentioned that it is used regularly in the shops of the makers for reducing 50-point carbon steel shafts as much as 7/8 inch in diameter with a feed of 1/32 inch per revolution, at a cutting speed of 60 feet per minute.

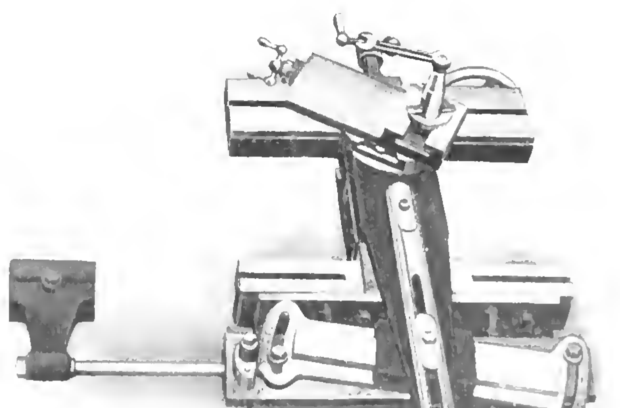

Fig. 3 Carriage Swivel Rest and Taper Attachment

It will be recalled from the previous description of this machine that it is furnished with a quick change gear-box either for screw-cutting or for feed changes. It may also be furnished either with a 3-step cone pulley and double

back-gears or with a 5-step cone pulley and single back-gears. With a two-speed countershaft this provides for eighteen or twenty changes of speed, covering a carefully selected range.

FIFIELD HEAVY ENGINE LATHE

The accompanying illustrations show an example of a new line of heavy engine lathes made by George W. Fifield, of Lowell, Mass. The lathes of this design range from 40 to 96 inches swing over the ways. They are of modern construction and are intended for heavy and accurate work and rapid production.

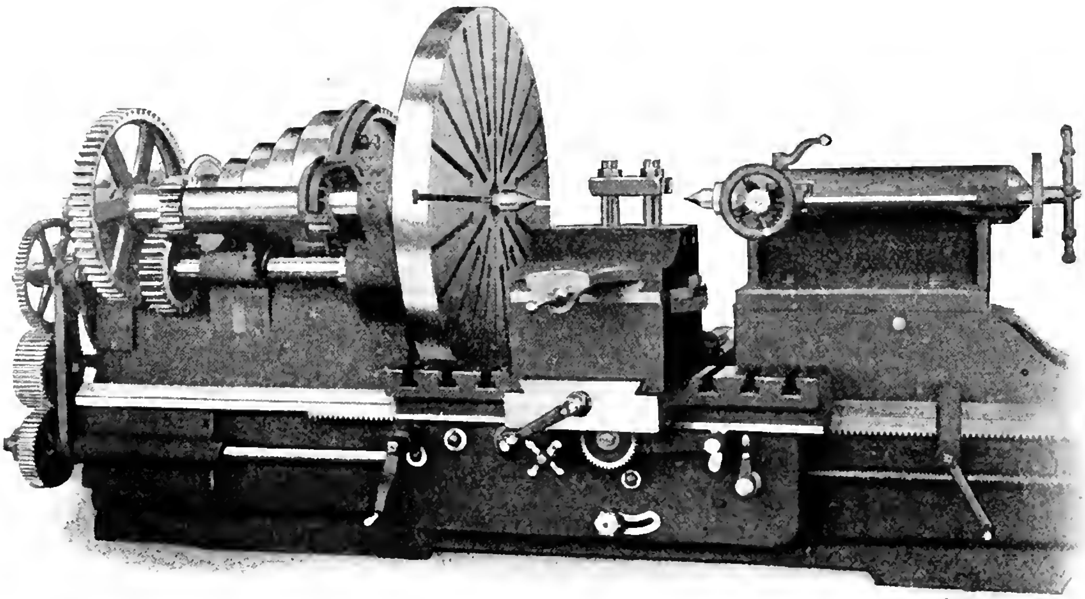

Fig. 1. An Example of a New Line of Heavy Engine Lathes

The illustrations show the general features of the design very plainly. The headstock is of the triple geared type with the "back-gearing" mounted on the front to facilitate operation. Power may be applied either directly from the cone pulley to the shaft, through back-gears in the usual manner, or through the lower or "triple gear" shaft, which carries a pinion meshing with the internal gear on the back of the faceplate. To connect with this faceplate drive, the lower shaft is thrown to the right by turning with a wrench the square-headed stud shown projecting from the left-hand bearing. This stud has pinion teeth cut in it meshing with grooves in the shaft which act as rack teeth. When the shaft is moved toward the right, the pinion on its outer end is thrown into mesh with the internal gear teeth, and the gear at the other end is moved into mesh with the middle pinion on the back-gear quill. When so set, the right hand pinion on the back-gear quill must, of course, be moved out of engagement with the spindle gear.

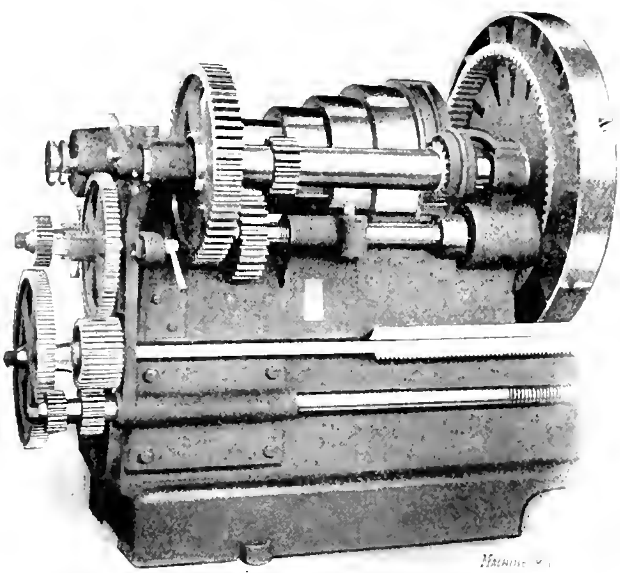

Fig. 2. Driving and Feed Gearing of Fifield Lathe

The connections at the end of the headstock provide for three changes of feed without a change of gearing. On the gear stud beneath the spindle in back of the first of the regular threading change gears, is mounted a cone of three gears. On a sector swinging about the splined lead-screw is mounted a large spur gear, adjustable to three positions longitudinally to correspond with the positions of the three members of the cone gears on the stud; a wide-face idler gear between it and the pinion on the lead-screw makes provision for this change of position. The sector is, of course, thrown in or out and clamped into position to agree with the diameter of the gear which is engaged at the time. The connections for thread cutting are made in the usual way.

The feed is reversed in the carriage. The top of the carriage is provided with a series of T-slots to hold special rests, and to clamp work for boring-bar and similar occasional operations. The tool-rest is of the four-stud type, this being most suitable for heavy work. A compound rest is furnished, and the power feed may be applied to both the cross-slide and the compound rest movements.

The 40-inch lathe is driven by a 4½-inch belt on a 5-step cone pulley whose largest diameter is 20 inches. The back-gearing is in the ratio of 1 to 13, while the triple gearing is in the ratio of 1 to 42. The weight is about 12,000 pounds. For the 96-inch swing lathe, the largest of the line, a 6-inch belt is used, running onto a 6-step cone pulley, whose largest diameter is 40 inches. The gearing ratios are, respectively, 1 to 32 and 1 to 250. This tool weighs approximately 70,000 pounds. All lathes are furnished with large faceplates, center-rests, change gears, wrenches and friction countershaft.

BAIRD WIRE-FORMING AND STAMPING MACHINE

The Baird Machine Co., of Oakville, Conn., makes the wire forming and stamping machine herewith illustrated. While this was intended originally for work such as shown in Fig. 2 (suspender loops, buckles and similar parts), the builders have found a wide range of use for it in general work. It is applicable wherever wire parts have to be bent and flattened out or stamped. The machine is essentially a combination of the standard wire-forming machine and a small punch press, the latter part of the mechanism being shown at the left-hand side of the bed.

The machine automatically takes wire from the coil, straightens, feeds and cuts it off, and then forms and stamps it. Work of the character described is made, complete, and dropped into a suitable receptacle at the rate of from 60 to

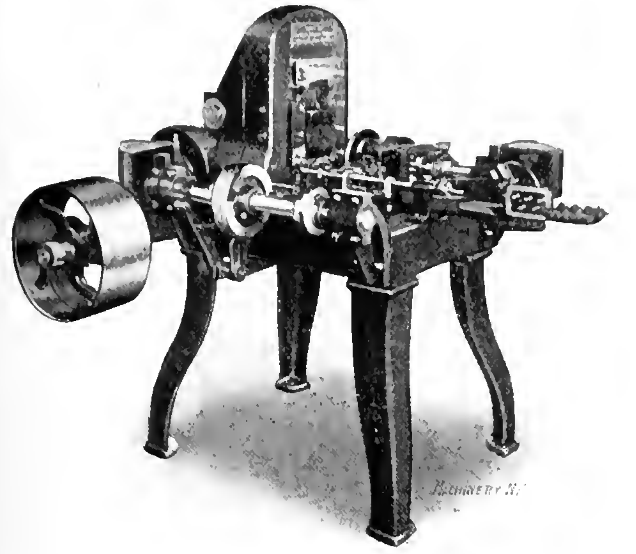

Fig. 1. An Automatic Machine for Bending and Stamping Work made from Wire

80 per minute according to the size and shape. No further attention is required than that of removing the finished work and keeping a supply of wire on hand.

High-grade materials and workmanship are used in the construction. All the bearing surfaces, such as cam linings, pins, etc., are of hardened tool steel. The sliding surfaces are

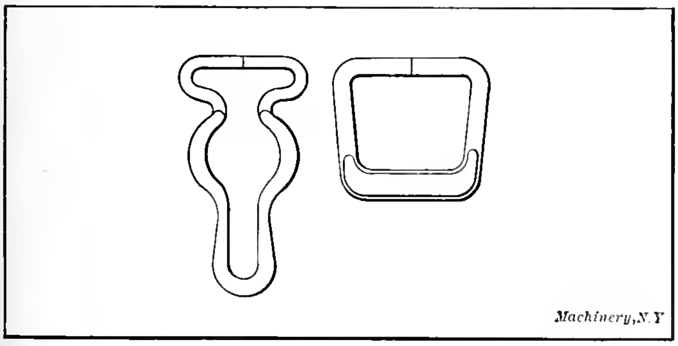

Fig. 2. Examples of Work Done on Machine shown in Fig. 1

hand-scraped to a bearing. The machine is regularly built in two sizes, the smaller of which is designed for articles which do not require more than 6 inches of wire with a maximum diameter of 0.125 inch. The larger size will make use of wire up to 9 inches long and 0.200 inch diameter.

LEIMAN ROTARY BLOWER AND VACUUM PUMP

A new design of rotary blower which is also intended to be used as a vacuum pump, has been brought out by Leiman Brothers, 62 John Street, New York. A diagrammatical view of the design of the device is shown in the line engraving, Fig. 1. In Fig. 2 the blower is shown driven by an electric motor and used as a vacuum pump; it has exhausted the air from a No. 20 gage galvanized iron tank, braced on the inside, which has collapsed on account of the vacuum produced.

As will be seen from Fig. 1, the design of the machine is very simple; the working parts consist only of a central drum or piston, and four wings attached to it by means of hinges. As soon as the machine is in motion, the outer end of these wings will come into contact with the cylinder walls, due in the first place to centrifugal action; but when the machine is in operation, the air that becomes compressed between the wings also tends to keep them in close contact with the cylinder walls, thus preventing leakage. This is one of the principal advantages of the machine, as there is no packing required, and the wings automatically, so to speak, take up their own wear. When each wing reaches the top where the air is exhausted it is kept close to the inner cylinder wall, so as to insure but a small amount of clearance, as an excessive amount of space here would impair the efficiency of the pump. At the top, the wing still presses against the cylinder wall, the bearing point gradually shifting toward the wing center. Obviously, when considerable wear has taken place on the wings as well as on the cylinder surface, the wings will still conform to the shape of the cylinder, and the efficiency of the device, even when worn, is practically unimpaired. The absence of springs and delicate parts which may break or get out of order, and also of special tips on the ends of the wings which would require frequent renewal, reduces the cost of maintenance to a great extent.

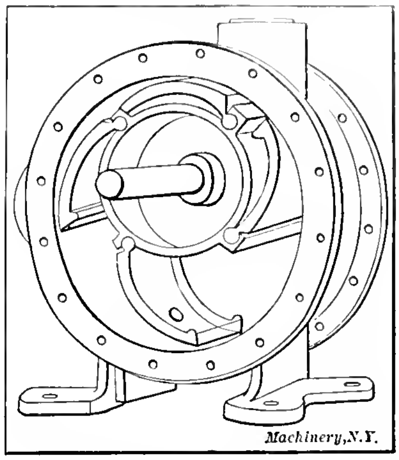

Fig. 1. Diagrammatical View, showing Design of Leiman Blower and Vacuum Pump

The main shaft bearings are provided with a double ring oiling device. The cylinder is oiled by means of the oil hole at the inlet on the side, but the use of a sight-feed oil cup is recommended. Each blower is supplied with loose and tight pulleys, and can be driven either from an individual motor or from a line-shaft. When the machine is used as a blower, it will produce a maximum pressure of 10 pounds per square inch, but if it is in constant operation it is not advisable to run it at higher speed than to produce a pressure of 6 pounds per square inch. It is made in seven sizes known by the letters A, B, C, D, E, F and G. When used as blowers, the capacity of the various sizes varies from 17 cubic inches of air delivered per revolution for the smallest size, up

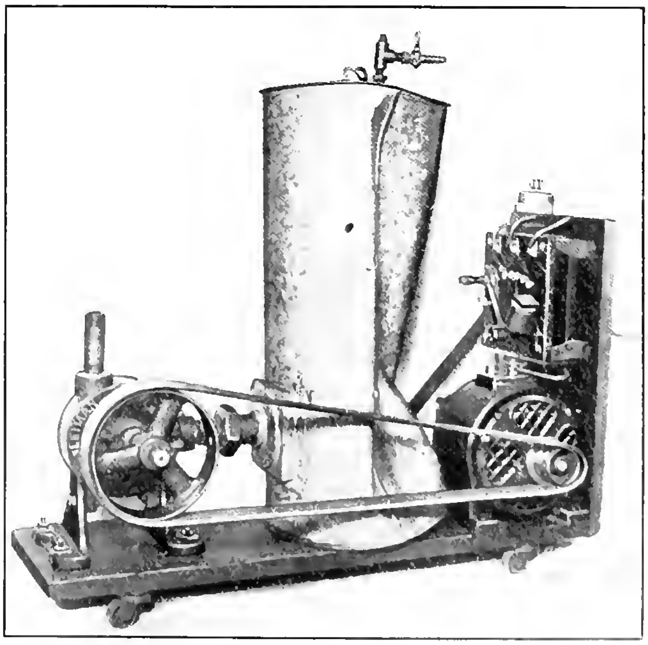

Fig. 2. Leiman Motor-driven Rotary Blower, having exhausted the air of an Internally-braced Tank, causing it to collapse

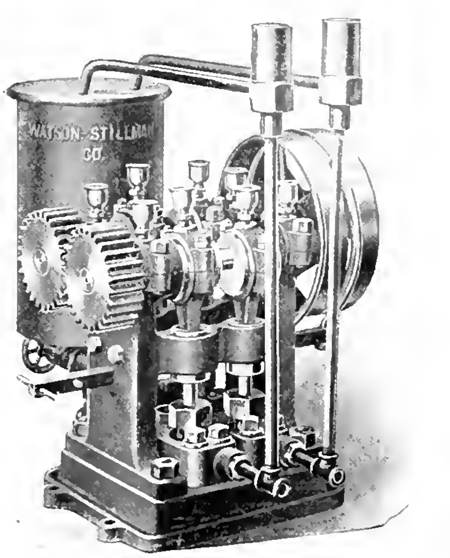
to 1,400 cubic inches for the largest size; the approximate horse-power for the smallest size is 1/10, and that for the largest size 2½. The maximum revolutions per minute vary from 600 on the smallest size to 200 on the largest, and the sizes of inlet and outlet from ½ to 2½ inches.

When used as a vacuum pump, the maximum vacuum is 20 inches, and the displacement per revolution corresponds to the air delivered per revolution by the machine when used as a blower. The approximate horse-power required for the vacuum pumps is the same as that for the blowers. The floor space of the smallest machine is 6 x 10 inches, and that of the largest 24 x 31 inches, the weight of the smallest being

only 20 pounds, while the weight of the largest size is 400 pounds. The vacuum pump is especially intended for all uses where a vacuum of 20 inches is sufficient for the required purpose, as, for example, in vacuum cleaners.

WATSON-STILLMAN SMALL HYDRAULIC PUMP

The accompanying illustration shows a four-cylinder hydraulic pump brought out by the Watson-Stillman Co., 192 Fulton St., New York. In the arrangement shown, two pressure lines are served independently of each other, from a common reservoir; but the type of pump illustrated permits of two, three or four pressure lines being independently served. Each pressure line has a separate pressure chamber, safety valve, and release line, and is served by a separate pair of cylinders with eccentrics set so as to produce a continuous flow. The diameter of the cylinders is ½ inch, by ½ inch stroke. Any pressure up to 600 pounds per square inch may be delivered into any line, the limit being determined by the setting of the safety valve which opens at excessive pressures and lets the surplus liquid through the release pipe to the reservoir. Any pressure line may be thrown out of service by opening the safety valve, in which case all the liquid will be pumped directly back into the reservoir. The design of the one, two, three and four pressure line pumps is practically the same, except, of course, that the bed-plate and the through shafts are longer. The pump may be provided with an electric motor instead of the fast and loose pulleys for belt drive shown in the illustration.



Four-cylinder, Two-pressure Line Small Hydraulic Pump, made by the Watson-Stillman Co. New York

STEEL SHELVING AND STORAGE EQUIPMENT FOR SHOP USE

The advantages of steel shelving in stock-rooms and store-rooms in machine shops are becoming more and more recognized. One of the most important advantages is the saving in space, as steel shelving requires to be but a fractional part of the thickness of wooden shelving to have an equivalent strength. It also reduces the fire hazard, is easier to keep clean, and the cost of maintenance is reduced to a very considerable extent. It is also possible to provide for interchangeability between the different racks and shelving systems in a way that is not possible when wooden shelving is used, and, in addition, it is easier to provide for adjustability as regards the height of the various shelves.

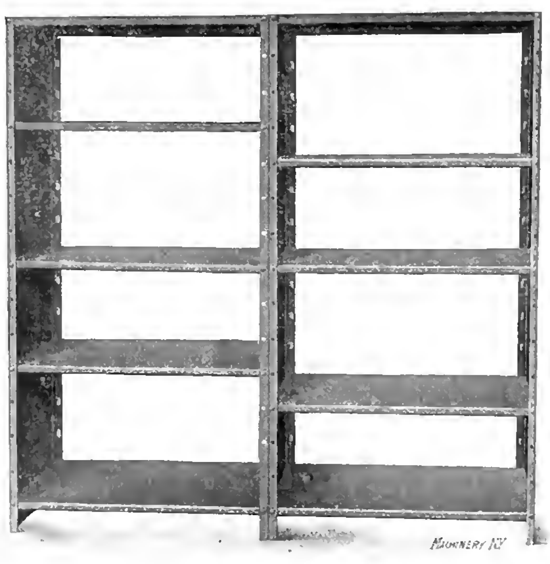


Fig. 1 Two Sections of Terrell's Steel Shelving for Shop Storage

Fig. 2. Rack especially adapted for Die and Tool Storage

The Terrell's Equipment Co., of Grand Rapids, Mich., has placed on the market a stock-room rack, bin rack and racks for die and tool storage, as well as a number of portable tool racks, trays and boxes provided with roller casters and with one or more shelves. In Fig. 1 are illustrated two sections of the regular stock-room rack. The end uprights are made of No. 20 gage steel, riveted to two strips of 1 by 1 by ⅛-inch reinforcing angles. In the front, the uprights are provided with holes for ¼-inch bolts, the vertical distances between the holes being 3¾ inches from center to center. In the back of the uprights, the angles are provided with catches stamped in them and located opposite the holes in the front. By this means rapid adjustment of the shelving is made possible, the space between the various shelves being adjustable to suit the tools stored upon them. This is clearly indicated in Fig. 1. The standard sizes of the uprights for this type of shelving are from 12 to 30 inches wide and from 3 to 15 feet high.

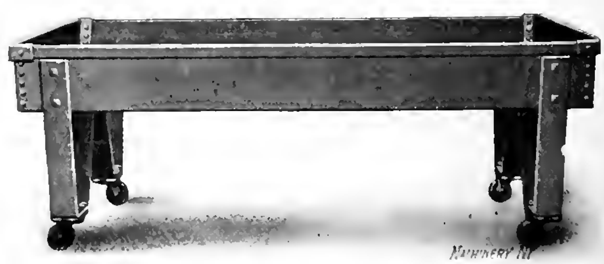

Fig 3 Box for Material in Process of Manufacture, Tools and Finished Stock

Storage shelving for dies, tools, etc., is usually provided with a back as shown in Fig. 2. The backs are made of No. 18 gage steel and catches are stamped in the backs corresponding with the holes and catches in the uprights. This construction insures a close contact between the shelves and the back so that no material can fall down between. The shelves are made from 24 inches to 40 inches long, the width, of course, corresponding to that of the uprights. They are flanged on the sides and ends, and the front and back edges are double folded to provide for the required strength. In addition to this, the front edge is reinforced with a strip of ¾ by ¾ by ⅛ inch angle which is placed inside the fold.

In Fig. 4 is shown a portable tool rack which is made with or without the drawer shown. The corner posts of this tool rack are made of 1¼ by 1¼ by ⅛ inch angles. The trays are made of No. 16 gage steel, double folded at the top edges, and attached to the corner post with set-screws so that the whole arrangement can be easily taken apart and assembled, and thus be shipped "knocked down." The drawer is made of No. 18

gage steel and is attached to the bottom of the top tray by a steel slide, permitting the drawer to slide easily.

In Fig. 3 is shown a steel box placed on casters, which is made in a large variety of sizes and intended for stock-room, tool-room and shop use for raw material being in process of manufacture as well as for finished stock. The tray or box is made of different gages of steel according to the size. The sides and ends are triple folded and the corners provided with additional reinforcement.

CLEVELAND DRILL CHUCK

The drill chuck shown in the accompanying engraving has been placed on the market by the Cleveland Collet & Machine Co., Cleveland, Ohio. It is designed for holding a drill to the limit of its torsional strength, yet it is easily released by hand. No wrench is necessary as the resistance of the cut is utilized for increasing the grip on the drill, while, when the pressure is relieved, the jaws open easily by turning the chuck body by hand. The chuck consists of a shank part threaded into the knurled chuck body, to the end of which latter a tapered sleeve ring is attached. Three jaws slide with their back faces against the inside of the sleeve ring. The jaw holder rotates independently of the body only when a drill is not locked between the jaws; but when the drill is in place, it is locked in the jaw holder and the jaw holder in the sleeve by screwing up the chuck body on the shank, thereby producing the required pressure on the back of the jaws by means of the tapered surface in the sleeve ring. A ball thrust bearing is provided for taking the axial thrust, and in this manner the thrust on the thread on the shank is minimized. Another valuable feature of this ball bearing is that it prevents the drill and jaws from becoming so tightly gripped that it would not be possible to release the grip by the hand alone. The construction of the tool is simple, and as there are but few working parts, it is not likely to get out of order. This is an important consideration, as the time lost in repairs is often considerable when tools are unnecessarily complicated.

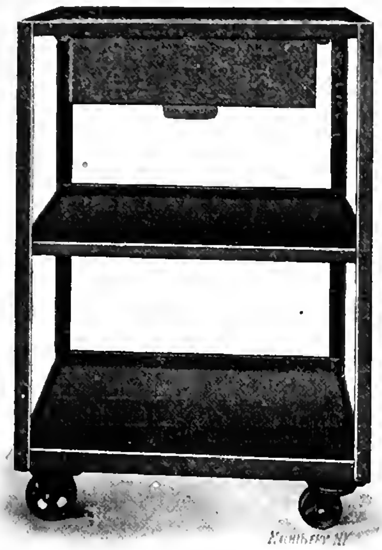

Fig. 4. Portable Tool and Storage Rack for the Shop

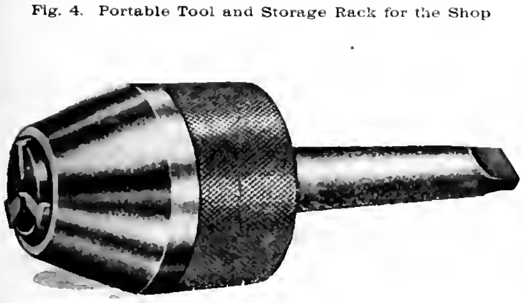

Drill Chuck made by the Cleveland Collet and Machine Co.

BLISS POWER PRESS FOR HEAVY COLD STAMPING

The straight-sided single-action press shown herewith was recently built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., for the Hydraulic Pressed Steel Co., of Cleveland, O. As indicated by the firm name of the customer, this tool was designed to replace the hydraulic machine on work of a character which has not hitherto been done by a crank machine. Its advantage, of course, lies in doing the work much more rapidly than is possible with hydraulic motive power, and more accurately as well, since the dies are bedded in long slides, gibbed with great care.

This press is of the makers built-up type, in which four vertical tie-rods of large diameter are depended on to receive the tensile stress imposed while the press is in operation, thus relieving the frame columns of all stress of this character. The columns are of heavy cross-section, giving great rigidity to the machine. Heavy extended feet are provided, so that ample stability is insured.

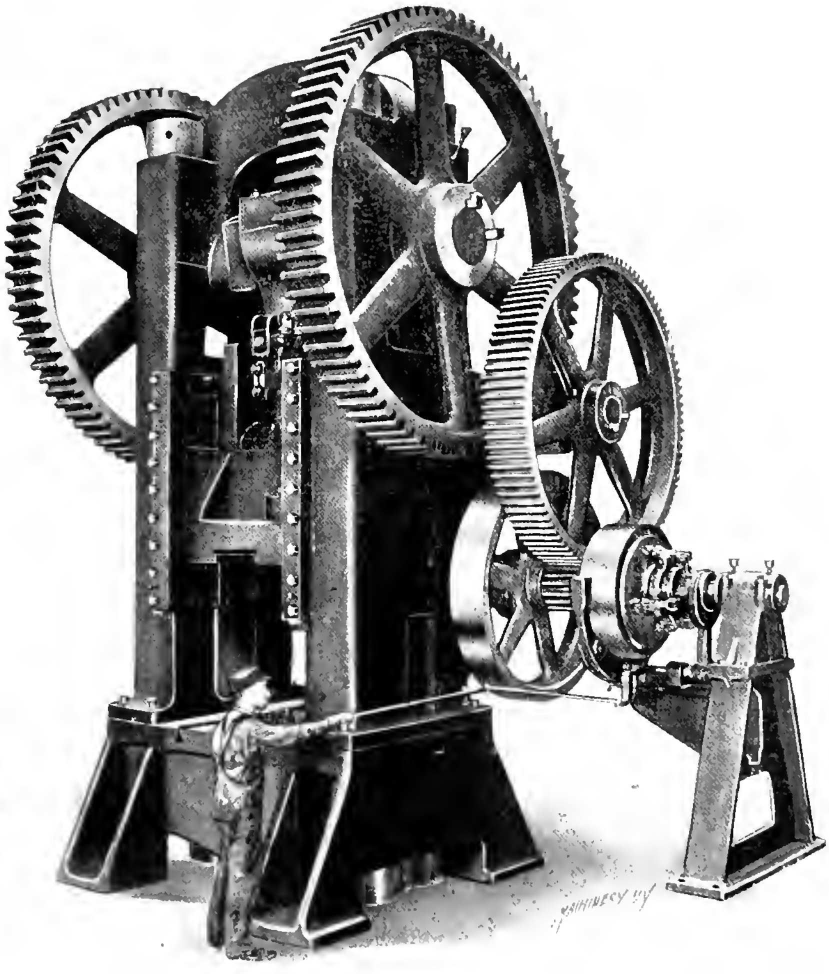

Fig 1. A Crank Press designed for Work formerly done on the Hydraulic Press

Some idea of the massiveness of the construction may be obtained from Fig. 3, which shows the slide, weighing over seven tons. Fig. 2 shows the crankshaft with its two main gears, one at each end. These weigh over 6 tons apiece. The double drive reduces the bending and torsional strain on the crankshaft. The driving gearing throughout is of steel, compactly arranged, and with machine cut teeth. The machine is controlled by a hand-lever, operating a combined friction clutch and brake. The clutch is of improved type with heavy rigid friction surfaces, arranged to be relieved of rubbing contact when not driving. A safety coupling attached to the fly-wheel permits it to free itself in case the press is subjected, through accident or carelessness, to a pressure greatly in excess to that for which it is intended.

The bed of this machine has an area of 60 by 48 inches. The crankshaft is 16 inches in diameter. The total weight is 161,000 pounds. It is believed to be the largest machine of its type ever built. Large double crank presses and drawing presses are not unusual, but this tool is designed to enter a

new field for the power press, in the cold forming of sheet metal of extra heavy gages. It is particularly adapted to such work as stamping sheet steel brake drums, axle housings, etc., for automobiles. On such work it gives more accurate results and a much higher production than the hydraulic press can attain.

BEAMAN & SMITH NO. 10 BORING AND MILLING MACHINE

The tool herewith illustrated and described is made by the Beaman & Smith Co., of Providence, R. I. It is of the type which has come into such extensive and well-deserved popularity in the past decade, in which the work is mounted on a table provided with longitudinal and cross movements, while the spindle is mounted in a saddle which may be adjusted

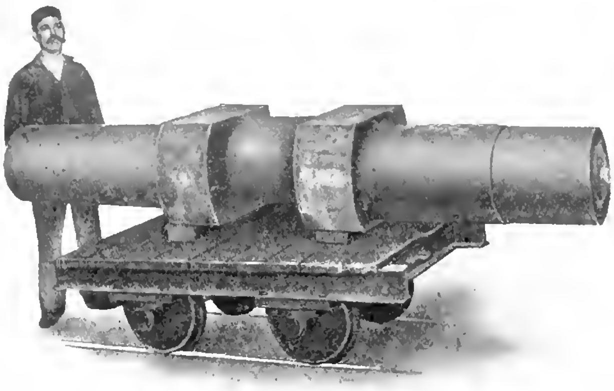

Fig. 2. A Crankshaft 15 inches in Diameter

or fed vertically on the face of an upright column. This arrangement supports the work and the boring-bar under the most favorable conditions for a wide range of operations.

A distinctive point in the design will be seen at once from an inspection of the engraving. This relates to the form of all the main castings of the machine. A tubular section has been used throughout, this being applied to the bed, the column, the outboard bearing and the feed bracket for the boring-bar. It is not necessary to expatiate on the stiffness of this form of section in resisting torsional strains or bending strains. It would seem to be especially suited for machine members of this kind, and its use gives the whole machine a distinctive and pleasing appearance, which is even more evident in the machine itself than in the photograph which we have reproduced.

The feed and speed changes are obtained by gearing from a constant speed pulley. There are 18 changes of speed, obtained through the gear-box shown at the extreme right of the engraving, in conjunction with the back-gear handle shown projecting through an opening in the gear guard at the top of the saddle. The changes range from 4.34 to 125 revolutions per minute, giving suitable speeds for the drilling of small holes and for large facing or heavy milling operations as well. Ample power is provided by the 5-inch belt drive on the 14-inch pulley, running at 230 revolutions per minute. The gearing ratios vary from 1 to 1.8 for the fastest speed, up to 1 to 52.5 turns of the pulley to one of the spindle for the slowest speed given above. The spindle has a No. 5 Morse taper hole with a driving slot across the end.

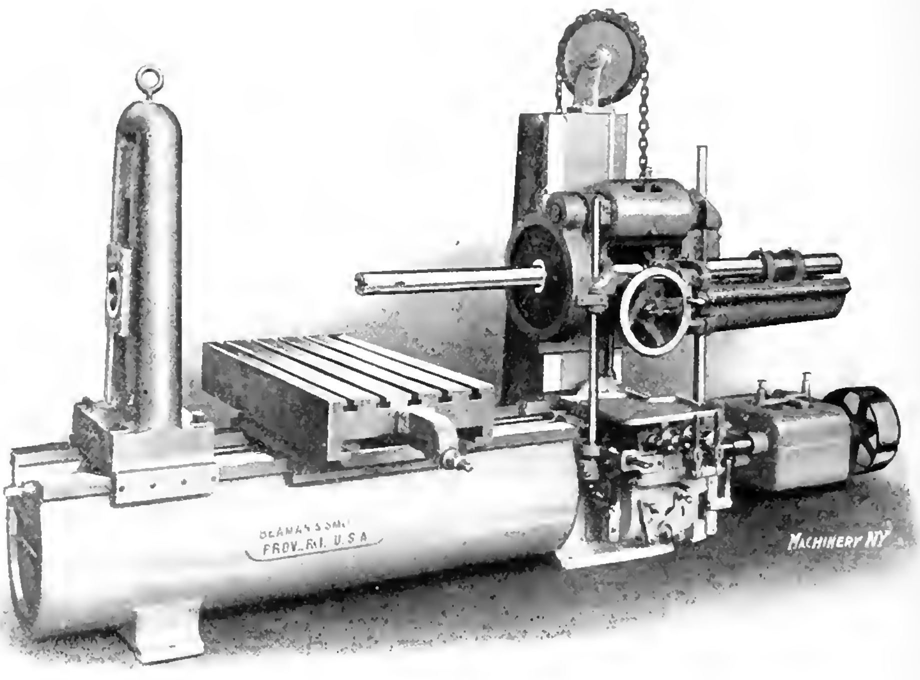

Fig. 1. Beaman & Smith Horizontal Boring and Milling Machine

The boring-bar has a continuous traverse of 30 inches and a maximum traverse of 60 inches by shifting its position. Eight feeds are provided, operated by the quick change gear mechanism shown at the foot of the column. These range from 0.009 to 0.252 inch per revolution of the spindle for drilling and boring. For milling, the speeds range from 0.56

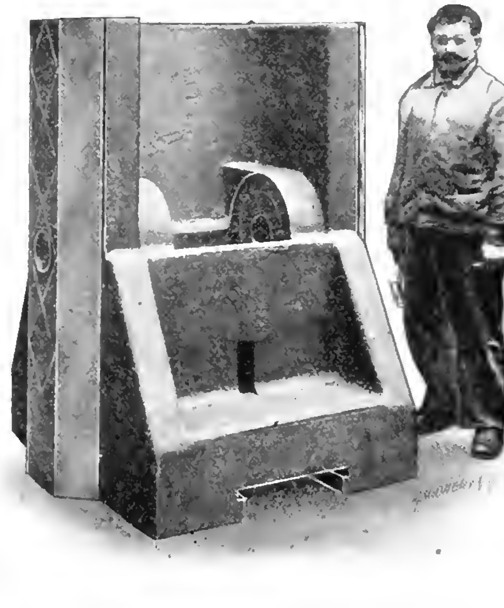

Fig. 3. A Massive Slide, weighing over Seven Tons

to 15.7 inches per minute at any spindle speed. It will be seen from this that the feed is connected with the constant speed driving shaft when milling, and with the spindle when drilling and boring, so that the arrangement of the feeds is exactly suited to each of these two operations. This construction is, so far as we know, a new one in machine tool design, machines having hitherto been constructed so that one of the two connections was made, but not so that both of them were available. For milling, the feeds are applicable to the cross-feed of the table as well as to the vertical feed of the saddle on the column. Power rapid traverse is also provided for these movements.

The outer support has a bushing hole 4½ inches in diameter, and is connected in unison with the head saddle so that the two are always in line, whether the adjustments are made by hand or power. The bushing block is carried between uprights, instead of on the side, so that the maximum of rigidity

is provided. Longitudinal adjustment on the bed is effected by a screw.

The general construction of the machine is of the highest grade. The sliding surfaces are accurately scraped. The adjusting screws are of generous dimensions. All gearing is cut from the solid, the bevel gears being generated by the Bilgram process. Bearings are bronze lined, wherever necessary. Spindles and shafts are accurately ground to size. As to the capacity of the machine, the least distance from the center of the spindle to the top of the table is 3 inches, and the greatest 25 inches; the vertical adjustment is 22 inches. From the spindle driving gear, which is 18 inches in diameter, to the outer support, the shortest distance is 27 inches and the greatest 5 feet 6 inches. The 24- by 48-inch table has a cross feed of 36 inches and a longitudinal movement on the bed of 40 inches. The weight of the machine is approximately 11,000 pounds.

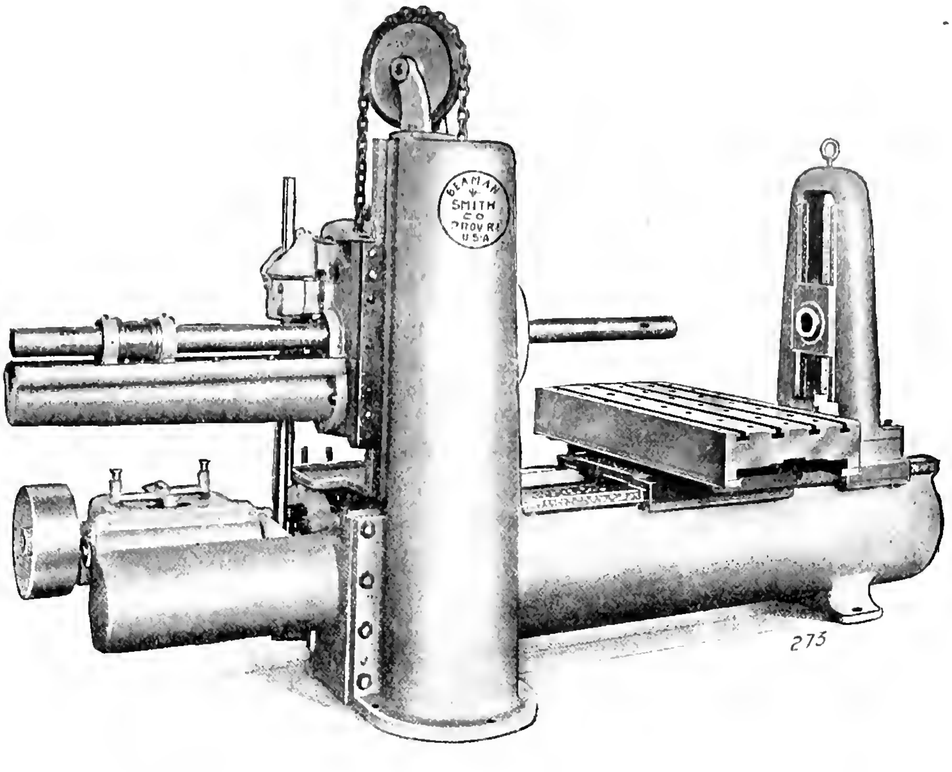

Fig. 2. Rear View showing Tubular Section used throughout in the Construction of Machine Members

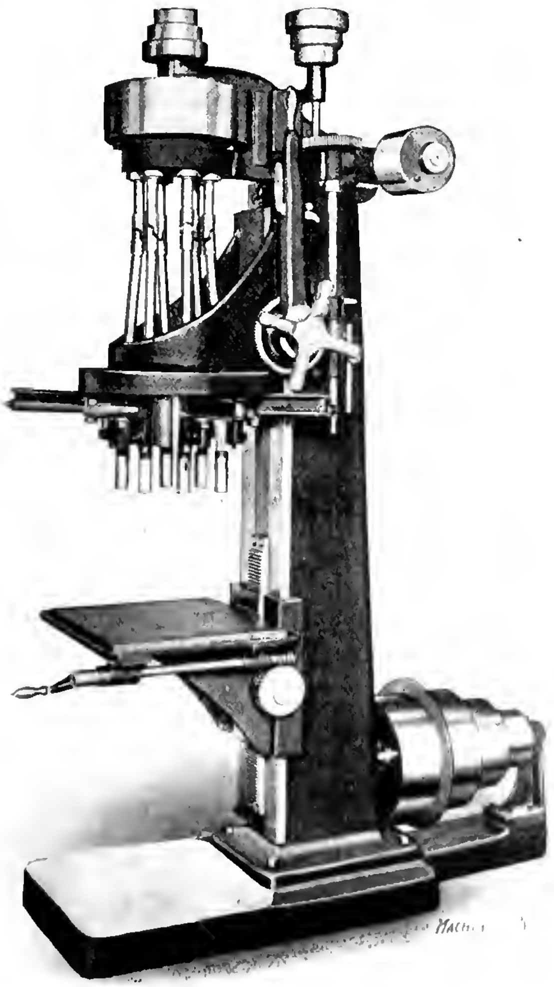
FOX MULTIPLE SPINDLE DRILL

The tool herewith illustrated is one of a line of multiple spindle drilling machines built by the Fox Machine Co., 815-825 N. Front St., Grand Rapids, Mich. These machines are designed especially for using high-speed drills, and will be found useful for automobile and gas engine work, and for general manufacturing.



Multiple Spindle Drill of the Adjustable Lay-out Type

The particular machine illustrated is the No. 1 size, provided with a round head. This is fed downward along the face of the column, inside of which is a weight for counterbalancing the movement. The power feed movement of 5 inches is transmitted through the swinging vertical shaft, which carries a worm engaging a worm-wheel on a rack pinion shaft. An automatic knock-off disengages the gearing at the end of the drilling operation. The hand lever shown provides for manual operation in the case of light work.

An exclusive feature of this machine is the design of the spindle bearings, mounted on the adjustable supporting arms. The construction gives a long stiff bearing, and one which is at the same time adjustable in a vertical direction without disturbing the setting of the other spindles. Patents are pending on this construction.

The base of this machine is 4 feet 6 inches by 18 inches. The table is 16 by 16 inches, having a vertical adjustment by a worm and worm-gear as shown in the engraving. Three spindle speeds are provided—262, 525 and 1050 revolutions per minute, respectively. The automatic feed has three changes, giving 0.0038, 0.0059, 0.0098 inch per revolution of the spindles, respectively. The driving connections by which these changes of feed and speed are obtained are exceedingly simple, and will be readily understood from the engraving.

* * *

During the month of August, 194 automobiles valued at \$333,960 and parts valued at \$114,973 were imported into the United States. Of the 194 cars imported, 109 came from France, 52 from Italy, 9 from Germany, 8 from the United Kingdom, and 16 from other countries. During the same month 360 automobiles were exported, valued at \$567,964. During the first eight months of the year 2,110 cars, valued at \$5,107,953 were exported. An interesting thing to note is the high average price of the exported cars, which is about \$2,500, indicating that the United States is rapidly taking a place among the nations exporting high grade automobiles.

* * *

The ordinary incandescent lamp with carbon filament requires about 3 watts per candle-power; the incandescent lamp with tungsten filament, 1.25 watt; the arc lamp, 1 watt; and the Cooper-Hewitt mercury vapor lamp ½ watt.

NEW MACHINERY AND TOOLS NOTES

No. 7 Disk Grinder: Gardner Machine Co., Beloit, Wis. This is a disk grinder of the same design as followed by the maker in the older members of his line, but intended for larger disks up to 30 inches in diameter. Greater belt power is also provided.

Furnace for Lead and Cyanide Baths: United States Gas Furnace Co., Providence, R. I. This furnace is intended particularly for heating baths of various substances for hardening steel parts. When used for lead, an open fire is permitted, but for cyanide a hood is fitted to carry the fumes away.

Die Sharpening Machine: National Machinery Co., Tiffin, O. This little tool is designed for threading dies or chasers for bolt and pipe work. It grinds these dies to uniform depth, giving them a proper cutting angle and clearance, so that each chaser will have the same amount of work to do. A 6-inch wheel is used, mounted on a spindle running in bronze bearings. Suitable graduations are provided for setting the machine.

Small Motor-Driven Shaper: L. E. Rhodes, Hartford, Conn. The Rhodes small shaper is now provided by its makers with a substantial iron base and a motor-drive, whenever required by the customer. A Lincoln motor is used, giving a 6 to 1 speed range; it is connected to the driving shaft by chain and sprockets. This combination should be useful in manual training schools, for model makers and others whose work is similar.

Oxy-acetylene Welding Apparatus: Oxy-Carbi Co., New Haven, Conn. This firm makes apparatus for the continuous generation of oxy-acetylene under suitable control, so as to be generated and mixed at the time it is used. The apparatus is made in either portable or stationary form. Suitable welding and cutting torches are furnished for the wide variety of work for which this process has been found adapted in the past two or three years.

Alligator and Combination Wrenches: W. S. Ducharme, Johnstown, Pa. The combination wrench made by this firm may be used as a pair of pliers or as a screw-driver, in addition to its use as a wrench. As a wrench it is self-adjustable, the jaws automatically closing as the pull increases. The alligator wrench is also adjustable, by means of a thumb-screw, adapting it to a wide range of sizes. A reversible jaw allows the wrench to be used in either direction.

Precision Spirit Level: Izard-Warren Co., 136 No. 12th St., Philadelphia, Pa. This style of precision level is built in six sizes, ranging from 2 to 24 inches in length. The bulbs are carefully made and are so ground as to indicate a variation of one-thousandth inch in the length of the level. A cross bulb is provided to make sure of the proper setting of the instrument. The body is of cast iron and the top of brass. The tool goes under the name of "Sterling Machinists' Precision Level."

Motor-Driven Precision Lathe Outfit: Rivett Lathe Mfg. Co., Brighton, Boston, Mass. This is a Rivett precision lathe mounted on a special cabinet with countershafts, etc., and a motor-drive enclosed in the base. The cabinet is of quartered oak, nicely finished, with a top surface which takes the place of the work bench on which the lathe is usually mounted. The whole arrangement provides places for the storing of attachments, tools, etc., in a way that is very convenient for a user of a precision tool.

Cold Heading Machine: Waterbury Farrell Foundry & Machine Co., Waterbury, Conn. This firm has lately produced what is supposed to be the largest cold heading machine made, being adapted to automatically produce work up to 7/8 inch in diameter and 4 inches long. The weight of the machine is over 42,000 pounds. It embodies the principles of the smaller machines of the same line, but changes have been made in details to cover the greater massiveness and rigidity required for heavy operations.

Improved Bevel Protractor: L. S. Starrett Co., Athol, Mass. This protractor is intended to be a member of the makers' well-known combination square sets, being used in connection with a graduated rule or straightedge. The improvement in the construction consists in the fact that its head extends on both sides of the blade, permitting angles to be transferred from either side of the frame without resetting. The readings indicate the supplement of the angle as well as the angle itself, thus facilitating the use of the tool.

Punch Press: Atlas Machine Co., Waterbury, Conn. This is a power-driven machine designed for light punching and stamping operations, and intended to take the place of the orthodox foot press, producing a more even pressure and more uniform work, and obviating the fatigue of the operator. The machine is controlled by a one-revolution clutch, connected to a treadle. The distance from the top of the bed to the lower end of the ways is 6 inches. The bed surface is 7½ by 12 inches. The total weight of the press complete is 500 pounds.

Scroll Chucks with Adjustable Jaws: D. E. Whiton Machine Co., New London, Conn. These tools are really a combination of independent and scroll chucks, inasmuch as they permit an individual adjustment for each jaw, this being provided by a screw mounted in the base of each which adjusts the scroll nut with relation to the jaw. This arrangement permits keeping the chuck true, without repeated grinding or boring of the jaw faces. These tools are also made with four jaws, so located that they may be used either as two-jaw or three-jaw chucks.

Adjustable Planer Gage: Tip Top Tool Co., 78 Vernon St., Worcester, Mass. This planer gage is of the type in which an anvil is adjusted up or down the inclined surface of a wedge, so as to form a measuring block having parallel surfaces which may be set for any distance apart from 3/16 inch to 1½ inch. This wide range is permitted by the fact that the measuring block has two steps of different heights. No graduations are furnished, it being designed to set the block by the aid of micrometer calipers. A fine adjustment is provided similar to that used on vernier calipers.

Nine-Spindle Milling Machine: Beaman & Smith Co., Providence, R. I. This firm has recently equipped its planer type of milling machines with a set of special heads carrying nine spindles. The side heads are provided with three spindles each, and the crossrail head has two on the front and one in the rear. This arrangement permits the machining simultaneously of the sides of the flange of automobile cylinders, the faces of the upper and lower valve openings, the spark plug boss and the inlet and exhaust connection bosses. The time required for finishing them is thus materially reduced.

Hack-Saw: Massachusetts Saw Works, Chicopee, Mass. This saw has a number of improvements in construction, of which the most notable one is a provision for adjusting the stroke automatically with the size of the work, so as to use, at all times, the full length of the saw blade. This adjustment is connected with the sliding vise jaw, so that no attention is required to it on the part of the operator. The blade is automatically relieved on the return stroke, which is made with an increased speed, due to the use of a quick-return mechanism. An automatic knock-off is provided to stop the machine when the cut is finished.

Universal Collet: Cleveland Collet & Machine Co., Cleveland, O. This is a chuck or collet of the draw-in type, intended for application to the engine lathe. Its principal advantage lies in the fact that it is adjustable for a wide range of work, it not being necessary to provide a large number of separate spring collets to cover the range, as is usual. The work is held by jaws which are opened or closed for a change in diameters, in a manner somewhat similar to the ordinary scroll chuck. The tightening of these jaws on the work, however, is effected as usual by a handwheel at the rear end of the spindle, acting on a tube passing through the latter.

Coil Clutch: Farrel Foundry & Machine Co., Ansonia, Conn. This clutch is of the type in which frictional contact is produced by the tightening of a heavy steel spring, which forms one member, about a drum or barrel, which forms the second member. As is well-known, this construction gives a very heavy gripping power for a slight pressure in the tightening of the spring. This particular design has been built for powers as high as 8,000 at 60 revolutions per minute in one English installation. The spring is hand-forged from a high-grade of steel and the drum is of chilled iron, making a very durable and substantial construction. The line covers a wide range of sizes.

Variable Speed Sensitive Drill Press: Villinger Mfg. Co., Williamsport, Pa. This drill press is a simple machine with a number of new features, among them being a connection of the feeding handle with a friction disk drive in such a way that this handle serves to vary the rate of speed as well as to feed the drill. Pushing the handle to right or left changes the speed, while drawing it down feeds the drill as usual. In addition, connections are provided which stop the spindle when the feed lever is turned back to its upright position. A key is provided which holds the table central with the drill at whatever vertical height it is adjusted. This key can be withdrawn, however, to permit swinging the table from one side to the other as may be required for special cases.

Crank Planing Machine: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. This is a tool which has found much favor in railroad and locomotive shops and other places where cuts are to be taken on comparatively small pieces of tough metal. The framework of the machine is of the planer type, but the table is actuated by a crank motion of variable stroke driven by a Whitworth quick return movement, similar to that used in many designs of shapers. The saddle is provided with power cross-feed on the rail, and the tool slide has a vertical or angular down feed on its slide. The machine is very strongly and ruggedly built, and is capable of taking heavy cuts, owing to the fact that all cutting strains are rigidly resisted by the disposition of the metal in the framework.

Cam Grinding Attachment for Standard Grinding Machines: Norton Grinding Co., Worcester, Mass. This attachment may be applied to the maker's standard type of grinding

machine. The desired outlines on the surfaces to be ground are produced by master cams or templets, which swing the work in toward the wheel or away from it as may be required to give the desired contour. A series of templets is provided, one for each of the different cams on the shaft, so that each is of the proper shape and properly located to give the correct timing. The whole arrangement is very simple, and easily applied and operated. It should result also in the production of cam surfaces of a high grade of accuracy. Provision is made in the device for grinding the templets or master cams from models, which are thus exactly reproduced in the contour of the work.

Blueprint Storage Tube: G. Chalmers Brown, New London, Conn. This tube is intended for the storage and use of blueprint paper from the roll. It may be fastened to a bench or side of the wall. The roll of paper is inserted in the end of an inner tube, after which this inner tube is turned around so that the opening in its side is out of line with the opening in the outer tube. The paper is thus safely sealed against the entrance of light. In removing the paper, the inner tube is turned around until the openings register and the paper is pulled out through the slot thus provided. A tape-measure is mounted on the apparatus which is pulled out at the same time with the paper, accurately measuring the length of the sheet removed. The paper is torn by drawing it cornerwise across the sharp edge of the opening. This tube should find favor on the score of economy and convenience in the use of blueprint paper.

36-Inch Radial Drill: Dreses Machine Tool Co., Cincinnati, O. This machine resembles the previous designs of the same builders in the construction of the spindle head, feed, etc. It is provided, however, with a new driving connection between the horizontal shaft on the arm and the vertical shaft inside the column, which does away with a considerable amount of mechanism, including two spur gears, a shaft and two bearings. The elevating screw is placed in a recess in the front of the column where it does not lessen the swing of the machine. An improved clamping device is provided which binds the column, the table and the stump together by a single movement of the lever. The table may be adjusted to keep it always perpendicular to the spindle. The machine will be furnished either with cone pulley or gearbox drive, or with constant or variable speed motor drive. It drills to the center of 73-inch circles, takes 78 inches between the center and the base and weighs about 3,600 pounds.

Lester Automatic Screw Machine: Davis Sewing Machine Co., Dayton, O. This is a multiple spindle machine involving a number of novel features in its construction. For one thing, it has three stock spindles in place of the usual four or five. The indexing and cam movements are so arranged that these three spindles, on simple work, can be made to form three pieces at each revolution of the cams, without indexing; these pieces may be alike or different as may be required. On plain work, it may thus be seen, the machine has a very high capacity. Another new point in the design is the large number of tools provided. There are six stations in the tool-holder and three cross-slide tools, this making nine cutting operations possible for each piece; and as many of these operations may be arranged to make use of multiple cuts, the range of work to which the machine is adapted is very large. The size of machine at present built has a capacity for stock up to 1 inch diameter, and a length of feed for turning up to 4 inches.

Machine for Testing Running Balance: The Norton Grinding Co., Worcester, Mass. The obtaining of standing balance in a rotating part is a comparatively simple operation, it being common to roll the work along knife edges or between centers, and mark the heavy side as indicated by the position in which the part comes to rest. The obtaining of a running balance, however, is another matter. It has always been done by homemade contrivances, more or less clumsy and slow. The Norton Grinding Co. has recently devised a piece of apparatus for this work which greatly simplifies the operation and permits it to be done much more quickly and accurately than ever before. Briefly, the part to be tested is provided with two supports, one on each end, on which it is rotated rapidly by an electric motor. These supports are floating, and indicate every vibration by means of a lever magnifying arrangement. Provision is made for marking the high side at each support to show the running out permitted by the floating bearing. By reversing the rate of ratio the lag due to the inertia of the floating and indicating parts is compensated for. For long and slender work provision is made for supporting and indicating at one or more intermediate points as well as at the ends. The whole apparatus is well-designed and conveniently arranged, and should prove especially useful in automobile work, high-speed drums and pulleys, and in woodworking machinery building in general.

The Pennsylvania R. R. tunnels from Bergen Hill, N. J., to Long Island City were practically completed December 3 when the final section of concrete was placed in line D, the fourth and last of the tunnels under the East River, to the Sunnyside Yard, Long Island City.

Copyright, 1902, by Gessford, N. Y.

GEORGE WESTINGHOUSE

ARTHUR WARREN

The new president of the American Society of Mechanical Engineers needs no introduction to engineers of any branch, nor to the general public the world over. He has been famous and honored everywhere these forty years, for it was in 1868, and at the age of twenty-two, that he brought forward his great invention, the air brake, which it has been said "ranks next to the press and the locomotive among those forces to which the material developments of the present age primarily are due." The evolution of the air brake under his personal inventiveness in the years that have passed since he first originated the device has made the modern railroad possible. Without the control which the air brake gives, high speed, frequent service, long trains, huge cars, heavy loads, would be unknown. The air brake, therefore, is not only a safety device; it is also a most important operating device on a railroad.

George Westinghouse was born October 6, 1846, at Central Bridge, Schoharie County, in the state of New York, a son of George and Emeline Vedder Westinghouse. His father was a manufacturer of agricultural machinery at Schenectady. Out of school hours the boy taught himself engineering, and it was his idea of a holiday and a vacation to work in his father's machine shop. Before he was seventeen he enlisted for the Civil War, serving first in an infantry regiment and next with the cavalry. Then, passing an examination for the purpose, he was transferred to the Navy where he served during the remainder of the war as an Assistant Engineer. In the same year that he returned to civil life, 1865, he entered Union College and invented a device for placing derailed cars on the track. Three years later he thought out and patented the air brake. He had to guarantee the railroad which made the first trial with the brake that he would pay for any damage that might be done to the train as a result of equipping it with the apparatus and running a trial trip. Instead of damaging the train, his brake prevented a fatal accident on the trial run and then the skeptical railroad officials expressed astonishment and enthusiasm, and men who had thought it "impossible to stop a train with air" were eager to buy the invention.

Young Westinghouse, however, declined to sell. He formed a company, took a workshop in Garrison Alley, Pittsburg, and began to manufacture the remarkable contrivance which he had invented. In a year the new works had thirty-six employes, including clerks and office boy. From that modest beginning have grown the great works of the Westinghouse Air Brake Co. at Wilmerding, Pa., and the town of Wilmerding itself. From the fruits of the inventor's genius, energy and capacity as an organizer of industry have developed thirty companies, of which he is president, employing 50,000 men, $120,000,000 of capital, and manufactories at East Pittsburg, Swissvale, Trafford City, and Wilmerding, in Pennsylvania, in London and Manchester, England, and in

France, Germany, Italy, Austria and Russia. There is not a civilized country in which the name Westinghouse is not familiar. Air brakes, electric motors and generators, steam and gas engines, steam turbines, railroad switches and signals, and a multitude of other things testify to the inventive and industrial energy of this distinguished man.

After inventing the brake he took up the study of railroad signals and switches and showed how these could be operated with compressed air. Having done this, he combined electricity with the pneumatic operation of these devices. Thus he was led further and further into the pursuit of the then new electrical art. Convinced of the practicability of conveying electrical currents over great distances, he resolved to develop the alternating system for that purpose. From Europe he acquired the patents of Gaulard and Gibbs. He brought Tesla to Pittsburg, backed him financially, placed laboratory and workshop facilities at his disposal, and the result was the invention of the induction motor for utilizing the alternating current for power purposes.

The great successes of Mr. Westinghouse have not been gained without opposition. His strength of character, mind and resource, however, has always been brought forth in encounters, and he has always won. Opposition to the alternating current system developed to an extraordinary extent. Men who should have known better, and do now, declared that the alternating current was impracticable, and that if ever made practicable its use would be deadly and a menace to the public welfare. Legislation was invoked against it in many states. These efforts were really meant to be, whatever the legislators may have thought, a systematic attempt to check George Westinghouse in his plans for bringing electricity within the reach of all. And to prove to the populace the "danger" of the system which he advocated, some of the opponents prevailed upon the authorities to use an electrical death-chair for the execution of convicted murderers! The originators of this brilliant idea, and of the campaign against the alternating current system, found themselves as impotent as King Canute when he commanded the incoming sea to retreat. Scientifically, commercially, and in every way, the alternating system proved to be what the world required for the general adoption of electric currents on a large scale, and the opposition was defeated. Similarly, in the hard times of the early nineties, men who desired to monopolize the manufacture of electrical machinery took advantage of the generally depressed conditions of affairs throughout the country, and endeavored to drive Mr. Westinghouse into a corner, and to obtain control of the electrical manufacturing company which he had founded, organized and built up into a great center of industry; but the attempt to overcome him was unsuccessful. The panic of 1907 caused a renewal of this kind of attack, but as Andrew Carnegie is reported to have said, "George Westinghouse is a genius. You cannot keep him down!" What is more, you cannot get him down. He is one of the world's strong men.

At the time of the Chicago exhibition the electrical illuminations of that vast and beautiful undertaking were the most remarkable that had ever been seen. George Westinghouse offered to take the electrical contract for a million dollars less than the figure which the exposition authorities were on the point of agreeing to pay the bidders who seemed to be the most successful. "It cannot be done," the competing bidders said to the exposition authorities. "But I will do it," said Westinghouse. And then they undertook to show that they monopolized the lamp patents of that time. This they thought would make him powerless in the matter, but he persuaded the authorities to postpone the decision, and they, glad enough to save a million dollars, and having faith in the man, consented to the postponement. Mr. Westinghouse returned to Pittsburg, invented a lamp, returned to Chicago, secured the contract and saved the exposition a million.

George Westinghouse has invented many things, and has encouraged invention in the engineers associated with him. He devised a system for mechanically controlling the flow of natural gas, and piping it over long distances for use as fuel in the industries and homes of Pittsburg. He built the first ten great generators for Niagara, and those for the elevated and subway lines in New York, and for the Metropolitan Railway in London. It is impossible within the present space to enumerate either his inventions or his business achievements. His work has frequently taken him into many countries, and distinguished men of all callings and sciences are, and long have been, among his personal friends. Of these, Lord Kelvin was the first recipient of the John Fritz medal. George Westinghouse, by the way, was the second person to receive the John Fritz medal. The French Republic, the late King Leopold of Belgium, and the late King Humbert of Italy decorated Mr. Westinghouse. The Königliche Technische Hochschule of Berlin gave him the degree of Doctor of Engineering. He was, in 1905, selected as one of the three trustees to hold the voting power of the stock control of the Equitable Assurance Society, being associated in this important trust with ex-President Grover Cleveland, and Justice Morgan J. O'Brien. He is president of the American Society of Mechanical Engineers, is one of the two honorary members of the American Association for the Advancement of Science, and an honorary member of the National Electric Light Association.

The latest activity of Mr. Westinghouse is the bringing before the attention of the marine engineers of America and Europe the reduction gearing and "floating frame" invented by Rear-Admiral Melville, ex-Engineer-in-Chief, U. S. N., and John H. Macalpine. The purpose of this invention is to enable high-speed steam turbines to drive the propellers of steam vessels, thus obtaining from the propellers and the turbines their highest efficiency. Mr. Westinghouse supplied the means for constructing and testing this important invention, and at the same time developed a marine turbine of his own which is said to be a great improvement over any now in use. This turbine has been used in the tests of the Melville-Macalpine gear, tests which are reported to be of a remarkably satisfactory character.

ANNUAL MEETING OF THE A. S. M. E.

The thirtieth annual meeting of the American Society of Mechanical Engineers was held in New York, December 7 to 10 inclusive, the Engineering Societies Building, 29 West 39th St., being the headquarters. The registration of members was 638, and including guests, 1063. The program was substantially as follows:

Tuesday.—President Smith's address, "The Profession of Engineering," and the introduction of President-elect George Westinghouse, followed by a reception held by the president, president-elect, Secretary Rice and Honorary Secretary Hutton with their ladies.

Wednesday.—Annual business meeting, reports of membership, standing and special committees and gas power section. In the afternoon a large party went through the new Pennsylvania R. R. terminal and passenger station at 7th Ave. and 31st and 33d Sts. In the evening an interesting stereopticon lecture was delivered by L. W. Ellis of the Bureau of Plant Industry, U. S. Department of Agriculture, Washington, D. C., entitled "The Era of Farm Machinery."

Thursday.—"Tests on a Venturi Meter for Boiler Feed" by Charles M. Allen; "Pitot Tube as a Steam Meter" by George F. Gebhardt; "Efficiency Tests of Steam Nozzles" by F. H. Sibley and T. S. Kemble; "Electric Gas Meter" by C. C. Thomas; "Tan Bark as a Boiler Fuel" by David M. Myers; "Cooling Towers for Steam and Gas Power Plants" by J. R. Bibbins; "Governing Rolling Mill Engines" by W. P. Caine; "Experience with Leaky Vertical Fire Tube Boilers" by F. W. Dean; "The Best Form of Longitudinal Joint for Boilers" by F. W. Dean; "Testing Suction Gas Producers with a Koerting Ejector" by C. M. Garland, A. P. Kratz;; "Bituminous Gas Producers" by J. R. Bibbins. In the evening the members of New York and vicinity gave a reception to the officers and members of the society, their ladies and guests at the Hotel Astor.

Friday.—"The Bucyrus Locomotive Pile Driver" by Walter Ferris; "Line Shaft Efficiency, Mechanical and Economic" by Henry Hess; "Pump Valves and Valve Areas" by A. F. Nagle; "A Report on Cast Iron Test Bars" by A. F. Nagle.

Besides the excursion mentioned there were other excursions of much interest as follows:

International Steam Pump Co., Harrison, N. J., to inspect a modern plant for the manufacture of pump and hydraulic machinery; General Electric Co., Harrison, N. J., to inspect incandescent lamp manufacture; Interborough Rapid Transit Co., W. 58th and 59th Sts. and west side of 11th Ave., to inspect a large central electric light and power station for public service; National Phonograph Co., Orange, N. J., to inspect the manufacture of Edison phonographs and records; De La Vergne Machine Co., E. 138th St., New York, to inspect a new type of oil engine; New York Telephone Co., 61 Irving Place, New York, to inspect the Gramercy and Stuyvesant central telephone exchanges; Crocker-Wheeler Co., Ampere, N. J., to inspect a modern plant for the manufacture of electric generators and motors; Westinghouse Lamp Co., Bloomfield, N. J., to inspect incandescent lamp manufacture; New York Edison Co., E. 38th to E. 40th Sts., New York, to inspect the Waterside electric light and power stations Nos. 1 and 2 for public and private service; Brooklyn Rapid Transit Co., Kent Ave. and Division St., Brooklyn, to inspect a modern central electric power station for public service; Rockland Electric Co., Hillburn, N. J., to inspect gas engines and producers in a modern public service plant; Singer Mfg. Co., 149 Broadway, to inspect the power plant and view the city from the tower 548 feet above the street; Trenton Iron Co., Trenton, N. J., to inspect a modern electric generator plant operated by gas engines; Watson-Stillman Co., Aldene, N. J., to inspect a 300 horse-power Riverside gas engine operating in connection with a Tait producer; Metropolitan Life Insurance Co., E. 23d St. and 4th Ave., to inspect the power plant and view the city from the tower.

The excursion through the Pennsylvania R. R. terminal was of extraordinary interest. The terminal, which is part of one of the world's greatest engineering works, occupies four blocks in the heart of New York, lying between 31st and 33d Sts. and 7th and 9th Aves. It is 784 feet long and 430 wide. Its average height above the street is 69 feet, and maximum height 153 feet. The main waiting room is 277 feet long, 103 feet wide and 150 feet high in the dome. At the track level the station covers an area of 7.74 acres and the total trackage is 16 miles. The number of standing tracks at the station is 21, and the number of passenger platforms is 11. The power house adjacent has a boiler capacity of 5,000 H. P.

The New York terminal extension consists of the Pennsylvania R. R. Tunnel and Terminal Roads forming a connection with the New York division of the Pennsylvania R. R. near Harrison, N. J., which runs over the meadows, under Bergen Hill, North River, Borough of Manhattan and East River through the Sunnyside yards to the Long Island Railroad near Woodside Ave., Queens Borough, Long Island. The total length of the extension is 14.9 miles, including 1.25 mile in the Harrison yard. Of this, 2.78 miles are land tunnels, 2.29 miles river tunnels. The terminal is really a way station on the connecting link between the Pennsylvania R. R. system and the Long Island Railroad system. The terminal building is a beautiful structure lined with Carrara marble and of most impressive proportions.

The large number of interesting excursions and other extraneous features incident to the meeting tended to detract from the value of the technical proceedings. The members generally neglected the sessions, the result being that they were poorly attended and the discussions largely perfunctory. It is a question whether a programme of papers could have been prepared that would have drawn more attendance in view of the manifold outside attractions. If not, it would seem that a change should be instituted in the entertainment and conduct of the meetings if the best interests of the society are to be conserved.

The following officers were elected: George Westinghouse, president; Charles Whiting Baker, W. F. M. Goss, E. D. Meier, vice-presidents; J. Sellers Bancroft, James Hartness, H. G. Reist, managers; William H. Wiley, treasurer.

* * *

Don't use wet or green timbers for countershaft hanging, without tightening up the bolts every week or two, for a while.

PERSONALS

H. L. Pelz is now foreman of the foundry of the Chicago & Alton R. R. at Bloomington, Ill.

L. Fleishfien has been put in charge of the machine department of the Chicago & Alton R. R. shops at Bloomington, Ill.

Fred H. Robinson, with the Bailey Automobile Co., Springfield, Mass., has been promoted to position of foreman of the machine shop.

A. L. Myers, a department foreman of the LeBlond Machine Tool Co., Cincinnati, Ohio, has been made assistant superintendent.

Walter C. English, manager of the Boston office of the *Iron Age* and associated publications, has retired after twenty-six years of service.

C. L. Woodward, mechanical engineer and designer, of the Bailey Automobile Co., Springfield, Mass., has been appointed superintendent of the factory.

The headquarters of Ethan Viall, western editor of MACHINERY, will be 1811 First National Bank Building, Cincinnati, Ohio, after January 15.

J. H. Stevens, who has been in the employ of the LeBlond Machine Tool Co., Cincinnati, Ohio, for some time, has been promoted to the position of machine tool foreman.

C. H. Tucker, recently of the Case Crane Co., is now in charge of the new department of the Toledo-Massillon Bridge Co., devoted to the manufacture of cranes, hoists, coal and ore-handling machinery, etc.

James Healy, for the past three years foreman of the gear-cutting department of the Stevens-Duryea Automobile Co., Chicopee Falls, Mass., has resigned and taken a similar position with the Pierce-Arrow Co., Buffalo, N. Y.

H. A. Isaacs, formerly master mechanic of the Chicago & Alton R. R. at Kansas City, Mo., and later with the Michigan R. R., has been appointed master mechanic of the Chicago & Northwestern Ry., with headquarters at Clarion, Iowa.

Charles Robbins, who for ten years has been employed in the industrial and power sales department of the Westinghouse Electric & Mfg. Co., Pittsburg, Pa., in connection with the sale of industrial motors, was recently appointed manager of this department.

George M. Vial, for the past five years in charge of the wood pattern department of the Stevens-Duryea Automobile Co., Chicopee Falls, Mass., has resigned to take charge of the wood-working department of the public manual training school of Chicopee, Mass.

Clark W. Parker, for the past three years employed by the Lamb Knitting Machine Co., Chicopee Falls, Mass., designing special automatic machinery, has resigned to become president and manager of the Parker Transmission and Appliance Co., Springfield, Mass., which is to manufacture and market one of his inventions.

S. J. Rowe, president of the Rowe Motor Co., Waynesboro, Pa., has been for the past fifteen months designing self-propelled fire apparatus for the American-La France Fire Engine Co., Elmira, N. Y. Mr. Rowe resigned his position with the company, to take effect January 1. He will hereafter devote his entire time to the business of the Rowe Motor Co.

E. P. Haight, well known in electrical circles as the treasurer of the Sprague Electric Co., was elected president of the Electric Trade Association of New York, of which Mr. Franz Neilson, 80 Wall St., is secretary. Mr. Haight's experience in the electrical trade and his energy and enthusiasm doubtless will make his administration of the society unusually successful.

Samuel A. Chase, who for the past few years was a detail and supply salesman in the New York sales office of the Westinghouse Electric & Mfg. Co., Pittsburg, Pa., recently resigned, and has taken a position with the White Investment Co., of New York, a financial investment company handling stock of many organizations. Mr. Chase will be in charge of the Chicago office of the company.

G. Brower Griffin was recently appointed manager of the sales policy of the detail and supplies sales department of the Westinghouse Electric & Mfg. Co., Pittsburg, Pa., in which department transformers, motors, switches and switch-boards, railway line material, etc., are sold. Mr. Griffin was assistant manager of the sales department for six years previous to his promotion to the position of manager, having previously been connected with the sale of detail apparatus, in the Boston office.

S. Nicholson was recently appointed general sales manager of the Westinghouse Electric & Mfg. Co., Pittsburg, Pa., and has taken charge of the policy of the entire company. He has been with the company for eleven years in different capacities. He is perhaps best known to electric motor manufacturers as the organizer and president of the American Association of Motor Manufacturers, an organization which has done much in the two short years of its life to improve the art of motor manufacture.

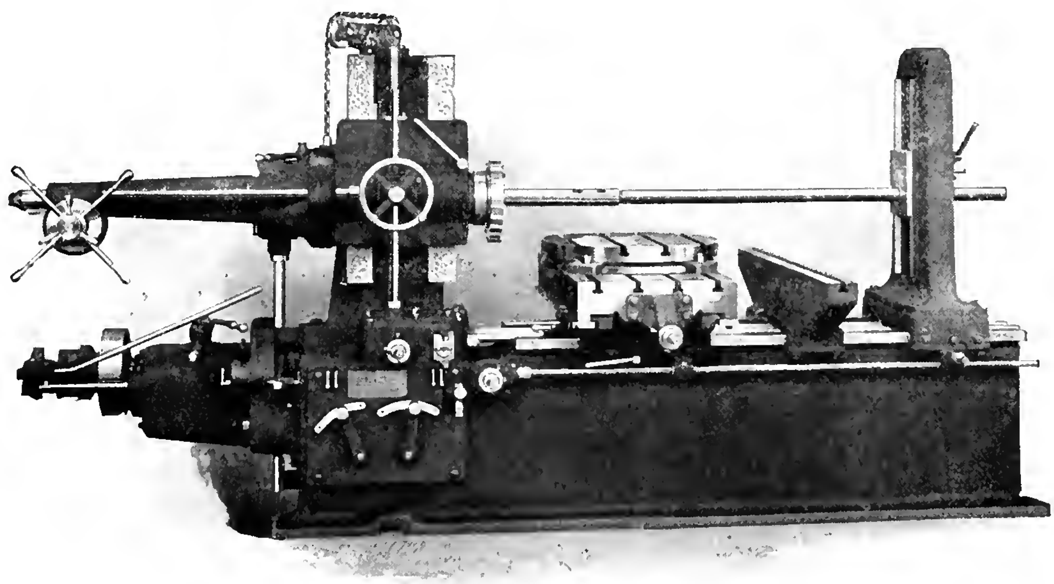
SOME gentleman with plenty of time at his disposal has figured that ONE TON OF IRON, after going through the necessary processes to make it into hair springs for watches, would be worth

TWENTY MILLION DOLLARS!

Made into almost any kind of a MACHINE it would be worth more than if made into SASH WEIGHTS.

We don't know just how much it would be worth per ton if made into a

"PRECISION"



Boring, Drilling and Milling Machine

because we don't particularly care and have never taken the time to figure it.

The DISTRIBUTION of metal concerns us more than its WEIGHT.

The metal in our machines is distributed as well as we know how to do it today, and if we can find a better way tomorrow to distribute it, WE SHALL DO IT.

Lucas Machine Tool Co., Now and always of Cleveland, O., U.S.A.

EUROPEAN AND AUSTRALIAN AGENTS: C. W. Burton, Griffiths & Co., London. Alfred H. Schutte, Cologne, Brussels, Liege, Paris, Milan, Bilbao, Barcelona. Schuchardt & Schutte, Berlin, Vienna, Stockholm, St. Petersburg, Copenhagen, Budapest. E. McCray & Co., Sydney, Australia.

Paul M. Chamberlain has opened an engineering office at 1522 Marquette Building, Chicago, Ill. Mr. Chamberlain was graduated from the Michigan Agricultural College in 1888 and Cornell University in 1890. For several years he was in practical work with the Brown Hoist Co., Cleveland, Ohio; Frick Co., Waynesboro, Pa.; Hercules Iron Works, Aurora, Ill. He then became assistant professor of mechanical engineering at the Michigan Agricultural College, and at the opening of the Lewis Institute at Chicago he took charge of the engineering work and brought it up to its well-known standard of excellence. Mr. Chamberlain has made a special study of boiler-room equipment, economy in fuel burning, and smoke abatement, and will devote his time principally to new designs and improvements in existing installations.

Franklin E. Snow, for twenty-nine years connected with the Wells Brothers Co., of Greenfield, Mass., and for a great part of that time its treasurer, has retired from the active management. F. O. Wells will continue as president and will also act as treasurer. Mr. Snow will be vice president and Edward Blake, Jr., who has been sales manager for some years, has been elected a director. Mr. Snow has been one of the most prominent factors in the development and prosperity of the Wells Brothers Co., and the growth of the business from a small concern on Mill Street to the present large plant on Sanderson Street has been coincident with his connection. Mr. Snow is also interested as a stockholder in a number of other Greenfield manufacturing enterprises, to the success of which his business ability has contributed in a marked degree. In the enjoyment of a well-earned rest he will doubtless still find time to perform, in his quiet and genial way, the various duties which fall to the lot of the public spirited citizen.

Charles H. Kirchhoff, for twenty years editor-in-chief of the *Iron Age*, retired December 1. Mr. Kirchhoff graduated from the Royal School of Mines, Clausthal, Germany, and before entering journalism in 1877 he was a mining engineer and metallurgist. He worked as a chemist for the Delaware Lead Refining Co., Philadelphia, Pa., from 1874 to 1877, and during that time began contributing to the *Metallurgical Review*, and later became its assistant editor, remaining on its staff two years. Leaving the *Metallurgical Review*, he joined the staff of the *Iron Age* as assistant editor, and after two years service became editor of the *Engineering and Mining Journal*. In 1884 he returned to the *Iron Age* as associate editor, and in 1889 became its editor-in-chief. Mr. Kirchhoff is generally regarded as an authority on metallurgy and steel manufacture. He has a wide acquaintance among the steel manufacturers, and his personality undoubtedly has been a potent factor in the success and prestige of the journal that he conducted so long.

* * *

OBITUARIES

Joseph Campbell, president of the Diamond Saw and Stamping Works, Buffalo, N. Y., died November 29.

John B. Chapman, senior member of J. B. Chapman & Co., brass founders, coppersmiths, and machinists, Springfield, Mass., died at his home in that city December 6, aged fifty-five years.

F. L. Gallagher secretary and treasurer of the Modern Tool Co., Erie, Pa., died suddenly November 29, aged forty-one years. Mr. Gallagher was formerly with the Metric Metal Works, with which concern he was employed as bookkeeper until about nine years ago, when he became manager and treasurer of the Modern Tool Co. He was a man of much popularity.

Alden Sampson, 2nd, proprietor of the Alden Sampson Mfg. Co., maker of automobile and automobile trucks, Pittsfield, Mass., died at his home, December 3, aged thirty-one years. Mr. Sampson contracted a cold which developed into double pneumonia while on his homeward trip from France in the middle of November, where he had gone to observe the use of automobile trucks in army manœuvres.

Dr. Charles B. Dudley, the well-known chemist in charge of the Pennsylvania R. R. Co.'s testing work, died at Altoona, Pa., December 21, of typhoid-pneumonia, aged sixty-seven years. He held the position with the Pennsylvania R. R. Co. since his graduation from the Sheffield Scientific School in 1874. He was twice president of the American Chemical Association, and was a vice-president of the American Institute of Mining Engineers. He was also president of the American Society for Testing Materials for several years.

William Metcalf, a pioneer steel manufacturer and one of the best known metallurgists in the United States, died at his home in Pittsburg, Pa., December 7, aged seventy-one years. During the Civil War Mr. Metcalf was in charge of the Fort Pitt foundry, Pittsburg, where much of the heavy artillery used by the Northern armies was made. It was in this foundry that the Rodman cannon were cast, the Rodman process being the first effort of importance to make cannon with the internal layers in a state of compression due to cooling the core rapidly. Mr. Metcalf was head of the Braeburn Steel Co., which he organized in 1897. He was the author of several books on steel and metallurgy; his book on tool steel was for many years the only authoritative American work on the subject. In 1880 he was elected president of the American Institute of Mining Engineers, and president of the American Society of Civil Engineers in 1893. He was also vice-president of the American Society of Mechanical Engineers in 1882-1884.

* * *

COMING EVENTS

January 1-8.—Tenth international exhibit of automobiles and automobile appliances, Grand Central Palace, New York, under the auspices of the American Motor Car Manufacturing Association. R. E. Olds, chairman, 505 Fifth Ave., New York.

January 8-15.—Association of Licensed Automobile Manufacturers' tenth annual exhibition of automobiles and automobile appliances, Madison Square Garden, New York. M. L. Downs, secretary, 7 East 42d St., New York.

January 18-20.—Annual meeting of the American Society of Heating and Ventilating Engineers. W. M. Mackay, secretary, P. O. Box 1818, New York.

January 19-20.—Annual meeting of American Society of Civil Engineers, New York. Charles W. Hunt, secretary, 220 West 57th St., New York.

May 31-June 3.—Spring meeting of the American Society of Mechanical Engineers, Atlantic City, N. J.

June 7-9.—Convention of the American Foundrymen's Association and American Brass Founders' Association, Detroit, Mich. Headquarters, Hotel Ponchartrain. Richard Moldenke, secretary. American Foundrymen's Association, Watchung, N. J. W. M. Corse, secretary. American Brass Founders' Association.

June 1-August 31, 1910.—American Exposition in Berlin, under illustrious auspices, to stimulate trade relations between Germany and America. This will be the first all-American exposition ever held in a foreign country and will be of interest to all Europe as well as America. It will be held during three of the best months of the year for an exposition, being at the full tide of the foreign travel when people will be attracted in large numbers. Max Vieweger, American Manager, 50 Church St., New York.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in England.

SOCIETIES AND COLLEGES

Iron & Steel Institute, G. C. Lloyd, secretary, London, England, announces that Mr. Andrew Carnegie, past president of the association, has presented the institute with $100,000 for research scholarships. The object of this scheme of scholarships is to enable students who have passed through college or who have been trained in industrial establishments to conduct research experiments in iron and steel and related subjects. The appointment for scholarship is for one year, but the council may at its discretion renew the scholarship for a further period. Further information may be obtained from the secretary.

Massachusetts Institute of Technology, Boston, Mass., during the past year has made the requirements for the degree of Doctor of Engineering more definite, and has placed it in the hands of the board which also administers the regulations for the degree of Doctor of Philosophy. The requirements for the degree of Doctor of Engineering and Doctor of Philosophy have now been made substantially equivalent. The executive committee has voted two Austin research scholarships carrying a sum of $500 each and remission of tuition fees. These are now open to candidates for degrees of Doctor of Engineering and Doctor of Philosophy.

Museum of Safety and Sanitation, 29 West 39th St., New York, through its secretary, Dr. William H. Tolman, is giving stereopticon lectures on safety devices. A description of the work of the safety committee of the United States Steel Corporation made in Rochester so impressed the superintendent of the Rochester Railway and Lighting Co. that he organized a committee of safety in his company which employs 2,500 people. The practical results of Dr. Tolman's work are made clear by events like this which promote methods, rules and regulations for the preservation of life and limb in industrial works, railroads and other activities of life.

University of Illinois, Urbana, Ill., has recently issued a circular descriptive of its course in mining engineering lately established. The bill establishing the department of mining engineering in the state university was passed by the last state legislature. The mining and metallurgical products of the state of Illinois, for 1907, represent an output value of over $150,000,000. Although Illinois is generally regarded as an agricultural state, it has for many years occupied second place among coal producing states and the rapid development of the iron industry about Chicago has already placed the state well up among the iron and steel producing states.

CATALOGUES AND CIRCULARS

Robbins Machine Co., Worcester, Mass. Circular of Robbins 14-inch engine lathe with compound and elevating rest.

Boicourt Co., Fort Worth, Texas. Circular of Boicourt steam power pumps, deep well pumps and deep well working head.

B. C. Ames Co., Waltham, Mass. Catalogue of bench lathes and fixtures, bench milling machines and dial gages. The company builds small machinery to order.

S. A. Woods Machine Co., Boston, Mass. Circular of inside molders, a new wood-working tool in which the advantages of a molder, shaper and matcher are comprised in one machine.

Massachusetts Institute of Technology, Boston, Mass. Catalogue of the Institute giving roster of officers and instructors, courses of study, roll of students and graduates, etc.

Chicago Pneumatic Tool Co., Chicago, Ill., and New York. Circular descriptive of Franklin tandem gasoline engine driven air compressors adapted for isolated compressed power units.

Northern Engineering Works, Detroit, Mich. Booklet 24-B of Northern electric traveling cranes, hand power cranes, jib cranes, overhead trolleys, electric hoists, steel derricks, etc.

General Electric Co., Schenectady, New York. Bulletin No. 4708 on Thompson direct current test meter type CB-3, designed as part of the equipment of central power stations for periodical meter testing.

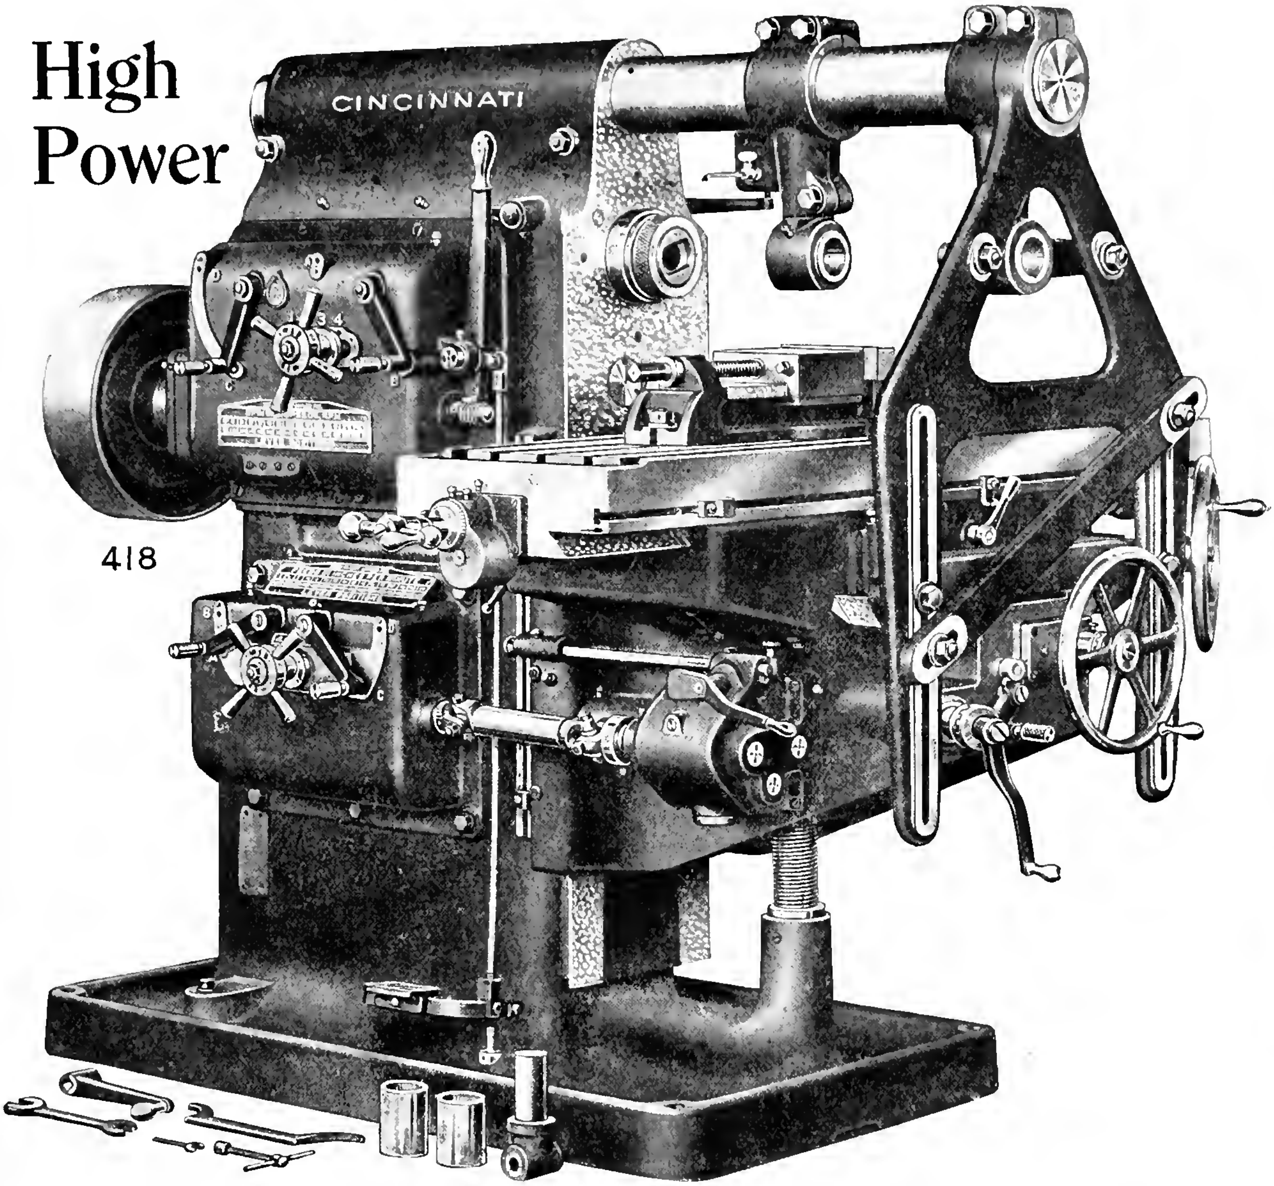
M. Rumely Co., La Porte, Ind. Pamphlet entitled "Toiling and Tilling the Soil," beautifully illustrated, advertising the Rumely "Oil Pull" tractor, a gasoline traction engine designed for plowing and hauling on farms.

Gisholt Machine Co., Madison, Wis. Leaf illustrating and describing Gisholt lathe equipment for finishing valve bodies and work of a similar nature. Also leaf illustrating Gisholt lathes used in automobile shops.

Mesta Machine Co., Pittsburg, Pa. Circular of Corliss-engine driven compressors for large capacities and pressures up to 1,000 pounds per square inch, and hoisting engines for heavy duty service and large capacities.

CINCINNATI MILLERS

High Power



THE NEWEST MILLER ON THE MARKET

All driving gears of steel with teeth of standard length and 20° pressure angle.
The drive is always through the face gear which is keyed to the spindle close against the front box.
Single plunger trip, can reverse all feeds at all times from tripped position, without interference with dogs.
Direct reading, simple, feed and speed index.
Table feed levers reverse, and also indicate direction of table travel.
Sight feed oilers on all important bearings.
Six different interchangeable drives. Change from the one in use to any other can be quickly made at any time by user in his own shop.

Ask for our 1909 catalog

THE CINCINNATI MILLING MACHINE CO.

CINCINNATI, OHIO, U. S. A.

EUROPEAN AGENTS—Schuchardt & Schutte, Berlin, Vienna, Stockholm, St. Petersburg, Copenhag[illegible] Budapest. Alfred H. Sch[illegible], Cologne, Brussels, Liege, Milan, Paris, Turin, Barcelona and Bilbao. Chas. Churchill & Co., London, Birmingham, Manchester, Newcas[illegible]-on-Tyne and Glasgow.
CANADIAN AGENT H. W. Petrie, Ltd., Toronto, Montreal and Vancouver.
AUSTRALIAN AGENTS Thos. McPherson & Son' Melbourne.

CONTENTS FOR JANUARY

AMERICAN BLOWER CO., Detroit, Mich. Copy of recent decision of Judge Hough of the United States Circuit Court sustaining its suit against the B. F. Sturtevant Co., Boston, Mass., for infringement of patent covering Sirocco fans and blowers.

CROCKER-WHEELER CO., Ampere, N. J. Bulletin No. 116 on motor generator sets for air pumps; bulletin No. 117, "Motor Drive in the Laundry;" and bulletin No. 118 on form L direct current motors 1/20 to 7½ H. P. and generators 0.6 to 3½ K. W.

AAGUTO OILLESS BEARING CO., Waynesboro, Pa. Folder advertising Arguto oilless bearings for lineshafts and countershafts in cotton mills and other locations where it is desirable to avoid the use of oil because of danger of contaminating the product.

WESTINGHOUSE ELECTRIC & MFG. CO., Pittsburg, Pa. Circular No. 1506 entitled "Recent Types of Arc Lamps and their Operation," by C. E. Stevens. The paper briefly discusses arc lamps in general, and describes the metallic flame arc lamp and its mechanism.

E. G. SMITH, Columbia, Pa. Catalogue of Columbia calipers, "which-way" pocket level, Columbia spherometer, steel rules, etc. The Columbia caliper is made in various styles, one of which is provided with a vernier that makes the reading of 64ths or 128ths as easy as 16ths with the ordinary plain graduation.

AMERICAN OXYHYDRIC CO., Milwaukee, Wis. Pamphlet on the oxyhydric process for cutting and welding metals. The apparatus and interesting examples of work done are illustrated, including clearing away the tangled steel debris resulting from a boiler explosion in the Pabst brewery, cutting 9-inch nickel-chrome armor plate, etc.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4705 on the Curtiss steam turbines for low pressure and mixed pressure. Various installations are illustrated, including a 5,000 K. W. low pressure Curtiss turbine generator at the 59th St. station of the Interborough Rapid Transit Co., New York.

GOULD & EBERHARDT, Newark, N. J. Folder entitled "The Building of a Reputation," giving a brief history of the concern and advertising the Eberhardt automatic gear-cutting machine for spur and bevel gears, automatic generating machinery for hobbing spur, worm and spiral gears, rack cutters and shapers.

COLBURN MACHINE TOOL CO., Franklin, Pa. Circular describing the Colburn floating reamer holder for use in boring mills with turret heads. (See MACHINERY, December, 1909.) These holders are made in two sizes, No. 1 having a No. 4 Morse taper socket and No. 2 a No. 5 socket, the maximum capacity being holes 3 and 4 inches diameter respectively.

ROCKWELL FURNACE CO., New York. Bulletin G on annealing, hardening, and tempering furnaces fired with oil or gas fuel. These furnaces are adapted for treating, hardening, tempering, case-hardening, and annealing tools, dies, taps, punches, cutters, screws, springs; nickel, chrome, vanadium, high-speed and carbon steel; brass, copper, silver, aluminum, etc.

GENERAL ELECTRIC CO., Schenectady, N. Y., has issued an attractive pamphlet, "The Dawn of a New Era in Lighting," which treats of the history of lighting from the tallow dip to the latest development in artificial lighting, *i. e.*, the tungsten lamp. The pamphlet describes the tungsten lamp and gives figures on its efficiency, cost of operation, and describes various applications of the lamp in interior lighting. The pamphlet is No. 3885 in the series of advertising material published by the company.

SCHUCHARDT & SCHUTTE, 90 West St., New York. Catalogue of automatic gear hobbing machines, hob grinding machines, hob milling machinery, profile milling machines and profile grinding machines. The catalogue will be found of general interest by gear makers. It contains an illustration of the Schuchardt & Schutte factory interiors, showing the erection of hobbing machines; also views of the Melville-Macalpine spiral reducing gear built for transmitting 6,000 horsepower from steam turbines to marine propellers.

BRISTOL CO., Waterbury, Conn. Bulletin No. 114, illustrating and describing Bristol's recording gages for pressure and vacuum; also Bristol's recording water level gages. The practice of recording data of pressures, vacuum, water level, etc., in power plants and other places is becoming more and more prevalent as the advantages of such records are recognized. The Bristol Co. has had twenty years' practical experience in the development and manufacture of recording instruments, and offers its experience to all interested in recording such data.

JOSEPH T. RYERSON & SON, Chicago, Ill. Ryerson Reference Book for 1910, being a complete list of the most comprehensive stock of iron, steel, machinery, and allied specialties in the world, to which are added useful tables and information for engineers, architects, contractors, structural iron workers, etc. The reference book contains 380 pages with index, and lists beams, angles, channels, T's, Z-bars, steel separators, flanges, and tank steel parts and other steel and iron specialties, boilermakers' machinery, including the Ryerson line of internal combustion machinery (see MACHINERY, July, 1909). The tables and other data will be found generally valuable by users of structural shapes, plates, etc.

CINCINNATI MILLING MACHINE CO., Cincinnati, Ohio. Catalogue of horizontal milling machines (cone and single-pulley types), vertical milling machines, accessories, attachments, etc. The catalogue contains 160 pages filled with illustrated and descriptive matter. Some important improvements on the Cincinnati Nos. 1, 1½, 2 and 3 cone-driven machines are shown, especially in the column and feed mechanism. The column now used is similar to that used on the Cincinnati high-power machines, being a complete box form, containing the entire feed mechanism. The catalogue also illustrates the Cincinnati universal cutter and tool grinder which is a necessary accessory of milling machine equipment. Mechanics will find it of interest and value, if for no other reason than because of the detail illustrations throughout, and the directions contained in the chapter "Erection and Care of Millers." A full index adds to the value by making reference to descriptions of machines, accessories, etc., easy, and obviates the necessity of thumbing over the pages until the desired matter is found.

NILES-BEMENT-POND CO., 111 Broadway, New York. Pamphlet entitled "Grinding—Not Milling—the Way to Machine Flat Surfaces," being an illustrated description of the Pratt & Whitney vertical surface grinder and some products. It is claimed that the Pratt & Whitney surface grinder with vertical spindle will grind from twelve to twenty times faster than ordinary surface grinders. The efficiency of the machine is partly due to the cup-shaped wheel, which covers the full width of the work while it reduces it to perfect flatness. The horizontal table facilitates chucking all ordinary work, and the magnetic chuck makes the chucking of small work very simple and rapid. Illustrations of work done comprise flat-irons aluminum castings, carbon segments, cast-iron flanges, circular saws, repeating rifle hammers and ejector levers, automatic pistol frames, knife blades, hardened steel planer knives, carpenters' planes, aluminum and iron automobile manifolds, automobile steering gear housings, automobile transmission gear cases, gear blanks, automobile cam shafts, typewriter parts, lathe chuck bodies, cast iron frames, etc. The pamphlet is a fine example of typographical work and will be found very interesting by all concerned in the economical and rapid production of surface ground work, whether they be shop managers, superintendents, foremen or machinists.

TRADE NOTES

WHITE CO., Philadelphia, Pa., is putting a gasoline-motor driven truck of 1½ ton nominal capacity on the market.

CHICAGO BELTING CO., Chicago, Ill., has opened a branch store at 71 Dey St., New York, with Mr. E. T. Toogood manager.

HUTHER BROS. SAW MANUFACTURING CO., Inc., Rochester, N. Y., announces that it also manufactures sheet steel specialties.

EXPORT CORPORATION, LTD., 29 Broadway, New York, wants estimates and plans of a complete plant for refining and briquetting salt.

RAE ELECTRIC VEHICLE CO., Springfield, Vt., is a new enterprise which will be ready for business in January. It is erecting a new factory.

THE SUPERIOR TAP CO., Springfield, Vt., has been reorganized, and will move to Charlestown, N. H., where a factory is being constructed for its use.

BAILEY AUTOMOBILE CO., Springfield, Mass., is making important changes in its factory and will bring out a new two-cycle motor for its 1910 cars. New machinery will be installed.

SPITZLE MFG. CO., Utica, N. Y., was recently made the sales agent of the Fulton Machine & Vise Co., Lowville, N. Y. The company will market the entire product of the Fulton Machine & Vise Co.

STANDARD WELDING CO., Cleveland, Ohio, has recently added to its large factory a two-story building giving 50,000 square feet additional space which will be utilized by the tube welding department.

WELLS BROS. CO., Greenfield, Mass., held its annual meeting of stockholders December 1 and elected the following officers: Frank O. Wells, president and treasurer; F. E. Snow, vice-president, and Messrs. Wells, Snow, White, Blake and Pratt, directors.

AIR BRAKE MAGAZINE, Meadville, Pa., is a new journal published by the Air Brake Magazine Co., and edited by Frank H. Dukesmith. As the name indicates, the journal is devoted to the principles, construction, action and use of steam and electric railway air brakes.

Q. M. S. CO. (Quincy-Manchester-Sargent Co.), Plainfield, N. J., has moved its Western office in Chicago from 1775 Old Colony Building to 738 First National Bank Building. The company's interests in the West will hereafter be taken care of by Mr. J. C. Hoof.

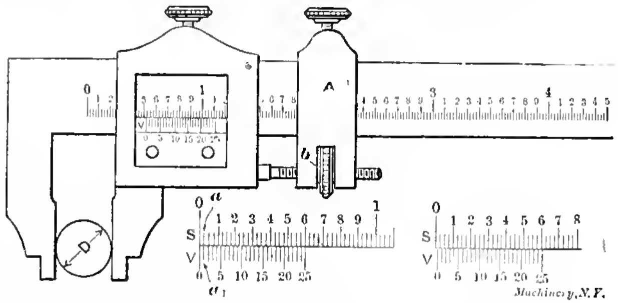
TOLEDO-MASSILLON BRIDGE CO., Toledo, Ohio, has recently added a new department to its business, having gone into the extensive manufacture of all kinds of cranes, hoists, coal and ore-handling machinery, etc. C. H. Tucker, recently of the Case Crane Co., is in charge of the new department.

Supplement to MACHINERY, February, 1910

Operations for the Article in this number entitled "Machine Shop Practice—The Vernier: Its Principle and Method of Reading"

SHOP OPERATION SHEET NO. 124

Franklin D. Jones — MACHINERY, February, 1910



Reading a Vernier

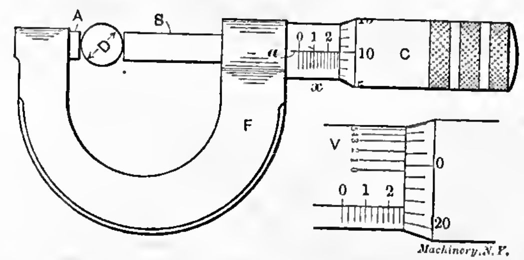
NOTE.—The vernier is an auxiliary scale that is attached to caliper squares, protractors, etc., for obtaining fractional parts of the sub-divisions of the true scale of the instrument. The above illustration shows a caliper square with a vernier scale V, reading to 0.001 inch.

1. A section of the true scale, together with the vernier scale, are shown in the enlarged detail views at S and V, respectively. On this particular instrument, the inch divisions of the regular scale are divided into tenths and each tenth into four parts, so that the finer divisions are fortieths of an inch. The vernier scale V has twenty-five divisions, and its total length is equal to twenty-four divisions on the regular scale or twenty-four fortieths of an inch. Therefore each division on the vernier equals 1/25 of 24/40 or 24/1000 inch (0.024). As 1/40 equals 25/1000 it will be seen that the vernier divisions are 1/1000 (0.001) inch shorter than those on the regular scale; so that when the zero marks of both scales coincide, the two first lines a and a_1 to the right, differ by 1/1000 inch; the next two by 2/1000, etc. Now if the zero line on the vernier is moved (as shown in the detail to the right), obviously the distance in thousandths of an inch will be indicated by the number of that line on the vernier that exactly coincides with a graduation line on the scale. In the illustration, it is the tenth line on the vernier that exactly coincides with one on the scale; therefore the distance between the two zero lines is 10/1000 (0.010) inch. If the vernier zero were moved to the right just twice this amount or 20/1000 (0.020) inch, the twentieth division would be exactly in line with one on the regular scale.

2. To measure the exact diameter D with a caliper square, adjust the sliding jaw until it is close to the work and then lock the slide A by the screw shown. With the nut b, which is used for making fine adjustments, move the jaw until it just touches the work. The distance that the vernier scale zero has moved to the right of the zero mark on the true scale (which equals diameter D) is then read directly in thousandths of an inch, by calling each tenth on the true scale that has been passed by the vernier zero, one hundred thousandths, and each fortieth twenty-five thousandths, and adding to this number as many thousandths as are indicated by the vernier. The vernier zero in the illustration is slightly beyond the five-tenths division; hence the reading is 0.500 plus the number of thousandths indicated by that line on the vernier that exactly coincides with one on the scale which, in this case, is 15, making the reading $0.500 + 0.015 = 0.515$ inch.

SHOP OPERATION SHEET NO. 125

Franklin D. Jones — MACHINERY, February, 1910



Reading a Micrometer

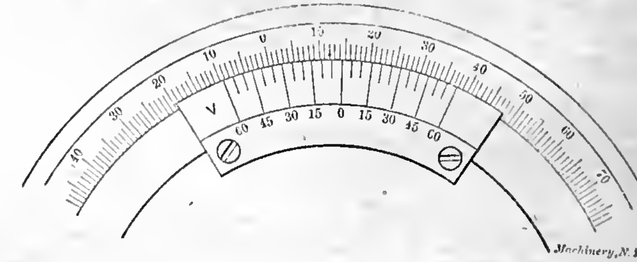
NOTE.—The micrometer caliper is used for taking very accurate measurements. The instrument consists principally of a main frame F, a measuring screw or spindle B which is threaded into a fixed nut in the frame F, and a thimble C, which turns with spindle B. The pitch of the thread on spindle B, and on practically all micrometer screws, is 1/40 of an inch, there being 40 threads on the screw for each inch of its length. Along the frame, as at x, there are graduations which are 1/40 inch apart; therefore when thimble C and spindle B are turned one complete revolution, they move in or out, a distance equal to one of the graduations or 1/40 inch, which equals 25/1000 inch. It is evident then that if instead of turning the thimble one complete revolution, it is turned say 1/25 of a revolution, that the distance between the anvil A and the end of spindle B will be increased or diminished 1/25 of 25/1000 of an inch. As the beveled edge of thimble C is graduated into twenty-five parts, measurements to within one thousandth of an inch are easily taken.

1. To measure the diameter D of a piece of work, adjust the spindle B until the work will pass between it and the anvil A, and then turn thimble C until the end of B just comes into contact with the work. Next count the number of whole divisions that are visible on the scale x of the frame, multiply this number by twenty-five (the number of thousandths of an inch that each division is equal to), and add to the product the number of that division on the thimble that coincides with the line a. The result will be the diameter expressed in thousandths of an inch. For example, the diameter indicated by the micrometer when set as shown in the illustration would be determined by multiplying the eleven divisions visible on the frame by twenty-five, and adding ten to the result, that being the graduation number on the thimble that coincides with the line a. Then D equals $11 \times 25 + 10 = 285/1000$ inch. As the numbers 1, 2, etc., on every fourth graduation, indicate hundreds of thousandths, the reading can be easily taken mentally.

2. By the addition of a vernier scale V on the frame (see enlarged detail view), measurements within one ten-thousandth part of an inch can be taken. Micrometers thus equipped are read as follows: First determine the number of thousandths, as with an ordinary micrometer. Next find a line on the vernier scale that exactly coincides with one on the thimble; the number of this line represents the number of ten-thousandths to be added to the number of thousandths obtained by the regular graduations. The reading shown in the illustration is $271/1000 + 3/10000 = 2713/10000$ inch.

SHOP OPERATION SHEET NO. 126

Franklin D. Jones — MACHINERY, February, 1910



Reading a Protractor Vernier

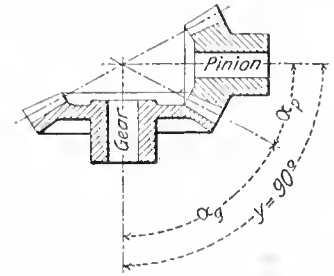
NOTE.—A protractor is an instrument that is used for the measurement of angles. The graduations on the protractors commonly used by machinists are ordinarily not finer than whole degrees, so that the instrument cannot be set to, nor measurements taken of, fractional parts of a degree with accuracy. By the addition of a vernier scale, the principle of which was explained on sheet No. 124, subdivisions of a degree are easily read.

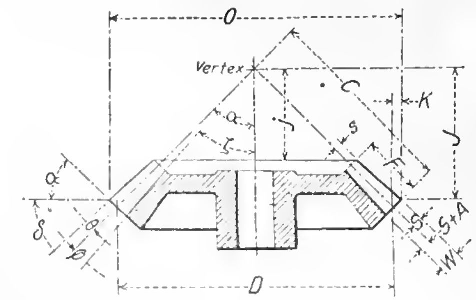
1. The vernier scale V of a Brown & Sharpe universal bevel protractor is shown in the illustration above. This particular vernier makes it possible to determine the angle to which the instrument is set within five minutes (5′) or one-twelfth of a degree. The degree, which is the unit of angular measurement—the same as the inch is a unit in linear measurement—is divided into sixty minutes, so that a division of a degree is expressed as so many minutes; thus 5½ degrees equals 5 degrees, 30 minutes (5° 30′). It will be noted that there are practically two scales of twelve divisions each, on either side of the vernier zero mark. The left-hand scale is used when the vernier zero is moved to the left of the zero of the true scale, while the right-hand scale is used when the movement is to the right. The total length of each of these vernier scales is equal to twenty-three degrees on the true scale, and as there are twelve divisions, each division equals 1/12 of 23 or 1 11/12 degree. One degree equals 60 minutes (60′), and 11/12 degree equals 11/12 of 60 or 55 minutes; hence each division on the vernier expressed in minutes equals $60' + 55' = 115$ minutes. Now as there are 120 minutes in 2 degrees, we see that each space on the vernier is 5 minutes shorter than 2 degrees; therefore, when the zero marks on the true and vernier scales are exactly in line, the first two graduations to the right or left are 5 minutes apart; the next two, 10 minutes; and the next two 15 minutes, etc. It is evident then that if the vernier zero is moved, say to the right, until the third line from it (also to the right) is exactly in line with one on the true scale, the movement will be equal to 15 minutes, as indicated by the number opposite this line on the vernier.

2. To read the protractor, first note the number of whole degrees passed by the vernier zero, and then count in the same direction the number of spaces between the vernier zero and that line which exactly coincides with one on the regular scale; this number of spaces multiplied by 5 will give the number of minutes to be added to the whole number of degrees. The reading of a protractor set as illustrated, would be 14 whole degrees plus 30 minutes (14° 30′).

I—BEVEL GEAR FORMULAS

Bevel Gears with Shafts at Right Angles.





Note: α_p = Pitch Cone Angle of Pinion
α_g = Pitch Cone Angle of Gear
N_p = Number of Teeth in Pinion, etc.

Use Rules and Formulas 1-21 in the order given.

No.	To Find	Rule	Formula
1	Pitch Cone Angle (or Edge Angle) of Pinion	Divide the number of teeth in the pinion by the number of teeth in the gear to get the tangent	$\tan \alpha_p = \frac{N_p}{N_g}$
2	Pitch Cone Angle (or Edge Angle) of Gear	Divide the number of teeth in the gear by the number of teeth in the pinion to get the tangent	$\tan \alpha_g = \frac{N_g}{N_p}$
3	Proof of Calculations for Pitch Cone Angles	The sum of the pitch cone angles of the pinion and gear equals 90 degrees	$\alpha_p + \alpha_g = 90°$
4	Pitch Diameter	Divide the number of teeth by the diametral pitch; or multiply the number of teeth by the circular pitch and divide by 3.1416	$D = \frac{N}{P} = \frac{NP'}{\pi}$
5	Addendum	Divide 1.0 by the diametral pitch; or multiply the circular pitch by 0.318	$S = \frac{1.0}{P} = 0.318P'$
6	Dedendum	Divide 1.157 by the diametral pitch; or multiply the circular pitch by 0.368	$S+A = \frac{1.157}{P} = 0.368P'$
7	Whole Depth of Tooth Space	Divide 2.157 by the diametral pitch; or multiply the circular pitch by 0.687	$W = \frac{2.157}{P} = 0.687P'$
8	Thickness of Tooth of Pitch Line	Divide 1.571 by the diametral pitch; or divide the circular pitch by 2.	$T = \frac{1.571}{P} = \frac{P'}{2}$
9	Pitch Cone Radius	Divide the pitch diameter by twice the sine of the pitch cone angle	$C = \frac{D}{2 \times \sin \alpha}$
10	Addendum at Small End of Tooth	Subtract the width of face from the pitch cone radius, divide the remainder by the pitch cone radius and multiply by the addendum	$s = S \times \frac{C-F}{C}$
11	Thickness of Tooth at Pitch Line at Small End	Subtract the width of face from the pitch cone radius, divide the remainder by the pitch cone radius and multiply by the thickness of the tooth at the pitch line	$t = T \times \frac{C-F}{C}$
12	Addendum Angle	Divide the addendum by the pitch cone radius to get the tangent	$\tan \theta = \frac{S}{C}$
13	Dedendum Angle	Divide the dedendum by the pitch cone radius to get the tangent	$\tan \varphi = \frac{S+A}{C}$

These dimensions are the same for both gear and pinion (Nos. 5–13).

THE MELVILLE AND MACALPINE REDUCTION GEAR FOR MARINE STEAM TURBINES

RALPH E. FLANDERS*

IT has been evident to the general public for some time past that the steam turbine has not been entirely satisfactory in its application to ship propulsion. There have been many direct evidences of this, such as the papers on the subject read before various technical societies in this country and Europe, and authoritative articles of the same character in various scientific journals. There have been even more ominous indications in the vicissitudes of actual installations. It has been very difficult, for instance, to get figures on the coal and steam consumption of the most important of the turbine-driven steamships. The figures would surely have been given out if they made even a satisfactory showing. There have, furthermore, been one or two actual failures, necessitating a return to reciprocating engines, though doubtless these failures were due to designing with insufficient knowledge or experience in this line.

The Nature of the Problem

The difficulty is that the turbine, to be efficient and compact, must have a high velocity of rotation, while the propeller, working in a dense medium and imparting a comparatively slow velocity to the ship which it propels, should work at a far less rotative speed. Up to the present time this discrepancy has been met by modifying the design of both the turbine and the propeller, running one at a slower speed and the other at a higher speed than would be indicated by a design for economy in either alone. As a result the combination has an efficiency which, while high enough to make its use commercially possible, is, nevertheless, very far below what ought to be obtained.

Among the various compromises that have been suggested are, the use of electrical transmission between a turbine-driven dynamo and a motor driving the screw; a hydraulic transmission set involving a turbine pump and motor; and the use of gearing. The problem has also in a way been attacked from another angle by using a combination of reciprocating and low-pressure turbine engines.

Of the various direct solutions of the problem proposed, but one has ever been tried on a large scale—the use of gearing to reduce the speed of an efficient turbine to that required for an efficient propeller. An experimental apparatus of this kind in a full size, high-power application has been designed by Rear Admiral Melville and his engineering associate, Mr. John H. Macalpine. This apparatus was built for them, through the good offices of Mr. George Westinghouse, at the Westinghouse Machine Co., of Pittsburg, Pa. Mr. Westinghouse invited MACHINERY to send an editorial representative to examine this reducing gearing, and investigate its design and construction.

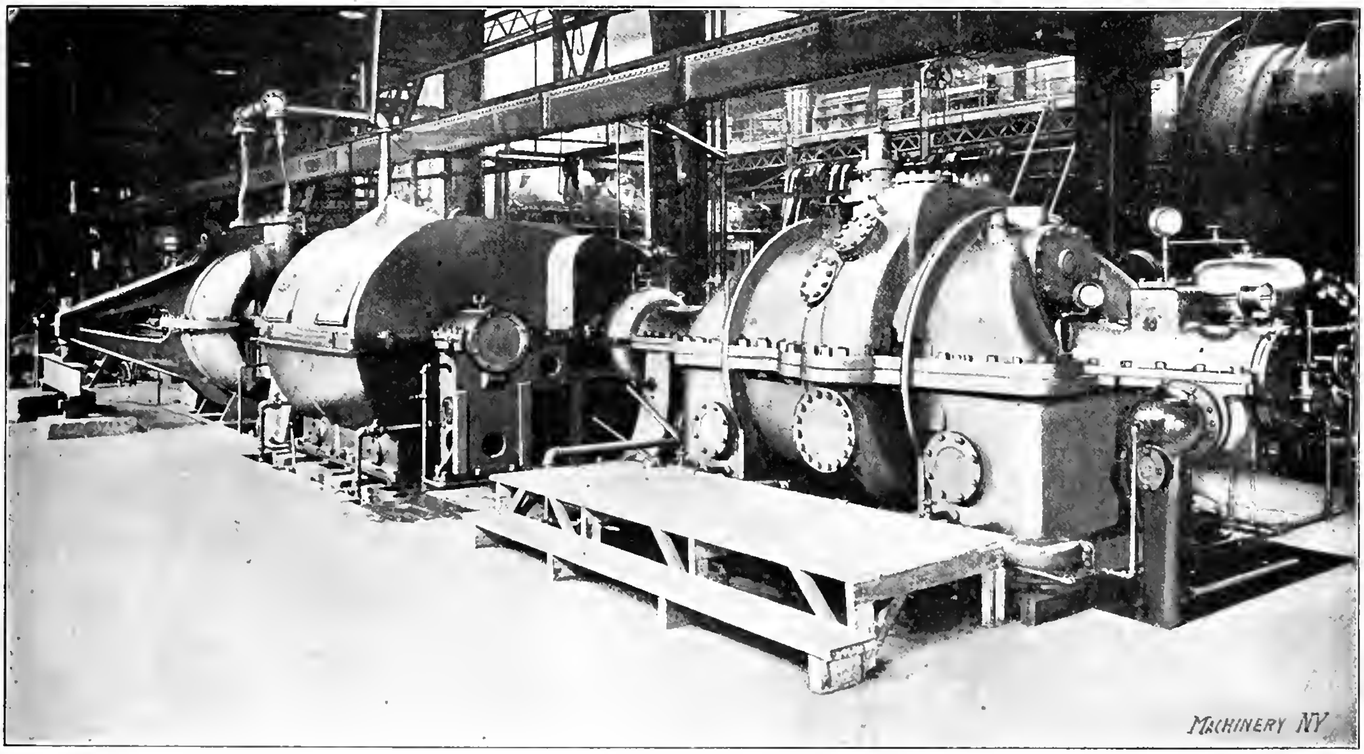

Fig. 1. 6,000-horsepower Steam Turbine, Melville-Macalpine Reducing Gearing, and Hydraulic Dynamometer, set up on Floor of Testing Department

General Description of the Gear

Mr. John H. Macalpine, one of the joint inventors of the gear, and Mr. H. T. Herr, general manager of the Westinghouse Machine Co., very courteously gave their time to explaining to the writer the principles of the construction and operation of the device. It is installed on the testing floor of the plant, as shown in Fig. 1. The steam turbine for driving the gearing in the test is shown at the right. This turbine, running at a normal speed of 1,500 revolutions per minute, is easily capable of giving 6,000 H. P. The gearing itself is mounted in the casing in the center of the line of mechanism. The third member is a water brake or dynamometer of unusually ingenious construction, which will be described later.

The construction of the gears and their supporting mechanism is clearly shown in Figs. 2, 3 and 4. A small pitch was deemed essential if a reasonable absence of noise was to be secured. This necessarily meant broad teeth, in view of the fact that the 6,000 horsepower had to be transmitted at a

* Associate Editor of MACHINERY.

pitch line velocity of nearly 100 feet per second, if the tooth pressure was to be kept within the limits desired. The gearing is of the herringbone type, as shown. The pinions have 35 teeth each, and the gears 176, a hunting tooth being introduced to equalize the wear. The pitch is 1¼ inch and the helix angle is 30 degrees. The thickness of the pinion teeth at the pitch line was made ⅛ inch greater than that of the gear, with the idea of compensating for the more rapid wear to which the pinion would be subjected. Detailed dimensions of the gear teeth are given in Fig. 6. The forgings for the gears were made of an ordinary grade of mild steel, obtained from Messrs. Krupp, and the cutting of the teeth was done by Messrs. Schuchardt and Schütte, of Chemnitz, on the Pfauter gear-hobbing machine. This machine and the hobbing process have been previously described in MACHINERY.*

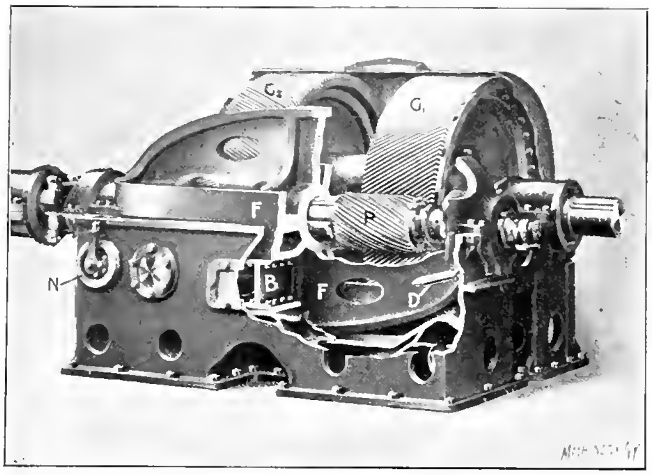

Fig. 2. Sectional View of the Reducing Gearing, showing the Floating Frame

The Floating Frame and Its Action

Two difficult problems had to be solved by the designers in the mounting and use of these gears. One problem is that of the application of a lubricant to teeth running at the high peripheral speed employed. The other problem is the maintenance of a working contact over the full length of face of gears as broad as those here used. In considering the magnitude of this last problem, the great size and power of the gears and the strain to which they are subjected should be remembered; and it should also be stated that, in the opinion of the designers, a separation of even 0.001 inch of the surfaces which should be in contact, would be considered beyond allowable limits. These difficulties have limited the use of herringbone gears in the DeLaval turbine to comparatively small powers; but by the invention of a new method of mounting, they have been here overcome.

In the first place, the sleeve on which the pinion teeth are cut is carried by three liberal bearings in the exceedingly rigid frame F, as shown in Figs. 2 and 4. In Fig. 3 the top of this frame is shown removed. The stiff frame supports the pinion so that its deflection under the load it transmits is negligible. The gear itself is stiff enough without added support, being of a hollow drum construction, somewhat different from that shown in Fig. 2.

It is not merely necessary, however, to give assurance that the pinion shall maintain its rigidity. It must further be so mounted as to accommodate itself to imperfections in its own teeth and those of the gear it runs with, if assurance is to be given that the contact and the distribution of pressure will extend over the whole face of these wide gears. This assurance is given by the mounting of frame F on a flexible support. This support is formed by two sections of an I-beam B, whose elastic web permits frame F to be rocked in a vertical plane parallel with the gear axes, under the influence of forces imposed by the tooth action. These forces will be best understood by reference to Fig. 5.

The pinion sleeve, it should be understood, is free to take its own position longitudinally within a limited range. Neglecting the very slight friction of the well-lubricated teeth, the total forces of the tooth contacts, as indicated by $B\,E$ and $B'\,E'$ in Fig. 5, will be nearly at right angles to the teeth at B and B'—that is to say, they will be at 30 degrees to the vertical; hence the two parallelograms of forces will be similar. Now the horizontal forces at $B\,D$ and $B'\,D'$ are the only axial forces acting on the pinion, owing to the method of driving, which will be explained later. If these forces are not equal, the pinion will at once shift longitudinally, which it is free to do until they are equal. The two parallelograms of forces then become equal to one another in every respect and the vertical force $B\,F$ is equal to the vertical force $B'\,F'$. But besides this longitudinal movement of the pinion, the frame in which it is mounted is free to rotate about the center point O by the flexing of the web of I-beam B (see Fig. 4); hence it follows that the moment of the vertical force $B\,F$ about O must be equal to that of $B'\,F'$ about the same point; as $B\,F$ equals $B'\,F'$, the arms of these levers $O\,B$ and $O\,B'$ must be equal. Thus it is claimed that not only will the total forces on the teeth of P_1 and P_2 be equal, but that the distribution will be made similar by the rocking of the floating frame and the longitudinal self-adjustment of the pinion sleeve, so that the centers of pressure B and B' will be similarly placed.

This equal distribution of the pressure, it will be seen, besides requiring the rocking of the frame, requires absolute freedom in the slight endwise movement of the pinion sleeve. This is secured by an ingenious driving device and universal coupling shown at the farther end of the pinion shaft at the left of Fig. 3, and indicated diagrammatically in Fig. 5. The coupling consists of two flanges C_1 and C_2 mounted on the turbine shaft T and the pinion shaft S. These two couplings are connected together by two transverse links $L_1\,L_2$ and by a center pintle, care being taken not to make this restraint redundant. The shaft T can, therefore, only rotate the shaft S through links L_1 and L_2, and no longitudinal force can be transmitted through these. Even when shaft S is moved longitudinally a considerable distance from its central position, the longitudinal forces are so small as to be negligible. The pinion, therefore, has perfect freedom of axial movement in its bearings. To permit the free rocking movement of the frame, the pinion is driven by shaft S, which passes completely through it to the end distant from the coupling, where it is keyed and bolted. This shaft has clearance in the central hole of the pinion sleeve, and is so flexible that it imposes practically no constraint on the pinion and floating frame.

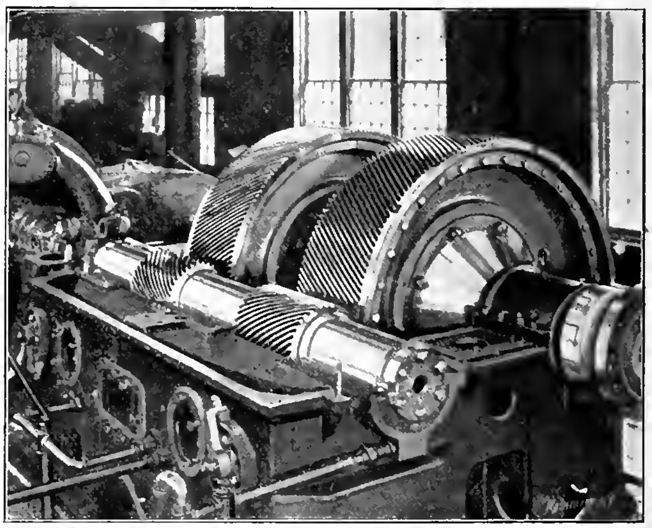

Fig. 3. The Gearing with the Cover and the Top Half of the Floating Frame Removed

Elaborate calculations were made by the designers to find out how much the teeth would come out of contact with each other in varying from normal alignment in the way permitted by the floating frame and its connections. The rigidity of the floating frame, it has been found, is so great, that under full load the end bearings will be lowered relatively to the center by not more than 0.0005 inch.

The effect of the floating frame, as has been described, is

* See article entitled "Gear Cutting Machinery" in MACHINERY, Engineering Edition, May, 1908.

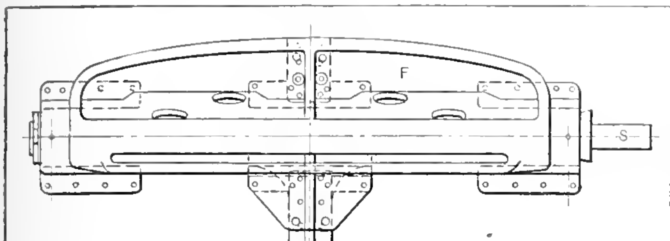
to prevent any opening of contact from errors in alignment in a vertical plane. Without this frame, such errors would be serious. The opening of contact due to a warping of the I-beam supports, and a consequent lack of parallelism in the horizontal plane, has also been investigated; it was found to be negligible for the involute form of tooth, but not so favorable for the cycloidal. The latter also has the disadvantage as compared with the involute that it will not run properly except at the exact center distance, so its use was not considered for this work. The involute form, on careful investigation, showed a number of other advantages which space forbids taking up here.

It was found that the warping of the I-beam supports of the floating frame, while it did not affect seriously the contact of the teeth, was nevertheless unstable. That is to say, there is no tendency to return to a normal position. It was therefore necessary to confine the movement of the frame in this direction. For this purpose struts D and D' are provided (see Figs. 2 and 4) which leave the frame free to rock, but hold it against horizontal movement. They bear in seats of the frame in one end and on the points of screws at the other, which are adjusted and locked by the mechanism shown at N in Fig. 2. This arrangement greatly facilitates the true setting up of the floating frame without interfering to the slightest degree with the freedom of movement in the vertical plane.

Oiling the Teeth and Bearings

It was mentioned that the oiling provisions had something to do with the success of the apparatus. Oil is supplied to the bearings under a pressure of about 10 pounds, and runs through them with a constant flow under conditions common to such machinery. Special provisions had to be made, however, to get the oil into the working surfaces of the teeth, where it must be used to reduce the friction or lost work to a minimum, and to give assurance of long life to these working surfaces. Owing to the high peripheral velocity (6,000 feet per minute) oil simply sprayed on the teeth would be immediately thrown off by centrifugal force.

The plan devised for employing the oil effectively consisted in providing a supply pipe with a series of jets directing the lubricant under a considerable head right at the point where the teeth of the pinion are rolling into mesh with the gear teeth. Even when thrown off of the pinion, under these conditions it is thrown back onto the gear, and *vice versa*; there is absolutely no escape for the oil except by running through the meshing teeth and out on the further side. This oil pipe has, of course, to be held securely, as it is in a position where it would wreck the gearing if it got loose. An examination of the precautions taken for holding it, however, gives the observer perfect confidence on this score. Piping is provided both above and below the gearing to permit the latter to be reversed, as is necessary for marine work. In connection with the amount of opening possible for the teeth, it should also be remembered that the presence of oil in the bearings and on the gear teeth tends to lessen this factor below the calculated amount.



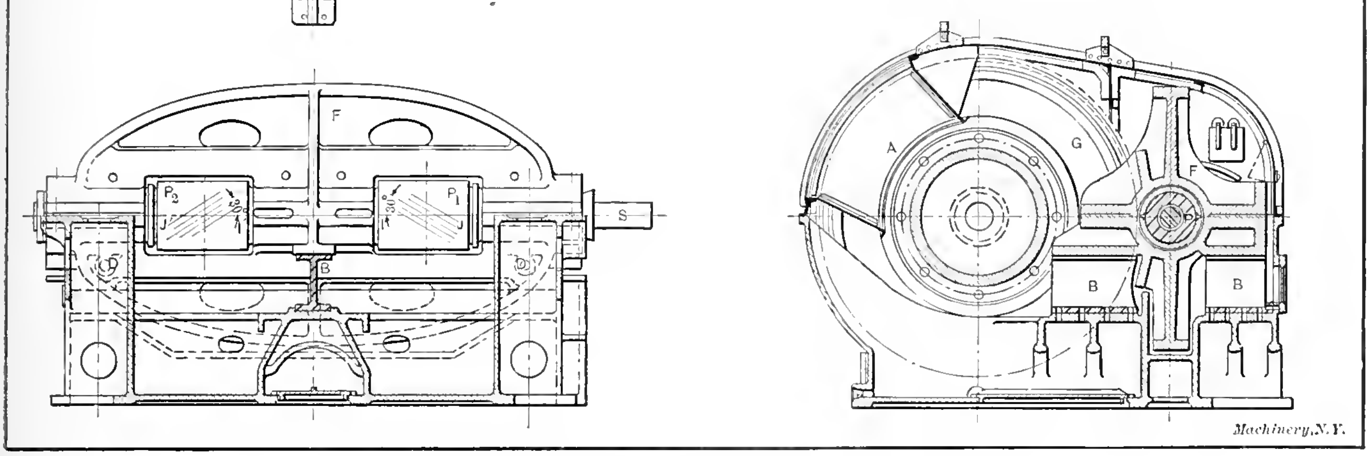


Fig. 4. Details of the Construction of the Gear, showing the Floating Frame, etc.

While it has not been possible to do more than touch lightly on the immense amount of calculation and investigation undertaken by the designers of this mechanism, the writer has said sufficient, he is sure, to show that the highest degree of technical skill has been brought to bear on the subject, and that the proposition is one of engineering pure and simple, there being no evidence of "cut-and-try" or guesswork methods in the design. It may be said in this connection that the gearing has been carefully calculated to have a large margin of strength over the shafting, which transmits the power to it from the turbine and connects it with the propeller. It is, therefore, confidently believed to be the strongest link in the chain between the turbine and the propeller; and the latter, or the shaft which drives it, will be the first to fail in the event of dangerous racing, the striking of wreckage, or other similar accident.

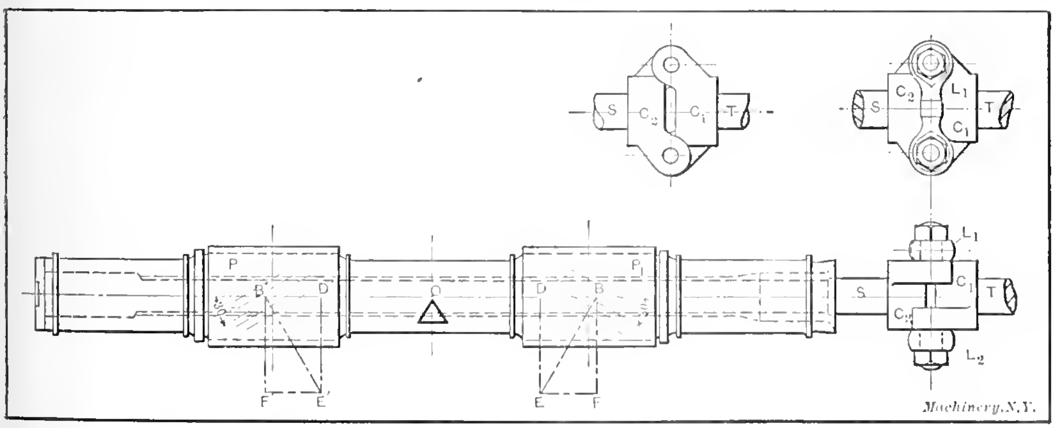

Fig. 5. Action of the Forces on the Gear Teeth in Distributing the Pressure over the Full Width of the Face

Testing the Effect of the Floating Frame

The two points in testing the apparatus were, of course, to determine, first, the character of the bearing obtained; and second, the efficiency of the mechanism. To be sure that the gears have the carrying capacity desired, it must be made certain that the floating frame and other precautions taken

distribute the bearing over the whole length of the teeth. The efficiency was important first from the standpoint of power consumption, and second from the standpoint of durability. The amount of power wasted in a mechanism bears naturally a close relation to its length of life. If it consumes a large amount of power in friction, it may be assumed that it will eat itself away in a short space of time.

Before starting up the machine under power, the teeth of the pinion were red leaded, and it was turned by hand until the large gear had revolved once. At this time the top part

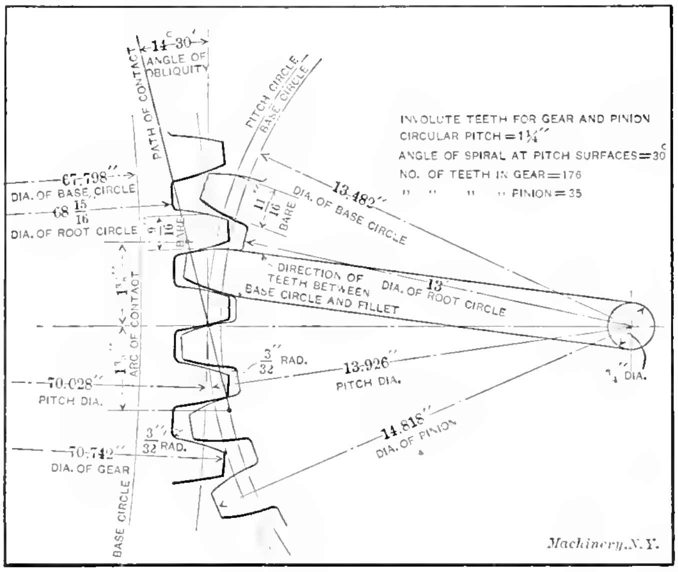

Fig. 6. View of Gear Teeth on Plane at Right Angles to their Axes, showing Dimensions for both Gear and Pinion

of the floating frame was not in place, so that both pinion and gear were fully exposed. It was found that the teeth bore a little hard from one to two inches at both ends of both the right- and left-hand spirals of both the pinion and the gear, and hardly at all in between these points. This was doubtless due to the slight spring in the hob in getting down in to the work and in leaving the cut.

The gear was then run by the turbine at three or four hundred revolutions per minute and with practically no load, without putting the top part of the frame in place. This, of

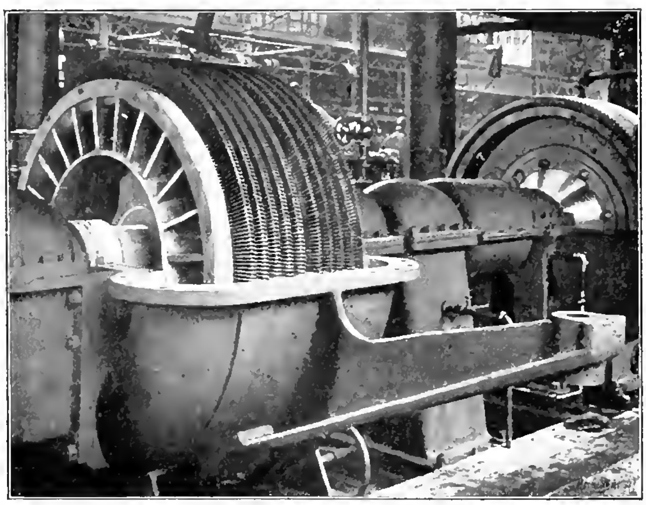

Fig. 7. The 6,000-horsepower Hydraulic Absorption Brake with Upper Half of the Casing Removed

course, brightened the hard bearings at the end of the teeth. These were scraped and then the erection of the gear was completed. After running a second time under light load the bearings came up in spots along the whole length. After a second scraping a load of 6,700 horsepower at 1,500 revolutions per minute was put on. From this time on the markings came up very satisfactorily. It is not probable that these marks are marks of real wear. They are more likely the effect of the application of pressure to the loosened surface left by the cutting and scraping tools.

The accurancy demanded in the cutting, and further refined by the simple scraping operations just described, was of a far higher degree than that met with in any other job of gear cutting within the writer's knowledge. First, the width of face in proportion to the pitch is very great (the total width of face being forty inches); and, second, the stiffness and rigidity of the gears and their mountings are such as to show plainly any inaccuracy of a kind that could not be compensated for by the floating frame.

The Hydraulic Brake

For the efficiency tests, to find a form of brake or dynamometer that would continuously absorb the 6,000 horsepower which it was desired to transmit through this gearing, was no easy matter. When it is considered that the heat generated per hour by the absorption of one horsepower is 2,545 British thermal units, and that for 6,000 horsepower it would be the equivalent of the combustion of 1,200 pounds of coal per hour, the magnitude of the problem is easily comprehended.

An ordinary Prony friction brake would certainly be out of the question. The use of a generator and water rheostat offered other difficulties, particularly in the matter of obtaining the degree of accuracy desired. It was, therefore, determined to build a modification of a hydraulic brake which had been in use in the plant of the Westinghouse Machine Company for many years for the testing of all steam turbines manufactured by it. This brake had to be redesigned for much lower speeds than the origiual construction, and consequently was of greatly increased size. It is shown set up on the testing floor at the extreme left in Fig. 1, while details of its construction are illustrated in Figs. 7 to 10 inclusive.

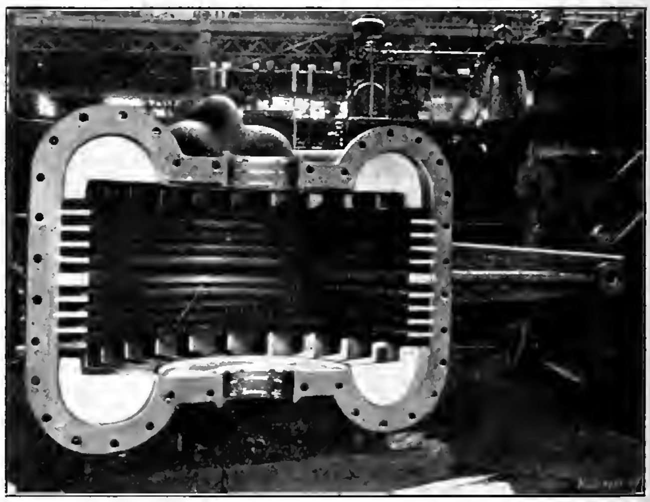

Fig. 8. Interior View of Upper Half of Casing, showing Blades

The dynamometer consists, briefly, of a rotor connected to the source of power and provided with regular turbine blades; a casing containing baffling blades ranged in alternate rows with the turbine blades of the rotor; provision for keeping the casing supplied with a greater or less amount of water which, by the action of the blades, furnishes the resistance; and a mounting for the casing so that it is pivoted about the axis of the rotor, and is restrained from revolving only by a weighing arm extending from the side, which bears on a lever connected to the scale.

Figs. 7 and 8 show the blading very well. This is mounted in the casing and the rotor in the same way as for regular turbine work. Fig. 9 shows the arrangement. The curved blades revolve, while the straight, cross-hatched ones are stationary. Water entering at *A* moves axially to the right and left, where it is picked up by the curved blades and started to whirling. As it passes through these it is dashed against the stationary blades and constrained to stop its peripheral movement, being forced again axially to the next row of revolving blades, which, in turn, start it to whirling again—and so on. This alternate picking up of the water by the rotor and checking of it by the stationary blades furnishes the resistance to the movement.

The path of the water after it leaves the blades is more plainly seen in Fig. 10. It passes through the curved side passages *F* in the direction shown, guided by baffle plates.

Here it is again thrown to the interior of the rotor, where it returns to the center opening, marked *A* in Fig. 9. The water is thus passed through the blades over and over again.

The amount of resistance which this dynamometer offers at a given speed is dependent on the amount of water in the casing, so that the load is increased by letting in more water. This is done through passages *C* and *C'*. The immense amount of heat generated may be allowed to pass off in the form of steam through openings *D* and *D'*. Instead of allowing the power to be dissipated entirely in steam, however, it is more practicable to keep a constant flow of water through the brake. The cool water comes in at *C* and *C'*, and goes out heated at *E* and *E'*. By proper manipulation of the valves the amount

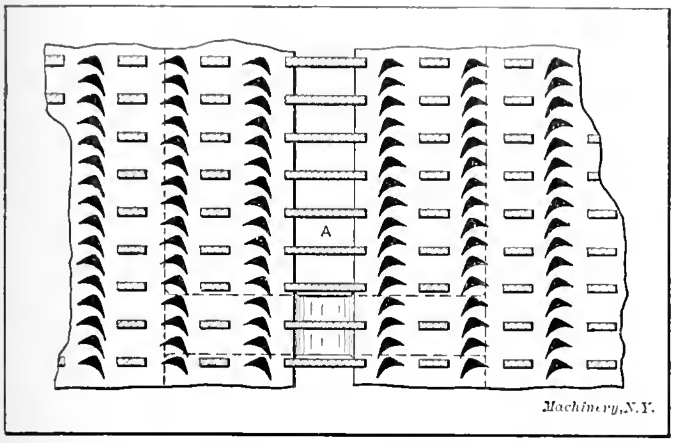

Fig. 9. Arrangement of Rotating and Stationary Bladee whose Action on the Contained Water furnishes the Reeistance

of water, and the consequent amount of power absorbed, can be very delicately regulated. In Fig. 1 the inlet openings are shown connected to the supply pipe by flexible hose.

Measuring the Power Furnished to the Gearing

The apparatus just described satisfactorily solved the problem of measuring the power delivered by the gearing, which, with the power furnished to the gearing, had to be known in order to ascertain the efficiency. At the beginning of these tests it was found that the ordinary means of measuring the power input, owing to the very high efficiency of the gearing, sometimes gave resulting efficiencies of over 100 per cent. Evidently then, most refined means must be taken for this work.

While the indicator method of calculating power cannot be used on the turbine, it is possible to calibrate any particular machine of this type so that its power is accurately obtained by using the absolute inlet pressure of commercially dry steam as a measure. To do this it was only necessary to keep the speed and the exhaust pressure constant. By substituting for the reduction gearing a dynamometer, connected directly to the turbine shaft, it was then possible to lay out a diagram in which the horsepower output was given for various inlet pressures. This line was practically straight, so that values interpolated between points obtained by actual observation are quite dependable. Tests of the apparatus made with this method of calculating the horsepower input gave efficiencies ranging from 98.5 to 99 per cent with the horsepower varying from 3,771 to 6,057.

The results obtained were so surprisingly good that it was thought advisable to check the tests by using some other method of determining the amount of power lost. For this the simple and very satisfactory method was followed of determining the amount of heat carried away by the lubricating oil coming from the bearings and the teeth of the gears. Practically all the transmission loss in the gear would appear as heat in the oil. In one of the tests checked by this method, when the brake horsepower read 5,088, it was concluded that 64.17 horsepower was accounted for by the heat of the oil, with a resulting efficiency of 98.75 per cent, which agreed with the results obtained in the previous tests. This figure is probably a little too high, as there is an indeterminate small quantity of heat radiated from the gear casing and the oil piping that has not been accounted for. Even if this were 20 per cent of that accounted for, which is not probable, the efficiency indicated would still be 98.5 per cent.

A Forty-hour Test

Besides many shorter trials an extended forty-hour endurance test was given the apparatus. This began at 3:15 P. M., Saturday, October 16, 1909, and continued until 7:15 A. M. on the following Monday morning. This test was witnessed by officials especially delegated for the purpose from the Bureau of Steam Engineering of the United States Navy. During this trial an average load of 6,048 horsepower was carried at a speed for the gear of 300.6 revolutions per minute. There was nothing in the operation of the gear to indicate that this load might not be carried indefinitely.

It will be readily understood that a constant draft of 6,000 to 7,000 horsepower on the boiler plant could not be long maintained without interfering with the regular operations of the company. As a consequence, the duration of the test was necessarily limited to the period between noon on Saturday and the early morning of the following Monday. A continuous test of five or six days, representing the time of an average transatlantic voyage, would doubtless be of more popular interest, but it would be of no more real scientific value. When the parts of the apparatus have once attained a maximum temperature, which remains constant for a reasonable period, and providing that temperature is within the limits generally recognized as conservative, a condition has been established which is capable of being maintained indefinitely. In the present instance the trial continued over thirty-four hours after the temperature conditions had become constant.

Personal Observations

It is, perhaps, as a job of gear cutting that this apparatus will be most interesting to the readers of MACHINERY. For that reason it may not be inappropriate to record some of the personal observations of the writer on the running of the gears. Exceptional opportunities were furnished for observation, as Mr. Herr kindly arranged for the running of the apparatus under a load of 3,000 horsepower which was the

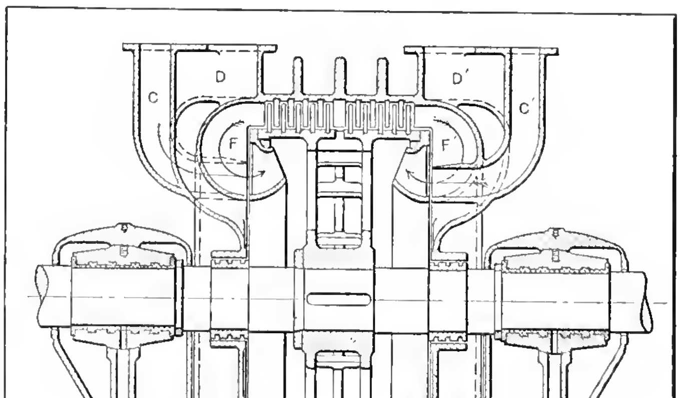

Fig. 10. Section through Hydraulic Brake, showing the Various Water and Steam Passages

full boiler capacity available for testing work without shutting down the machine shop.

Transmitting this 3,000 horsepower and reducing the speed from 1,500 to 300 revolutions per minute, the gearing ran in a way to inspire a high degree of confidence. What noise there was was not objectionable, and some of it was doubtless accounted for by air waves set up by the revolving teeth. There was little or no trace of sounds synchronous with the revolutions of the large gear. The metallic sounds emanating from the casing were of a resonant character, with no indication of grinding or rubbing. This was true even when the sound was transmitted by a pencil resting on the machine

frame and pressed against the lobe of the ear, or by a knife held between the teeth and resting on the frame.

The wide and satisfactory bearing across the whole working surface of the teeth, mentioned in an earlier paragraph, was plainly seen. The action of the floating frame could also be easily observed, owing to the fact that a little inaccuracy had been committed somewhere, perhaps in the mounting of the gears, which caused the pinion and frame to vibrate vertically at each revolution of the large gear. The full bearing just described was maintained by the floating frame under these conditions. The writer was unable to detect with assurance any sound or vibration synchronous with the rate of revolution of the large gear and the rocking of the floating frame, so that the action appeared to be as easy and regular as if conditions had been perfect. In setting up the apparatus the shafts of the two gears were set some 0.020 inch nearer together at one end than at the other, so that this inaccuracy also was taken care of without any harmful effects.

The writer noted scraper marks along the pitch lines of the pinion. On inquiry it was learned that scraping was done to relieve the bearing at the pitch line, where there is no rubbing and consequently little wear. Doing this, it was thought, would tend to make the gears wear more evenly over the whole area. The further away from the pitch line we get in an involute gear tooth the more rapid is the wear. Diagrams showing this have previously been published in MACHINERY.* It has been proposed that this scraping be done occasionally on the pinions while they are in service.

It appears that there is but one probable source of inaccuracy which the floating frame will not take care of. This is inaccuracy in the helix angle. The included angle between the teeth of the gears must be the same as the included angle between the teeth of the pinion. To insure this, so far as the original construction is concerned, it is only necessary to have the gearing ratios in the hobbing machine when cutting the gear and pinion in exactly the same proportion as the ratios between the numbers of teeth in the gear and pinion. It will not do to obtain approximate helix angles. Inaccurate mounting of the large gears might tilt them so that the helix angle would be variable about the circumference. Running with red lead, as described, is a safe test of accuracy in this respect.

At first the writer was inclined to criticise the use of as steep a helix angle as 30 degrees. So far as running smoothly is concerned, the full requirements appear to be met when the gears are given merely enough slant so as to gain a tooth or slightly more in the width of the face of the gear. A very much less angle than 30 degrees would be sufficient under the conditions of lubrication provided for securing the desired sensitiveness to the end movement with varying pressure. There is one other consideration which enters here, however, which inclines one to believe that the larger angle is the better. As explained, the natural tendency of the gears is to wear out of shape and bear only at the pitch line. This would result in a series of point bearings. Now, with a 30-degree angle, such as is shown in Fig. 5, there would be bearing wherever each of the tooth faces, as shown by the diagonal lines, crosses the center line of the engraving. If the angle were smaller there would be fewer points of contact, and if there were a gain of only one tooth in the width of face the tendency would be to wear down to a single point bearing at a time on a single tooth. This, however, would be a tendency only, and would never actually occur, but it is proper to avoid that tendency by increasing the pressure angle. The only disadvantage of a large pressure angle lies in the fact that it makes it more difficult to get a good job of gear hobbing; but as a good job was obtained with the 30-degree angle there was no chance for criticism here.

In the operation of this device it is evident that the temperature of the oil will play an important part in giving warning of possible trouble, in the same way that it determined the efficiency of the apparatus. So long as the oil runs cool, within certain temperatures determined by experiment and experience, so long may the engineer rest assured that the apparatus is working efficiently and without rapid deterioration. The heating of the oil will give him notice to look for trouble. As for errors from accidents, as already explained, the gear teeth are the strongest link in the chain between the turbine and the propeller, so that trouble will be expected elsewhere first.

In regard to the matter of oil temperature it may be stated that in the forty-hour test previously described, absorbing 6,000 horsepower, the average running conditions gave a temperature rise of about 30 degrees Fahrenheit with a flow of about 591 pounds of oil per minute. These temperatures are so low and the consequent efficiency so high that the designers feel confident that the normal capacity of the gear may safely be set much higher than 6,000 horsepower—perhaps as high as 10,000 horsepower.

It will be noted that a rather low grade of material was used. This allows room for a considerable increase in strength and durability without change of proportions. It is possible also to nearly equalize the life of the pinion and the gear by making the former of a considerably higher grade of material. It would be advisable, however, to permit the pinion to wear out the faster, as it is more easily and cheaply renewed than the gear. In view of the high efficiency and consequent small wear of the teeth it would not seem to be necessary to make the pinion teeth thicker than the gear teeth as they are shown in Fig. 6, so the expense of making two hobs for this work can be saved.

Expected Results in Practice

It may, perhaps, be interesting to note some of the advantages that will follow a successful application of this device to marine propulsion. In the case of the *Mauretania* or the *Lusitania*, for instance, it is probable that the steam consumption is at least 14.5 pounds per shaft horsepower per hour, while turbines of similar capacity running at normal speeds, operating with the reducing gear, should not exceed 11 pounds per shaft horsepower per hour. This means that the boiler capacity (taking into account also the improved efficiency of a low speed propeller) could be reduced from 70,000 shaft horsepower to about 45,000 horsepower, making a reduction of over 35 per cent in the coal consumption. Reckoning on unofficial figures, this would make a saving in coal of $5,300 per voyage, with a corresponding decrease in the cost of wages and maintenance. An increased cargo capacity would also result, not only from the reduction of over 1,600 tons in coal, but also in the great reduction in weight of machinery and the space necessary to accommodate it.

Still further advantages are claimed for war vessels, particularly in the matter of economy at the regular cruising speeds. With the smaller dimensions also of the high-speed turbines thus made possible the engineer will be able to start them cold instead of having to pass through the long and (in war time) dangerous warming-up process that now appears to be necessary. Further improvements contemplated for these turbines will entirely obviate any danger in quick starting. The inquiries sent in and the tentative plans under way for both naval and merchant vessel installations for this reducing gear indicate the interest that is felt in it by naval engineers.

Too much cannot be said for the firmness of Messrs. Melville and Macalpine and the courage of Mr. Westinghouse, in determining to make the trial of this construction on a full size model. Anything less than this would have been unsatisfactory. The questionable point was the ability of the apparatus to transmit high powers at high velocities with high efficiency, and this question could only be settled by actually transmitting high powers at high velocities with high efficiency. As an example of engineering and invention this reducing gearing is admirable; as a piece of gear cutting, it is remarkable. Its practical application will be awaited with great interest, and with great confidence as well, on the part of those who have had an opportunity to investigate it.

* * *

One of the most essential details of the aeroplane flying machine is a light-weight motor, which combines reliability and high power with small weight. It is stated by an English journal that Sir Hiram Maxim has designed an all-steel motor of 87 H. P. which weighs only 210 pounds.

HEATING AND VENTILATING OFFICES IN SHOPS AND FACTORIES*

CHARLES L. HUBBARD†

The writer's articles in past issues of MACHINERY on shop heating and ventilation have been confined to the machine and erecting rooms, without any special mention of the conditions to be met with in the proper ventilation of the offices and drafting-rooms. As a matter of fact, the requirements are more exacting here than in the shop proper where the cubic space is usually large compared with the number of occupants, and where, under average conditions, the workmen are more actively engaged than those employed in office work. If clear and alert minds are required anywhere about a manufacturing establishment, it is in the offices and drafting-rooms, and such a condition can be brought about only by providing the rooms with an abundance of pure, fresh air at the proper temperature and without drafts.

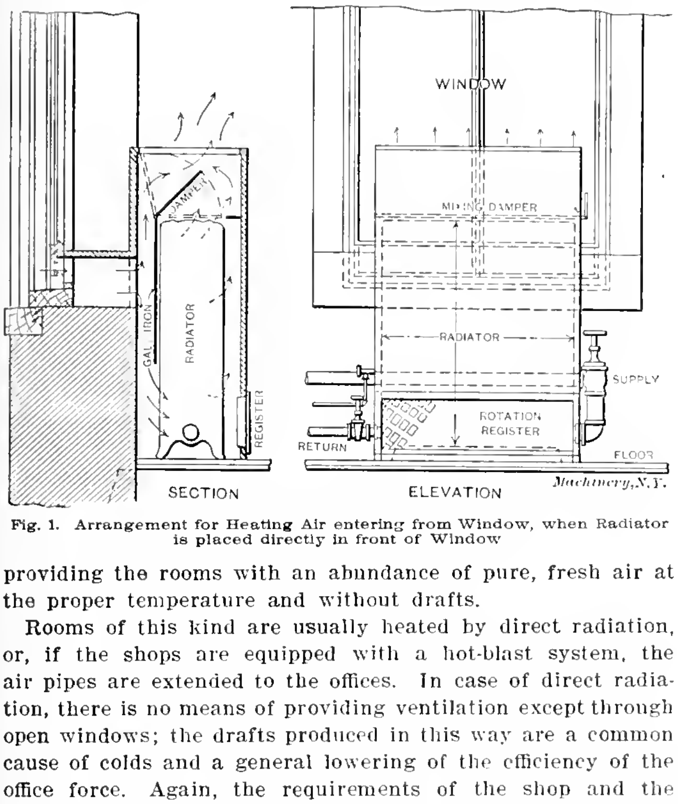

Fig. 1. Arrangement for Heating Air entering from Window, when Radiator is placed directly in front of Window

Rooms of this kind are usually heated by direct radiation, or, if the shops are equipped with a hot-blast system, the air pipes are extended to the offices. In case of direct radiation, there is no means of providing ventilation except through open windows; the drafts produced in this way are a common cause of colds and a general lowering of the efficiency of the office force. Again, the requirements of the shop and the office are not the same, and a hot-blast system which gives satisfactory results in the former may be far from suitable for office ventilation. When the air is rotated within the building it is hardly suitable for the offices on account of odors which it may contain and also because its purity is hardly up to the standard required for this purpose. Again, if the entire air supply for the hot-blast apparatus is taken from out-of-doors, and is therefore of the required purity, the temperature requirements may not be the same for the office as for the shop, and the chances are that the former will become overheated unless the registers or dampers are partly closed which, of course, results in a corresponding reduction in the air supply.

Simple Means for Heating and Ventilating Without Using a Fan

It is the object of this article to point out several different ways, more or less efficient according to their cost, by means of which the ventilation of the offices may be improved. Let us first take the case of an office heated by direct radiators and where the finish of the room is such that the matter of appearance is not of great importance. The arrangements shown in Figs. 1, 2, 3, and 4 can be made without great expense by the shop carpenter, with a little assistance from a galvanized iron worker. The idea in each of these cases is to bring fresh air in through the window by raising the lower sash slightly, and to pass the air over and between the sections of the radiator before delivering it into the room. Arrangements of this kind cannot be depended upon to always deliver a fixed quantity of air like a fan, because the amount will vary somewhat with the strength and direction of the wind and also with the outside temperature, but fair results may be obtained in this way at a very reasonable cost.

The objection is sometimes raised that the radiator being proportioned for direct work only, cannot be depended upon to warm outside air for ventilation also. In a considerable number of cases coming to the attention of the writer, no trouble has ever been experienced from this cause. Direct radiators are commonly proportioned for zero weather and therefore, much of the time, are larger than are necessary, and also, as the air passes over them at a higher velocity and lower temperature, their efficiency is much increased. In extreme weather the amount of fresh air can be reduced temporarily, or the window can be closed entirely and the air rotated over the radiator by openings provided for that purpose.

Fig. 1 shows the method of enclosing a radiator which stands directly in front of a window and projects above the sill. The casing is made of ⅞-inch sheathing with galvanized iron damper and inner casings as shown. When the mixing damper is thrown to its extreme upper position, as shown by dotted lines, all of the entering air passes downward back of the radiator, and then upward between the sections, where it becomes heated and is discharged into the room through the open top of the casing. When it is desired to reduce the temperature of the room, the mixing damper can be thrown to the right, thus admitting a mixture of hot and cold air without reducing to any great extent the volume of air supplied. By closing down the damper on top of the radiator, practically all heat will be shut off. A register placed in the front of the casing, near the bottom, serves to take air from the room when it is desired to use the radiator for heating only, as at night time.

Fig. 3 shows a plan, elevation and section of the casing and damper when the radiator stands at the side of a window instead of in front, as in Fig. 1. In this instance the whole casing is made of galvanized iron, although wood may be used if desired. The general principle is the same here as in Fig. 1, the only difference being its adaptation to another position of the radiator. The register for the rotation of air in this case is replaced by a door in the front of the casing, which may be opened at night or when ventilation is not required.

In Fig. 2 the radiator occupies a position across the end of the room at right angles to the window. Here the arrangement of casing and damper is somewhat different from those already described. In this case the air is delivered into the room through a register face or grille at the end of the boxing, instead of at the top, as before. This arrangement is only adapted to pipe radiators or a deep sectional radiator of very open pattern, as the air passes through it lengthwise instead of upward between the sections. The mixing damper here extends across the end of the radiator and deflects the entering air either through the radiator or over it, according to the temperature desired. The radiator is enclosed in a galvanized iron casing open at each end, while the passages for the cold air are of wooden sheathing, as shown. Air is admitted for rotation through a door or register in the wooden boxing.

Sometimes, in buildings of mill construction with heavy brick walls, the radiators are set in recesses in front of the windows. A very satisfactory way of encasing them and admitting fresh air is shown in Fig. 4. With this arrangement no extra space is required, as the front of the casing is in line with the inner face of the wall and does not project into the room. A thorough mixture of the warm and cold air currents is obtained by carrying up a shield above the mixing damper, as shown, and delivering the air near the sash.

Using Fans for Impelling the Air for Heating and Ventilation

Having taken up some of the simpler methods of improving the ventilation in offices and drafting-rooms, let us now consider various ways in which the air supply may be made more reliable under all conditions. The only practical way of doing this is by the use of a fan, and to get the most satisfac-

* For additional information on heating and ventilation, see "Sizes of Pipe Mains for Hot Water Heating," and articles there referred to, in the September, 1909, issue of MACHINERY; also Reference Series No. 39, "Fans, Ventilation and Heating."

† Address: 283 Central St., Auburndale, Mass.

tory results it is best to provide a separate apparatus for these rooms, unless special means are used for regulating the temperature of the air supplied when the regular shop system is made use of. There are two ways of ventilating by means of a fan; one is to exhaust the vitiated air and depend upon inward leakage around doors and windows for a fresh supply, and the other is to force in fresh air and allow the foul air to find its way out either by leakage or through specially provided flues or transoms. Both supply and vent fans are made use of in special cases, but this is not usually necessary under

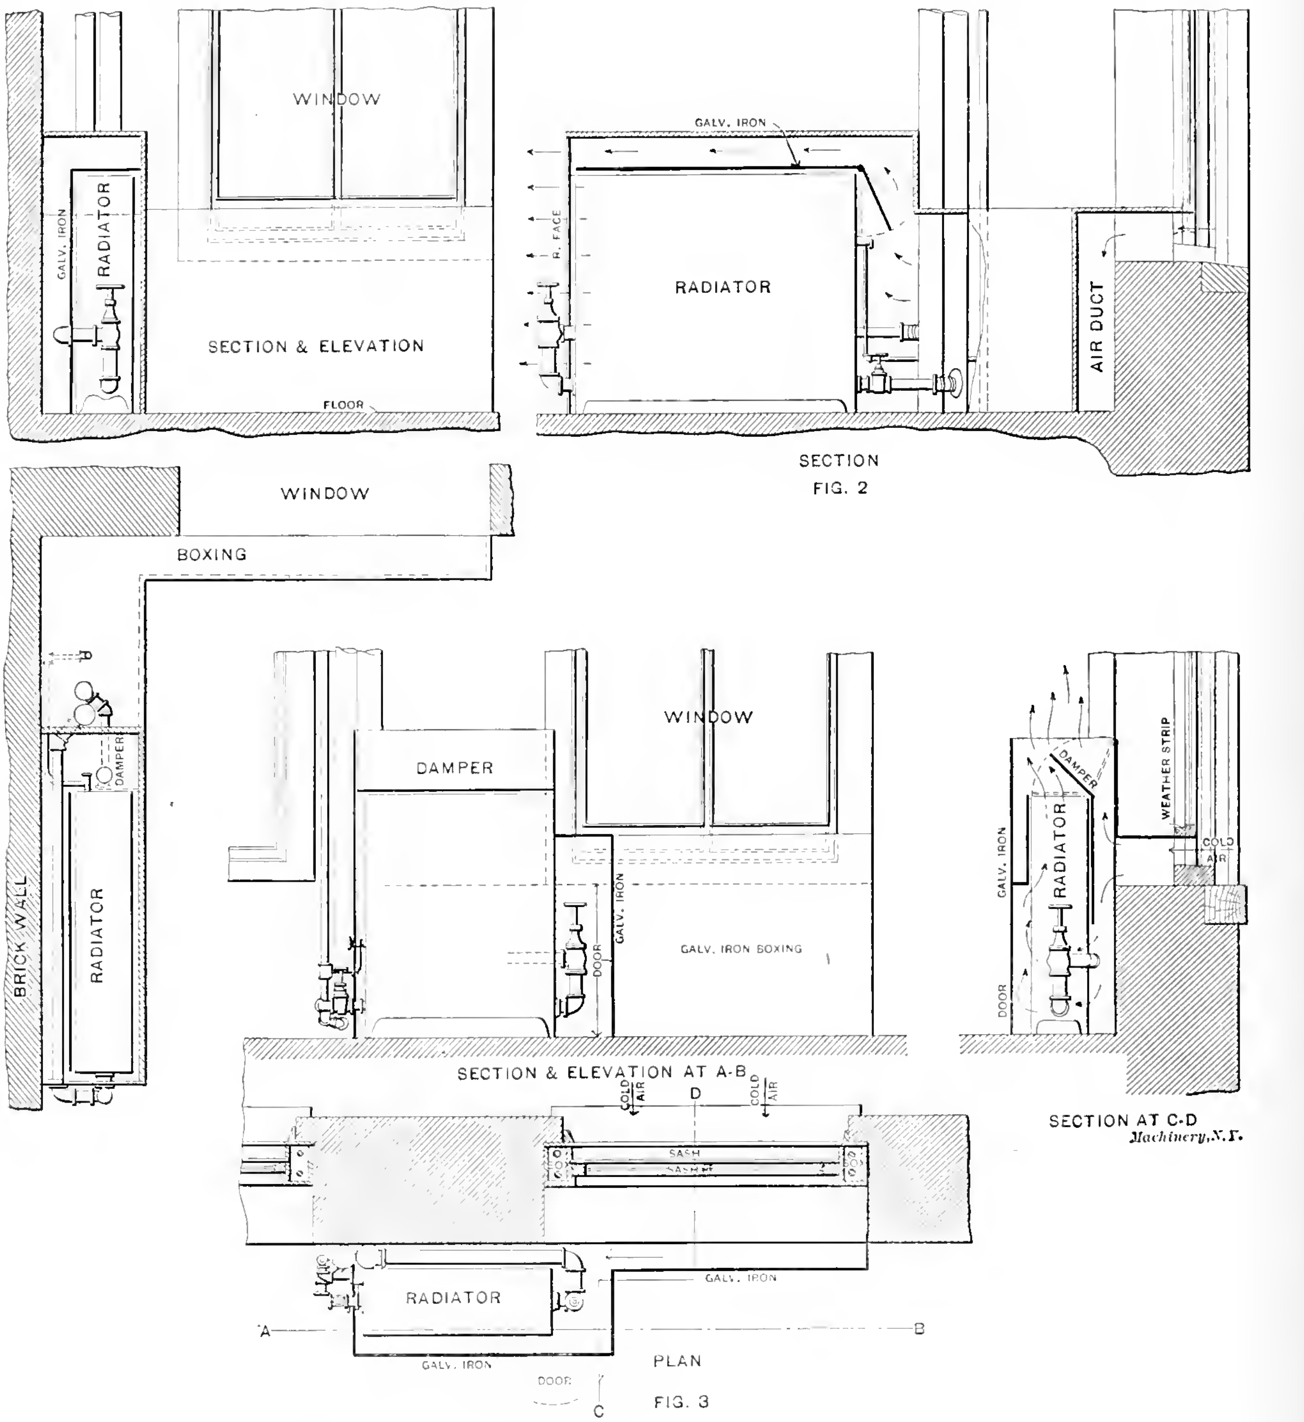

Fig. 2. Arrangement used when the Radiator is placed along a Wall at Right Angles to the Window
Fig. 3. Arrangement used when the Radiator is not placed in front of the Window

ordinary conditions. The method of supplying fresh air under pressure is more satisfactory for general ventilation, as it gives an opportunity of warming it and also permits of better distribution. When the exhaust system is used the fresh air at outside temperature leaks in, and in so doing is very liable to produce uncomfortable drafts near doors and windows.

The device shown in Fig. 5 is the simplest form of fan supply. This, in a sense, is a makeshift, but for single rooms where it is desired to improve the ventilation without very much expense it may be made to give very good results when properly installed and operated. This is adapted to rooms with sufficient direct radiation to warm them comfortably in zero weather. Such rooms, as already stated, will be overheated a greater part of the time, unless part of the radiators are shut off. The upper part of rooms heated in this way contain a considerable body of pure air at a temperature ten to fifteen degrees higher than that of the air near the floor; hence, if a certain amount of outside air can be mixed with this to bring the temperature down to 68 or 70 degrees, it will gradually fall to the breathing level, and thus, by proportioning the outside air supply to the surplus heat given off by the radiators, a very marked improvement in the purity of the air may be obtained.

The apparatus consists of an ordinary desk fan placed in a wooden boxing so arranged as to draw outside air from the top of a window, the upper sash being dropped slightly, and to discharge it in a thin fan-like sheet near the ceiling. The object of this is to thoroughly mix it with the warm air of the room before it has a chance to fall in the form of a cold draft. Narrow registers, with cords for opening and closing from the floor, are placed in each side of the boxing around the fan, as shown. When the cold air supply is too great,

and drafts are felt, the sash may be partially closed and the side registers opened slightly, as may be required. In this way the cold air is reduced and part of the supply is drawn from the room and recirculated. This, of course, reduces the ventilation, but the volume of fresh air must be sacrificed rather than to allow the presence of cool drafts. A 12-inch desk fan run on the medium speed will answer very well for

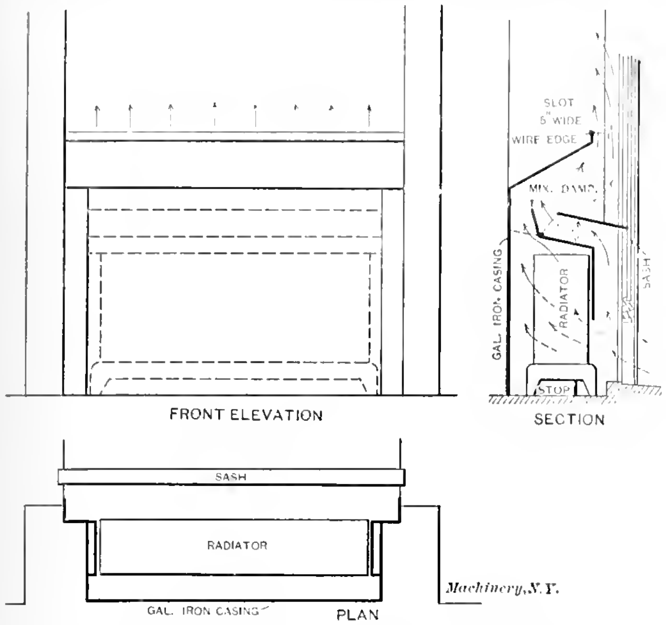

Fig. 4. Radiator placed in front of the Window, in a Niche in Thick Brick Wall

a room containing from 6 to 8 people. The diffuser opening may be about 4 inches in depth by 4 feet in length, the object being to secure a thorough mixing of the air.

A better arrangement, though more expensive, is shown in Fig. 6. This is adapted to the ventilation of several rooms by extending the distributing duct from the fans by means of suitable branches. The apparatus is hung from the ceiling

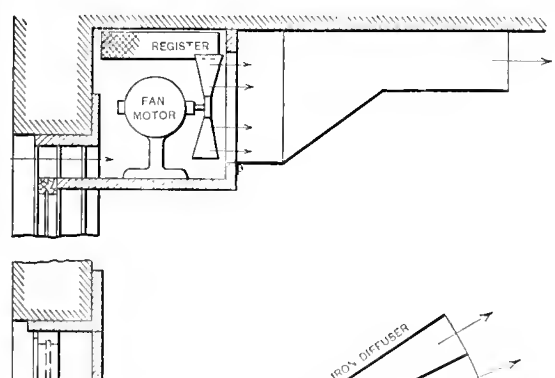

Fig. 5. Simple Arrangement for Desk Fan Ventilation

at some convenient point in the shop, as shown in Fig. 7, and takes its air from the upper part of a near-by window. The air is warmed by means of a special heater made up of pin radiators, and divided into three or four separately-valved sections for regulating the quantity of heat as required at different seasons of the year. Close regulation for varying the temperature of the air during different parts of the day is secured by the use of a mixing damper which "by-passes" a part of the air through a separate passage under the heater, where it mixes with the hot air just before it enters the fan.

An important point in an arrangement of this kind is to keep the cold air by-pass entirely separate, as shown in the section in Fig. 6, so that the air will not be warmed to any extent while being drawn past the heater. Otherwise it will be difficult to secure a sufficiently low temperature in mild weather. The mixing damper may be operated by hand, being adjustable, so that it can be set in any desired position. A better arrangement is to use one of the systems of automatic control, with a "graduated" mixing damper, as by this means the apparatus requires no particular attention after the thermostat is once set.

This type of apparatus is more especially adapted to cases where the rooms are heated by direct radiation, and the air supplied at a temperature of 68 or 70 degrees, for ventilation only. The heater can be made of sufficient size to both ventilate and warm the rooms if desired, although if the space to be warmed is of considerable extent, it is more common to use the outfit shown in Fig. 8, simply because it is more compact. If the heater in Fig. 6 is used for ventilation only, a "hot-air" thermostat should be placed in the duct and set to maintain an air temperature of 68 or 70 degrees. If the heater is proportioned to warm the rooms as well, a "room" thermostat should be used instead, this being placed upon an

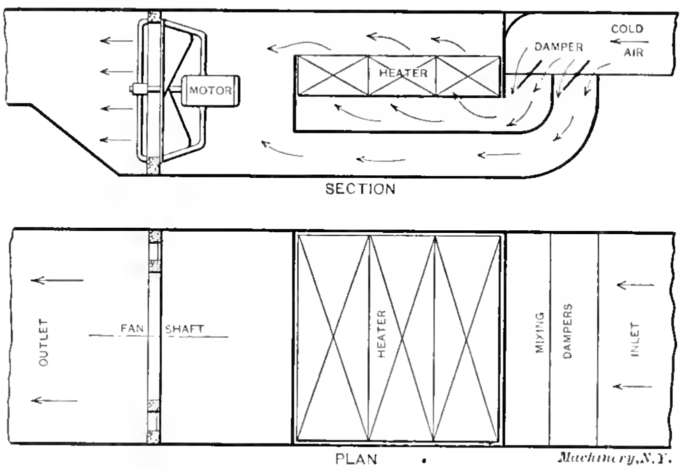

Fig. 6. Arrangement for Ventilating with Heated Air, or for both Heating and Ventilation

inner wall of the room. In case the air is to be delivered at a fixed temperature for ventilation only, a dial thermometer should be placed in the side of the air duct at some convenient point beyond the fan. This is necessary for setting and adjusting the thermostat if automatic control is used, and for operating the hand mixing damper in other cases. When the apparatus is used for heating also, all adjustments of thermostat and damper are done by means of an ordinary wall thermometer, which indicates the temperature of the room. The fan shown in this case is of the disk type, driven by a direct-connected motor. If more convenient, a belted high-speed motor may be used, or the fan may be driven from a convenient countershaft. High-speed motors are not usually objectionable about a shop, as quietness of operation is not of great importance in locations of this kind.

The computations for determining the size of fan and heater are simple. The air supply should be based on 2,400 to 3,000 cubic feet per occupant per hour, which allows a small margin for overcrowding at times without inconvenience. The square feet of surface in the heater for ventilation may be computed by the equation

$$S = \frac{O \times C \times 1.3}{1,500} \qquad (1)$$

in which

S = square feet of radiating surface

O = number of occupants,

C = cubic feet of air per hour per occupant = 2,400 to 3,000.

When the heater is used for warming the rooms in addition to ventilation, the following may be used:

$$S = \frac{(O \times C \times 1.3) + T}{1{,}000} \qquad (2)$$

in which S, O, and C are the same as in (1), and T = the total heat loss from the rooms in heat units per hour. The value of T in average cases may be found by multiplying the glass surface by 90, the net wall surface by 20, adding the results, and multiplying by the following factors, according to exposure:

TABLE I

Exposure	Factor	Exposure	Factor
North	1.32	Northwest	1.26
East	1.12	Southwest	1.10
South	1.0	Northeast	1.22
West	1.20	Southeast	1.06

The size and speed for the average disk fan and the horsepower of motor is given below.

TABLE II

Diam. of Fan, Inches	Revolutions per Minute	Cubic Feet of Air per Minute	Horsepower of Motor
18	530	1,000	0.08
21	450	1,400	0.09
24	400	1,800	0.12
30	320	2,900	0.18
36	270	4,200	0.25

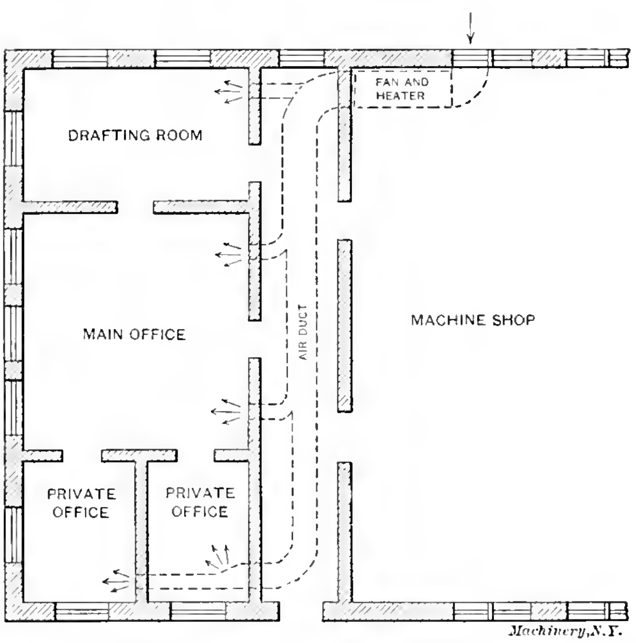

Fig. 7. Plan of Offices with Apparatus shown in Detail in Fig. 6 installed

Example: The offices and drafting-room in a shop contain an average of 36 people; there are 300 square feet of window surface and 600 square feet of wall surface. The exposure is west. What will be the size and speed of disk fan, and horsepower of motor to drive it? Also, how many square feet of pin radiation will be required.

We have 36 × 3,000 ÷ 60 = 1,800 cubic feet of air required per minute, which from Table II calls for a 24-inch fan running at 400 revolutions per minute and requires 0.12 horsepower to drive it. The square feet of surface in the heater is found by substituting the known quantities in equation (2); the first step is to find the value of T.

(glass) 300 × 90 = 27,000
(wall) 600 × 20 = 12,000

39,000 × 1.20 = 46,800.

Substituting in the equation, we have

$$S = \frac{(36 \times 3{,}000 \times 1.3) + 46{,}800}{1{,}000} = 187.$$

Fig. 8 shows an outfit which may be used in the same way as the one just described, when it is desired to have the apparatus as compact as possible. In this case a blower of the steel plate type is used instead of a disk fan, and a pipe heater of the regular hot-blast type takes the place of the pin radiators. This apparatus may be supported upon a platform or upon I-beams suspended from the ceiling or roof of the shop. The same idea regarding air-ways and mixing damper as in the arrangement shown in Fig. 6, is carried out here. The deflector in front of the heater prevents the air from being drawn directly across the hot pipes when the mixing damper is set for all, or nearly all, cool air. The mixing damper shown is for hand manipulation. In case the automatic arrangement is employed, the double damper shown in Fig. 6 should be used.

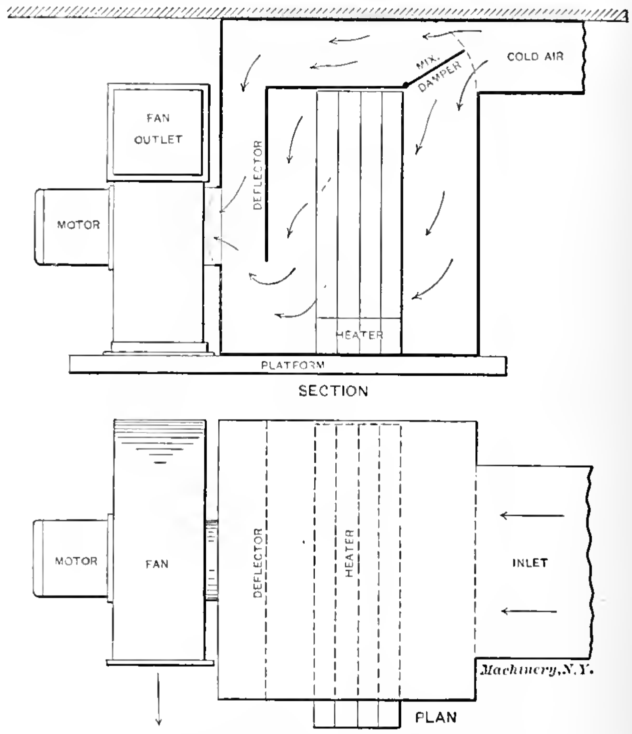

Fig. 8. A Compact Apparatus for both Heating and Ventilation

Pipe heaters for ventilation only should be 6 or 8 pipes deep, and the square feet of heating surface may be computed by equation (1) by substituting 1,800 for 1,500 in the denominator of the second member. When used for heating as well as ventilating, the heater should be from 12 to 14 pipes deep, and the surface computed by equation (2), substituting 1,200 for 1,000 in the denominator. In all of the computations for heaters it has been assumed that steam at a pressure of about 5 pounds would be used.

The piping for a heater of the hot-blast type is shown in Fig. 9. The special point brought out here is the method of making the return connections from the different sections with the main return. Each separate return in this case is sealed against the others by a siphon loop to prevent the condensation from backing from one into the other, which is apt to occur if this precaution is not taken to prevent it. As the coldest air strikes the outer sections, condensation is more rapid and the pressure is slightly less than in the inner ones; hence the necessity of sealing the returns. As the pressure in the return main is always slightly higher than in the heater, owing to the drip connection with the supply main, it is necessary to make the legs connecting with the heater longer than the others, as the highest column of water is always in this side of the loop.

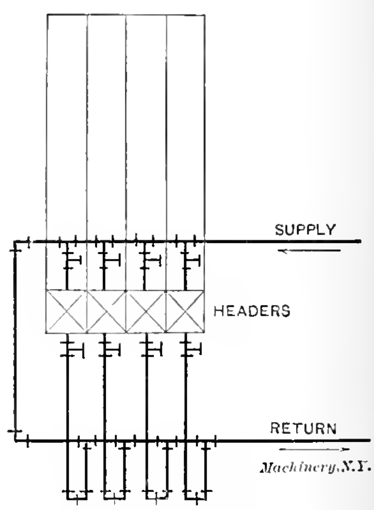

Fig. 9. Piping for a Heater of the Hot Blast Type

Of equal importance with the fan and heater is the method of distributing and discharging the air to get the best results without perceptible drafts. Fig. 10 shows an outlet for delivering air from the side of a duct where diffuser blades are

used for spreading the air as it enters the room. An adjustable deflector is provided to catch the desired amount of air it is desired to deliver at each outlet. Fig. 11 shows a diffuser outlet and adjusting damper for use when the air is discharged at the end of a branch instead of from the side of a duct as in Fig. 10.

When the main shop is heated by a hot-blast system taking all, or a considerable portion of its air from out-of-doors, an

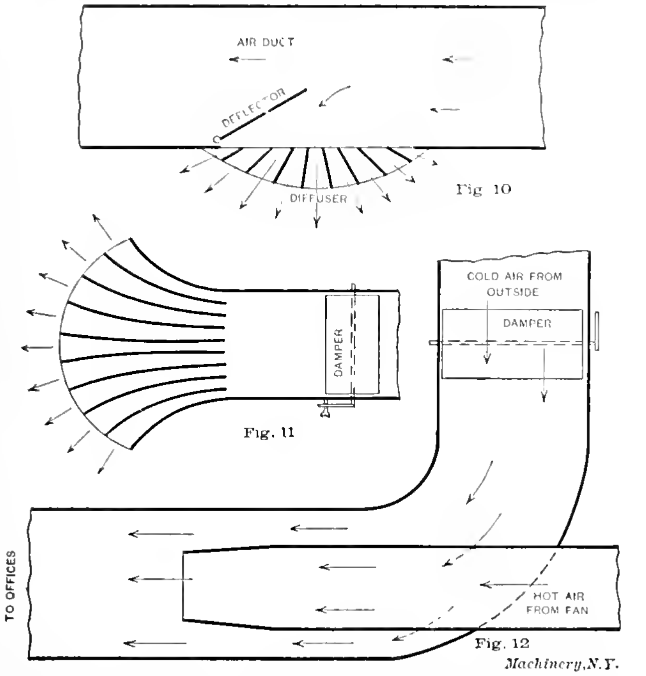

Fig. 10. Outlet for Hot Air from Side of Duct. Fig. 11. Diffuser Outlet and Adjusting Damper for End of Branch Duct. Fig. 12. Injector Arrangement for Mixing Hot and Cold Air

"injector" arrangement like that shown in Fig. 12 may be used for mixing a certain amount of cold outside air with the hot air from the fan, when the temperature of the rooms becomes too high. In this way the temperature may be lowered without reducing the air supply; instead, it will be increased, because the amount of hot air will remain the same while a certain amount of outside air has been added for cooling it. Fig. 13 shows the way of connecting the outside air supply to the "injector." It is well to make this connection some distance back from the outlets to the rooms, in order to give an opportunity for a thorough mixture of the air before reaching the rooms. The amount of cool air required can be regulated by means of a damper.

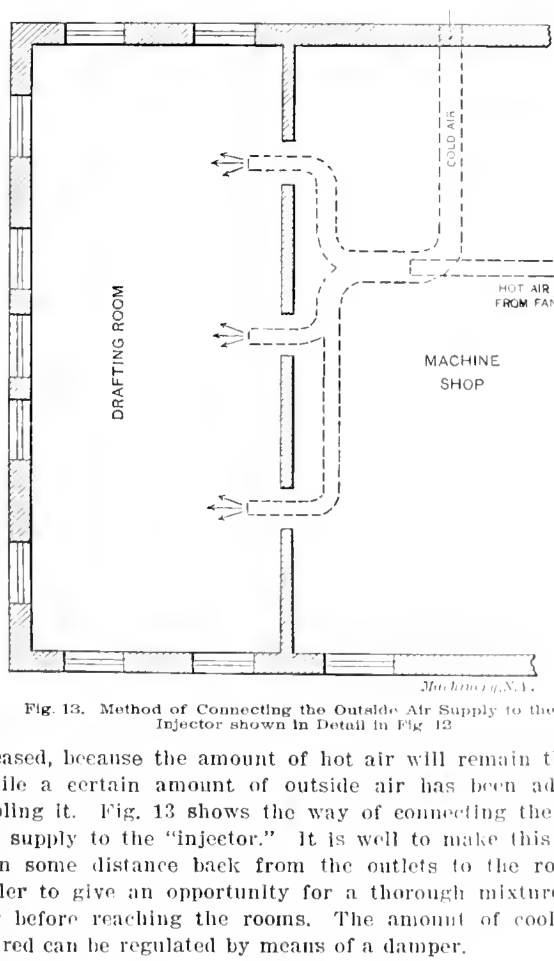

Fig. 13. Method of Connecting the Outside Air Supply to the Injector shown in Detail in Fig. 12

The size and speed of the blower type fan and the horsepower of motor, can be obtained from Table III, which has been computed for this class of work.

TABLE III

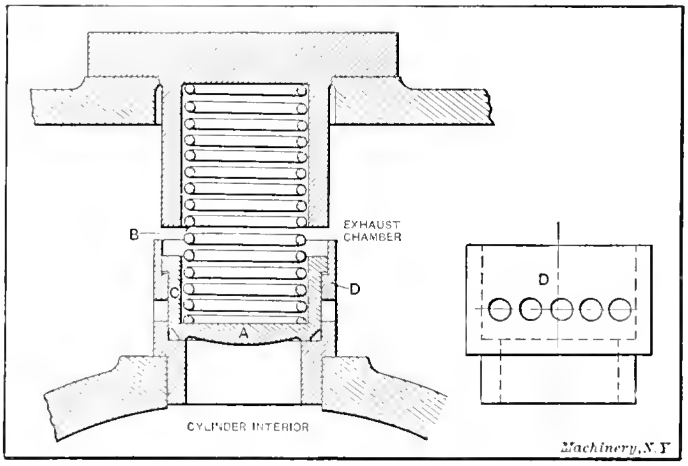
RELIEF VALVE FOR STEAM ENGINE CYLINDERS

The pop safety valve now almost universally used on American locomotive and marine boilers and largely on stationary boilers rapidly reduces the boiler pressure when it "blows off." The construction of the valve is such that the area effectively exposed to steam pressure is considerably increased when the valve lifts, the steam having to escape past the lip of the valve through an opening technically known as a "stricture." This increase of effective pressure overcomes the spring pressure, sufficiently to open the valve wide and permit the steam to escape freely. When the pressure has reduced a few pounds, the valve closes as suddenly as it opened, the effective pressure being as quickly reduced as it was



Bollinckx Improved Relief Valve for Cylinders

increased. The quick and positive action rapidly lowers the boiler pressure and also reduces the deterioration of the valve seats to a minimum because of reducing the time of blowing off and the cutting action of steam blowing through a partially opened valve. The pop valve is either open or closed whereas the ordinary safety valve sputters, blows, again sputters and slowly closes leaving perhaps a slight leak to cut away the valve bearing.

An analogous construction is employed in an improved form of steam cylinder relief valve devised by H. Bollinckx, steam engine builder, Brussels, Belgium, to prevent hammering of the valve on the seat. Ordinary relief valves give trouble by hammering on their seats if adjusted closely to the maximum compression allowed. In the Bollinckx design it will be observed that the valve is made in the form of a piston *C* closely fitting the cage *D*. Through the sides of the cage are holes communicating with the exhaust chamber. The valve *A* has a flat seat of the ordinary form outside of which it is beveled off, thus forming an annular cavity. In order to relieve the pressure, the valve must lift from its seat sufficiently to permit the steam or water to escape through the ports in the side of the cage *D*. If the valve lifts and falls rapidly, it cannot pound the seat because the steam trapped in the annular cavity cushions it, deadening the shock.

Five miles of the Panama Canal have been opened to navigation. This includes the channel from the point in the Bay of Panama where the water is 45 feet deep at mean tide to the wharf at Balboa. Steamships are using this part of the canal daily.

INTERESTING TOOLS AND METHODS OF CINCINNATI SHOPS—3

THE G. A. GRAY CO.

ETHAN VIALL*

Of the many interesting shops of Cincinnati, not one is more interesting than that of the G. A. Gray Co.; and yet there is none more difficult to adequately describe, for it is not so much the machines and devices one sees there as it is the methods and workmanship, which are above the ordinary. Huge planer parts weighing thousands of pounds are machine finished, and with absolutely no hand work are made as interchangeable as the parts of a watch. This seems almost impossible, and only a personal visit to this shop can really convince one. Of course the absolute interchangeability of parts is a very desirable feature for any class of machines, for as a rule, the average shop whether large or small, pays out more money in the erecting or assembling department than in any other single department just because of the immense amount of hand fitting, scraping and filing that must be done in order to make the alleged interchangeable parts go together. On very small or medium-sized parts the problem is not so difficult as it is on large work, yet that large parts weighing hundreds or thousands of pounds each can be made interchangeable, is an absolute fact and this too without any scraping or other hand work whatever. In other words, parts may be so finished in a machine that one or a hundred will fit into its appointed place with perfect accuracy.

Fig 1. Blocks placed in Clapper-boxes in Different Positions to show Accuracy of Fitting

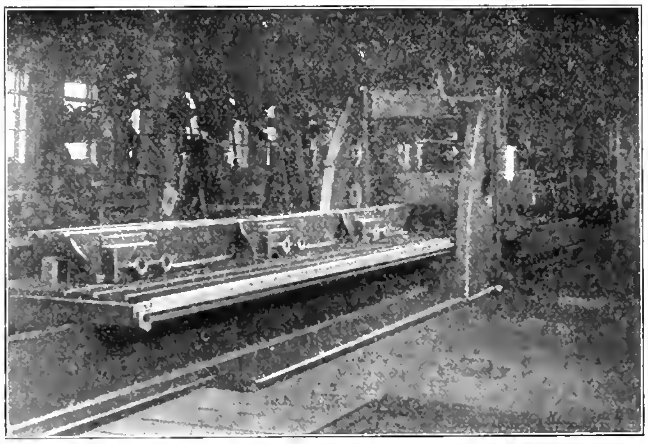

Fig. 2. Planing Four Small Planer Beds on a 34-foot Planer

Naturally, judging from the foregoing, anyone can see that the G. A. Gray Co. does not rush the work through the shop at the rate of sixty miles an hour and then put on an extra force of men in order to get it through the assembling department before the Panama Canal is finished.

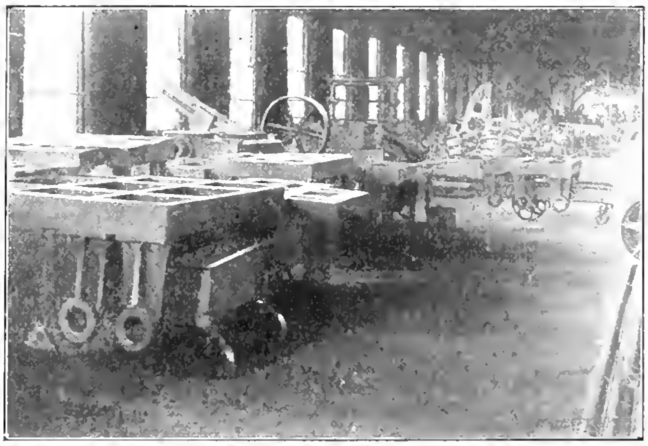

Fig 3 Planer Bed Boring Jigs and Trucks on which they are stored

Fig 4 Crossrail Assembling Room

In the shop, twenty-three planers are in constant use, which gives the firm a chance to test the machines which are built, under every conceivable condition. As the company owns its own foundry, the proper metal for each part is secured—hard, close-grained iron for parts subject to wear and tough iron for those under strain and liable to fracture—and so it is evident that the importance of the foundry, as well as the machine shop, is appreciated.

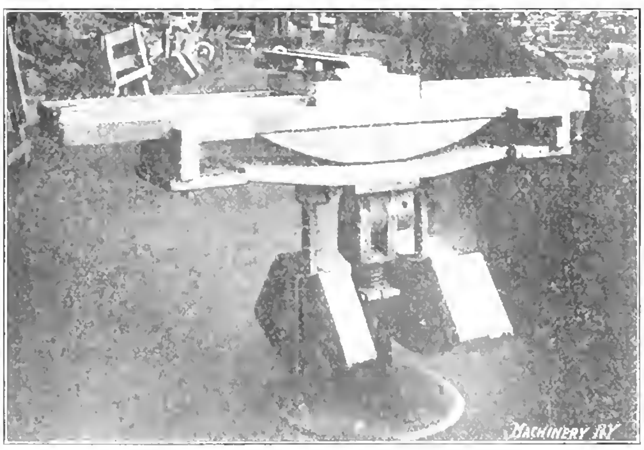

Fig 5 Universal Stand to hold Crossrails when fitting the Slides

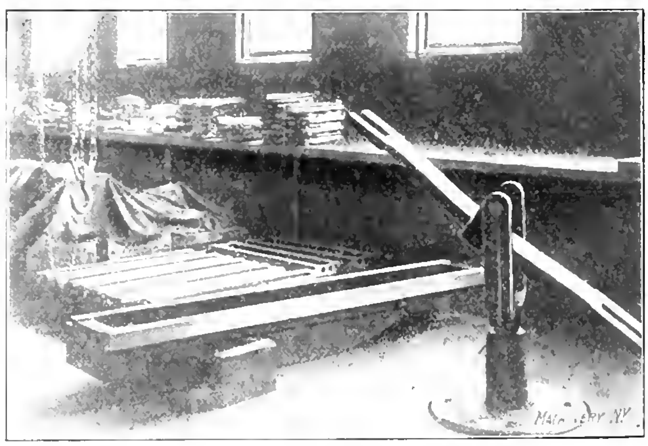

Fig 6. Stand for Holding Rails while Scraping the Ends

* Associate Editor of MACHINERY.

Briefly glancing at a few of the points in the Gray planer construction, we find that the driving gears and racks are made of a special semi-steel mixture, which tests 41 per cent more than cast iron. All rail and feed screws are of 50 point, and shafts of 55 to 60 point carbon, hammered crucible steel. Driving shafts run in solid cast iron bushings accurately ground, and set into holes correctly located and bored directly into the bed of the planer, and the holes in bushings, gears and pulleys, as well as all holes for feed rods and the like are reamed to plug gages. Any parts which are reamed too large are scrapped, and not fitted with a special bushing or part. Keys are milled to snap gage sizes, instead of using cold rolled stock filed to approximate fits. Keyways are milled to standard sizes in an automatic machine, built for this purpose. All cylindrical parts are ground. The housings are made absolutely square with no provision whatever for shims to make a "Dutch fit."

Fig. 7. Special Countershaft Brackets fitted to Planer Housings

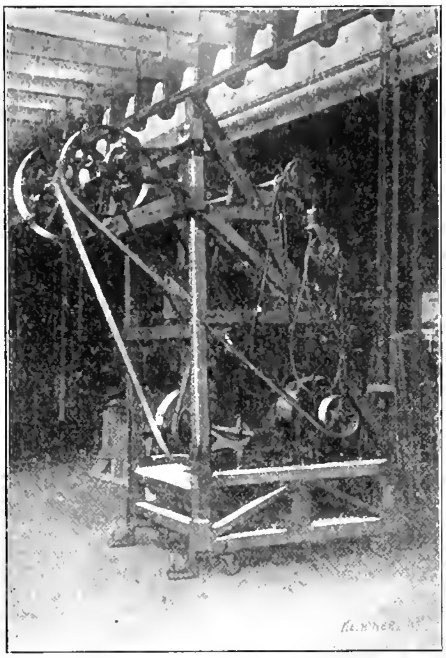

Fig. 8. Portable Motor-driven Countershaft for Testing

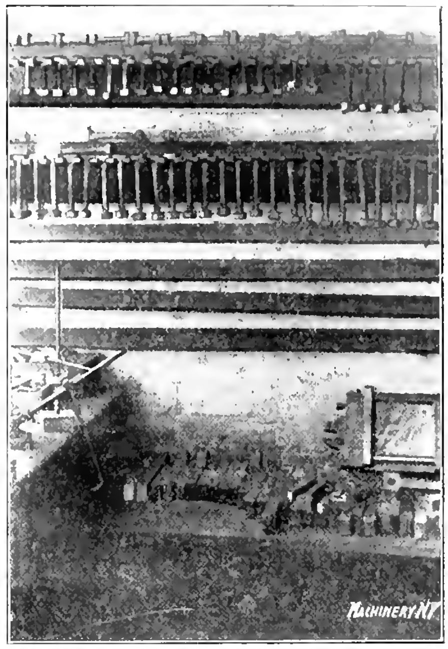

Fig. 9. Planer Operator's Corner showing Bolt-racks and Tools

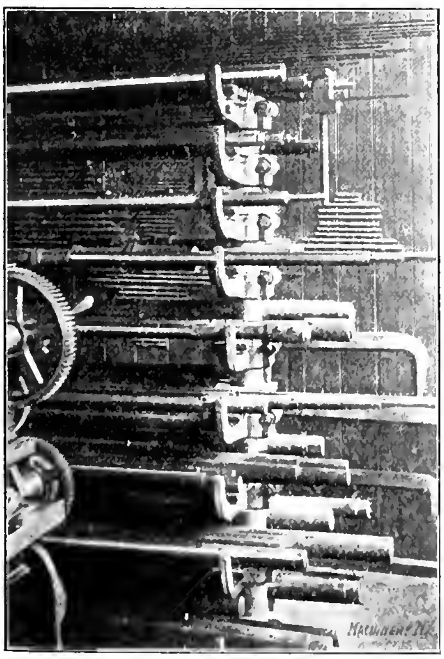

Fig. 10 Boring-bar Racks and Cages

I could go on indefinitely enumerating the points picked up during my visit, but the above must suffice for the present; there is one very important thing, however, that is often overlooked by users which is that besides being made right, a planer must be leveled up properly where it is to be run, and kept so. In order to make this leveling or testing as simple as possible, the four top surfaces of the V's are planed perfectly true at the same setting in which the V's themselves are planed, so that a level may be applied directly on top of them; therefore it isn't necessary to hunt for round bars of the same size to lay in the V's before using a level.

Nothing that I saw in the shop impressed me more, as regards accurate workmanship, than an inspection of a pile of clapper boxes and tool-blocks. Out of perhaps a hundred, I selected four at random and placed the blocks in a different position in each one. The parts had not been touched by a scraper—or anything but a planer tool—and were just as they came from the machine; yet absolutely no difference could be detected in the fit, no matter in what position the block was placed in the box. The fit was close enough to hold the blocks suspended at any point, yet a push of the fingers easily carried them to the bottom, and the fit of any one block was as good in one apron as in another. The four clapper boxes with the blocks in four different positions are shown in Fig. 1. At *A* the block is shown high in the box; *B* shows it turned end for end; *C* shows it bottom side up with the ends in the right direction, while *D* shows it bottom side up but turned in the opposite direction.

In Fig. 2 are shown four small planer beds being planed at once on a 34-foot planer with a 62-foot bed. When a planer bed is finished, no mark of any kind is put on it to indicate which end is to be toward the front of the machine, as it will fit just as perfectly one way as the other on any machine of its size, and this, too, with no scraping except the broad cross scraping, which is done to harden the surface and to remove the "loose metal" left by the planer tools, which, if it were not removed, would soon cut out the bearing.

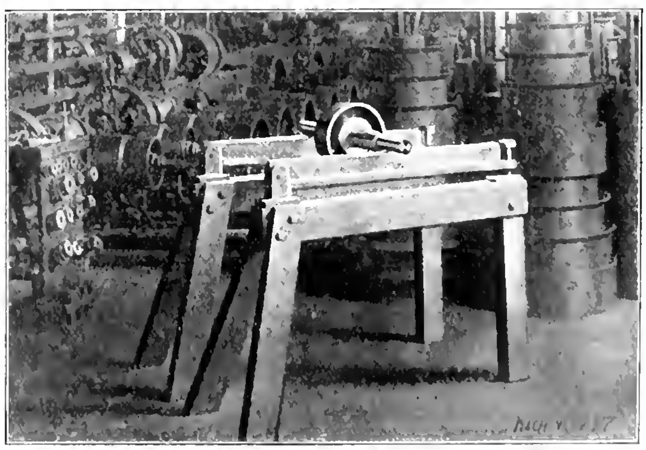

Fig. 11. Iron Ways on which Pulleys are balanced

The various jigs used for accurately locating the different holes in planer beds, and the special trucks on which they are kept, are shown in Fig. 3. This method of storing makes the handling of these heavy jigs a very easy matter.

A view of the department in which the crossrails and their fittings are put onto the housings is shown in Fig. 4, and in Fig. 5 is shown a balanced, universal scraping stand for cross

rails and slides, these being among the parts that have to be drilled and tapped after planing and, consequently, are liable to be sprung by these subsequent operations, and so must be corrected by scraping. In mounting the cross rails on the stands, they are held in practically the same way as when

Fig. 8 is a portable motor-driven countershaft used for trying out planers on the testing floor. By using this countershaft, a planer may be tested anywhere it may be placed.

A planer man's corner with its tools and neat bolt rack is shown in Fig. 9, and in Fig. 10 is shown the racks used in

bolted to the housings, in order to eliminate the error which might result were they clamped to the stand one way and bolted to the planer in another.

Fig. 6 is a stand used for finishing the ends of rails.

Fig. 7 shows the way a planer has been fitted with a special countershaft mounted on brackets bolted to the housings, in order to belt to the lineshaft without interfering with some low steam pipes.

the toolroom to hold the big boring-bars, reamers and other heavy bar tools, while on the wall are some of the large inside and outside gages.

The spirals used for spiral geared planers are milled on a special extra-heavy milling machine (Fig. 12) built for this purpose only. The gears are cut from the solid with a formed end mill, first being roughed out and then allowed to "season" before finishing.

Fig. 13 is a view of the foundry taken just after an unusually busy period, and shows the convenient crane system used.

Pulleys are held in the chucking stand (Fig. 11), and the holes carefully reamed to size with an adjustable reamer suspended from a counterbalanced bracket as shown. All pulleys are carefully balanced on the three-legged balancing ways (Fig. 11) which are made, legs and all, of iron, the V's being adjustable so as to be easily leveled.

Fig. 19. Nut Grinding Fixture and Arbors used

Spur gears are cut on Brown & Sharpe automatic gear cutters, and bevel gears are planed on a special gear planer. To insure the perfect running of all these gears, they are tested

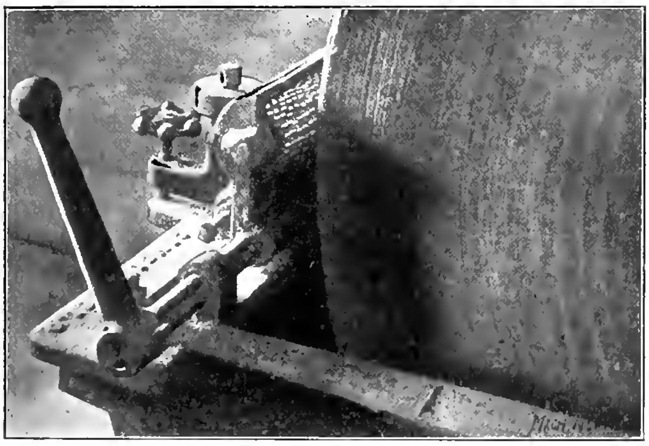

Fig. 20. Tool for Truing the Grindstone

on the special machine shown in Fig. 15, which is operated by a variable speed motor which permits the gears being run at any speed desired. The machine is equipped with dou-

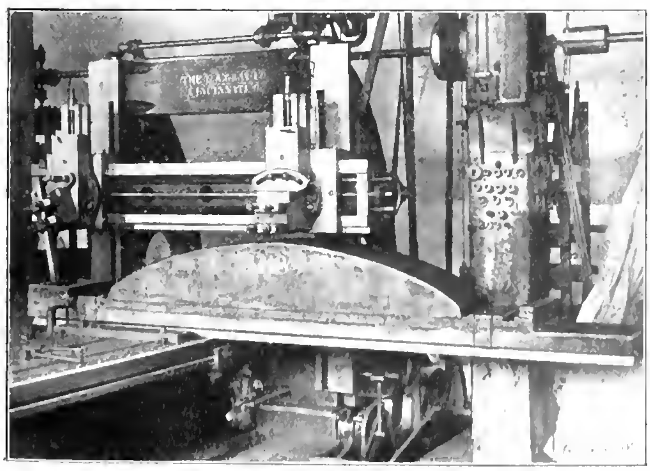

Fig. 21. Planing the End of a Large Crossrail

ble brakes, so that the gears can be run under resistance in either direction. The spindles carrying the gears to be tested can be set at any angle with each other. When tested in this way, it is definitely known that gears will run properly, not only on machines being erected, but also on any which may need repairs.

All driving shafts are chased with spiral oil grooves in the lathe shown in Fig. 16, which, owing to the great lead of the spiral, is not driven from the cone pulley on the spindle, as usual, but from a pulley placed on the lead-screw as shown, thus doing away with the abnormal strain that the gears would otherwise be under. For convenience, the machine, when used for cutting oil grooves, is driven from below by a belt running through the floor, the shifter being arranged as shown. The oil holes for these shafts are not drilled at random as is generally the case, but are all jigged.

Some of the small racks are milled, and this is done on a machine which is fitted with an individual exhaust fan, as shown in Fig. 17.

Mistakes in graduating on a milling machine are so frequent where a considerable amount of this work has to be done, that some sort of an automatic machine is almost a necessity, so the one shown in Fig. 18 has been built for this work. The piece to be graduated is first set at the proper angle so that the marking may begin at the right place, by means of a sliding angle-plate, after which it is tightened on the indexing spindle and the angle-plate is drawn back out of the way. The long and short lines are automatically spaced by means of a cam-wheel with one long and four short

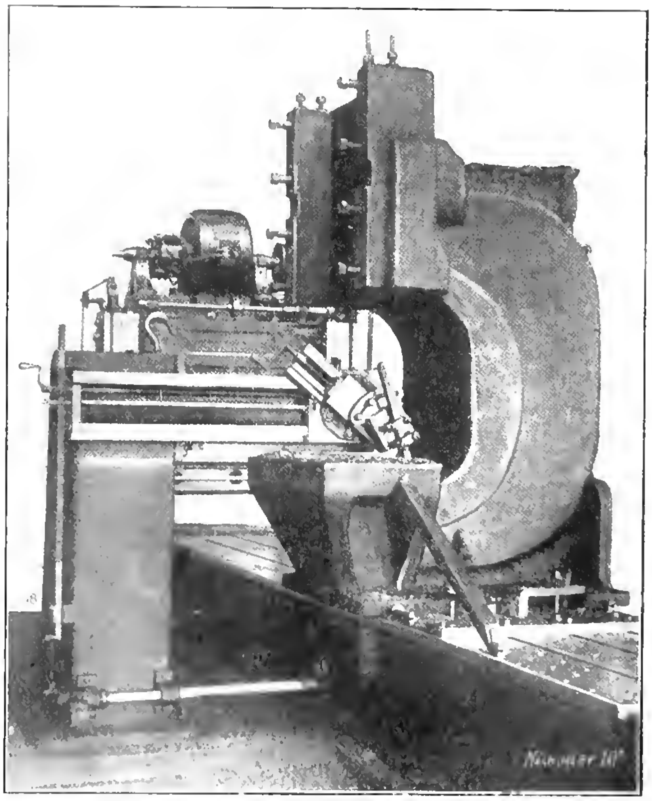

Fig. 22 Planing the Lower Jaw of a 16,000 pound Shear Casting

rises, and the marks are *rolled* in instead of cut, which forces the material into the pores of the metal and insures perfectly sharp, true dividing lines of equal depth, without tearing.

Nuts are ground on the bottom true with the tapped hole, so that they will bear evenly and not be under a side strain, by placing them top first on compensating arbors like *A* or *B*, Fig. 19, which are held in the spindle of the grinding fixture *C*, which is made to fit the regular grinder table.

The big grindstones in the shop are kept true by using the patented truing device which is plainly shown in Fig. 20.

Several jobs of more than passing interest have been done at the Gray shop at different times, one of the jobs being the planing of the lower jaw of a huge shear weighing 16,000 pounds. The independent housing shown in Fig. 22 was used. Fig. 21 illustrates the difficult feat of planing the end of a big 3,118-pound crossrail in which the great overhang and short stroke made the job one to test the capabilities of any planer, both in the rigidity of the table and the reliability of the reversing mechanism.

* * *

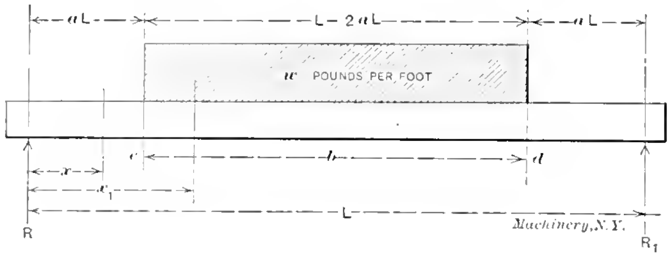
Don't try to make a motor pick up its load too quickly, or before it gets up to its speed.

DEFLECTION OF BEAM UNIFORMLY LOADED FOR PART OF ITS LENGTH

GEO. E. BARRETT*

A recent problem in design involved the calculation of the deflection of a simple beam uniformly loaded for part of its length, as illustrated, and a careful search was made of all the hand-books, American as well as foreign, and of the text-books available that could throw any light on the subject, but no formula was found from which the maximum deflection could be computed, so the next step was to deduce one. At first, it was thought that the result would be too complicated and too long for practical consideration, but, as a matter of fact, the formula is not difficult to handle, especially with a table of logarithms, and then the fact that accurate results can be found without resorting to an approximate method ought to commend its use.

Referring to the engraving, the load is symmetrical and uniformly distributed for a distance b with an intensity of w pounds per foot. Let the distance from each reaction R and R_1 to the load be aL, where a is less than unity.



Beam Uniformly Loaded for Part of its Length

$$R = R_1 = \frac{w\,(L - 2\,aL)}{2} = \frac{wL\,(1 - 2a)}{2} \qquad (1)$$

For any distance x between the left reaction and c the bending moment will be

$$Rx. \qquad (2)$$

For any distance x_1 between c and d, the bending moment will be

$$R x_1 - \frac{w\,(x_1 - a\,L)^2}{2} = R\,x_1 - \frac{1}{2}\,w\,x_1^2 + w\,a\,L\,x_1 - \frac{1}{2}\,w\,a^2\,L^2 \qquad (3)$$

The well-known equation for the elastic curve $EI\dfrac{d^2y}{dx^2} = M$, where E equals the modulus of elasticity of the material used, I, the moment of inertia of the section, and M, the bending moment at any distance x or x_1, can be now used to deduce an expression for the deflection.

Between R and c

$$E\,I\frac{d^2y}{dx^2} = R\,x. \quad \text{See formula (2)} \qquad (4)$$

$$E\,I\frac{dy}{dx} = \frac{1}{2}\,R\,x^2 + C \qquad (5)$$

$$E\,I\,y = \frac{1}{6}\,R\,x^3 + C\,x + C_1 \qquad (6)$$

Between c and d

$$E\,I\frac{d^2y}{dx^2} = R\,x_1 - \frac{1}{2}\,w\,x_1^2 + w\,a\,L\,x_1 - \frac{1}{2}\,w\,a^2\,L^2 \qquad (7)$$

See formula (3)

$$E\,I\frac{dy}{dx} = \frac{1}{2}\,R\,x_1^2 - \frac{1}{6}\,w\,x_1^3 + \frac{1}{2}\,w\,a\,L\,x_1^2 - \frac{1}{2}\,w\,a^2\,L^2\,x_1 + C_2 \qquad (8)$$

$$E\,I\,y = \frac{1}{6}\,R\,x_1^3 - \frac{1}{24}\,w\,x_1^4 + \frac{1}{6}\,w\,a\,L\,x_1^3 - \frac{1}{4}\,w\,a^2\,L^2\,x_1^2 + C_2\,x_1 + C_3 \qquad (9)$$

y in (6) $= o$ when $x = o$; then $C_1 = o$.

$\dfrac{dy}{dx}$ in (8) $= o$ when $x_1 = \dfrac{L}{2}$; then $C_2 = \dfrac{1}{48}\,w\,L^3 - \dfrac{1}{8}\,R\,L^2 - \dfrac{1}{8}\,w\,a\,L^3 + \dfrac{1}{4}\,w\,a^2\,L^3$

Formula (5) $=$ (8) when $x = x_1 = aL$; this will give a value of

$$C = -\frac{1}{6}\,w\,a^3\,L^3 + \frac{1}{48}\,w\,L^3 - \frac{1}{8}\,R\,L^2 - \frac{1}{8}\,w\,a\,L^3 + \frac{1}{4}\,w\,a^2\,L^3$$

Substituting this value of C in (6) gives the following expression for the deflection of the beam for any position between R and c.

$$E\,I\,y = \frac{1}{6}\,R\,x^3 - \frac{1}{6}\,w\,a^3\,L^3\,x + \frac{1}{48}\,w\,L^3\,x - \frac{1}{8}\,R\,L^2\,x - \frac{1}{8}\,w\,a\,L^3\,x + \frac{1}{4}\,w\,a^2\,L^3\,x.$$

Formula (6) $=$ (9) when $x = x_1 = aL$; substituting this value for x and x_1 in (6) and (9) and placing them equal to each other gives a value for C_3 of $-\dfrac{1}{24}\,wa^4L^4$. The maximum value for y will occur when $x_1 = \dfrac{L}{2}$. Substituting this value for x_1 and the value obtained for C_2, in (9) give

$$E\,I\,f = \frac{w\,L^4}{384}\,(-5 + 24\,a^2 - 16\,a^4)$$

where f is the maximum deflection. Substituting for w, the expression for total weight W is

$$E\,I\,f = \frac{W\,L^3}{384\,(1 - 2\,a)}\,(5 - 24\,a^2 + 16\,a^4)$$

$$f = \frac{W\,L^3}{E\,I\,384\,(1 - 2\,a)}\,(5 - 24\,a^2 + 16\,a^4) \qquad (10)$$

The expression for maximum bending moment is

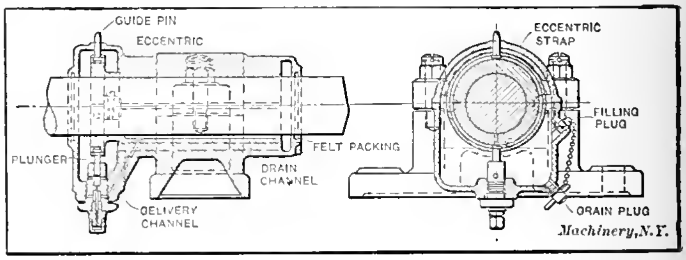
$$M_{max} = \frac{1}{8}\,W\,L\,(1 + 2\,a) \qquad (11)$$

* * *

BEARING WITH SELF-CONTAINED OIL PUMP

JOSEPH G. HORNER*

A new automatic forced lubrication system is being introduced for bearings of various kinds by Messrs. Vickers, Sons & Maxim, Ltd., who have several works in England devoted to various manufactures. The novelty is that the pump



Bearing with Automatic Oil Pump for Forced Lubrication

is enclosed in the bearing in an oil chamber at one end, and is driven by the rotation of the shaft so that the volume of lubricant varies with the demands made upon it. An eccentric (see the illustration) mounted on the shaft within the chamber drives the pump plunger which delivers the oil up through a sloping channel to the under side of the shaft where it is mostly required. The waste oil collects in a drain channel and returns to the chamber. The pump plunger has a stroke of about 5/16 inch, with a diameter of about 3/8 inch. In general the eccentric is surrounded with a strap the action of which is positive on both strokes, but in some cases the strap is dispensed with and the plunger is forced downward by the eccentric and returned by a coiled spring. In another modification for axle-boxes, a tube is carried from the pump to the top of the bearing to lubricate the pad there. In others a row of pumps actuated by one shaft supplies oil to multiple sight-feed lubricators for engine parts.

[The principle of the automatic oil pump arrangement is the same as that illustrated and described in MACHINERY, Dec., 1906, in an item entitled: "A Shafting Hanger With Forced Lubrication."—Editor.]

MAKING HEAVY CHAIN AND ANCHORS FOR UNCLE SAM

CHESTER L. LUCAS*

"In time of peace prepare for war" is an old adage that seems to be especially heeded by the great naval powers of the world. Forward strides have been made in methods of naval warfare, and the achievements in building battleships and their equipments have been little short of marvelous. One of the primary requisites of a battleship is speed, and while we hear much of the results along this line, little has been said of the modern methods that are employed for anchoring and holding in check these valuable warships; for it must be remembered that a battleship can go to destruction as quickly on a reef as under the enemy's fire. Realizing the importance of this factor, the United States government has a well-equipped department at the Charlestown Navy Yard wherein every link of chain and every anchor used in the navy is made. Through the courtesy of Commander H. E. Parmenter, MACHINERY's representative was allowed to photograph and record the various processes and machinery used in chain and anchor making.

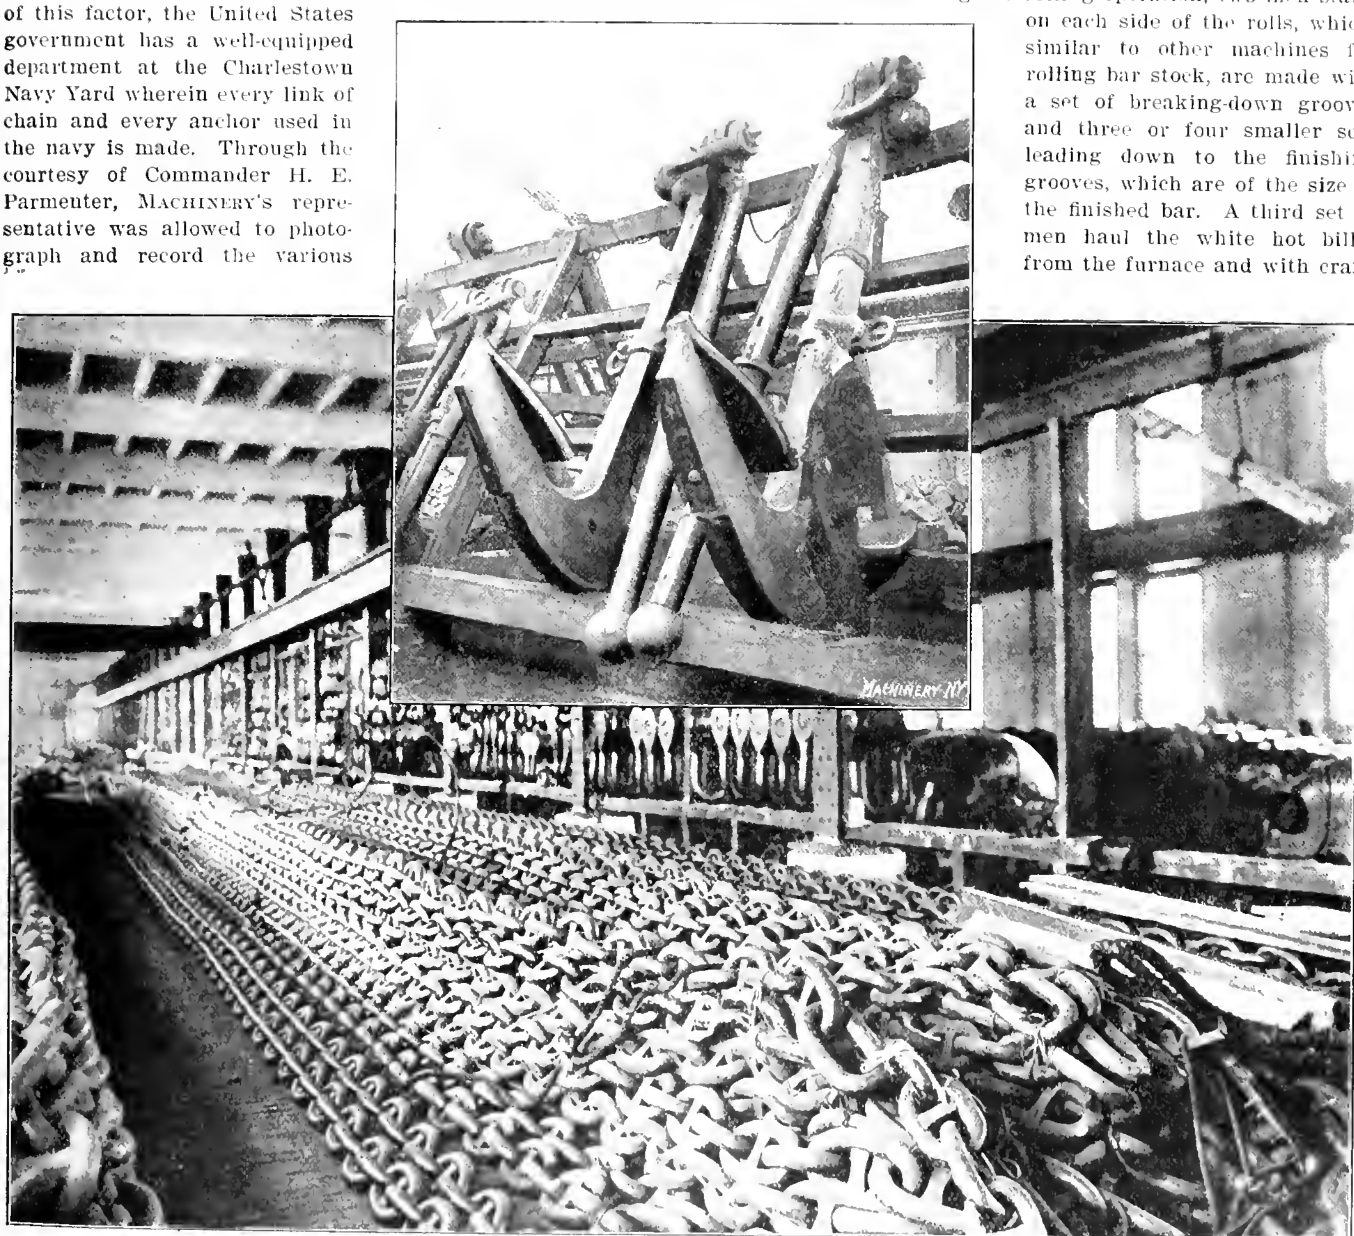

Fig. 1. Anchor Chain Storage, and 17,500 pound Anchors

The Iron

But one make and one quality of iron is used for the heavy chains in the navy, and by heavy chains are meant those with links made of bars from $2\frac{1}{2}$ inches to $3\frac{1}{4}$ inches in diameter. This iron comes from one of the best makers in Pennsylvania, and is received in square muck-bars $1\frac{3}{8}$ inch in diameter. It is accepted only after passing the rigid physical and chemical tests imposed by the government. One requirement of the chemical test is that the percentages of sulphur and phosphorus be very low. By getting the iron in the muck-bar, it is assured that the metal has received the lowest number of heats possible before the chain-smiths of the navy yard begin to work it.

Rolling the Bars

The first step in making the heavy chain, taking for example the $2\frac{1}{2}$-inch size, is to cut the muck-bars to lengths of about 2 feet, the cutting being done cold by means of large alligator shears. These short lengths are then wired into bundles of about 25 each. As these bundles weigh from 250 to 300 pounds, they are handled with crane-tongs and in this manner slid into the huge furnaces. From the furnaces these white hot billets are passed to the rolls and converted into bars of the required diameter—in this case $2\frac{1}{2}$ inches. Fig. 2 shows a view of the rolling department of the chain shop with the furnaces on the left and the rolls on the right. The chain shop is in charge of Mr. William Kelley. In front of the furnaces may be seen piles of cut muck-bars ready to be bundled for the furnace. During the rolling operation, two men stand on each side of the rolls, which, similar to other machines for rolling bar stock, are made with a set of breaking-down grooves and three or four smaller sets leading down to the finishing grooves, which are of the size of the finished bar. A third set of men haul the white hot billet from the furnace and with crane tongs rush it to the breaking-down rolls. To successfully start the billet through the first set of grooves is the hardest part of the rolling, but as this set of grooves is made with short, cleat-like teeth, the metal is sent through without much trouble. Fig. 3 shows the starting of a white hot billet. If the iron starts to slip, a handful of sand is thrown in and the slipping tendency overcome. After the iron has gone through the breaking-down grooves it is passed back over the rolls and entered in the next set. As the metal is passed through the smaller grooves in the rolls it is, of course, stretched to a greater length, and after the last set has been passed the bar is ten feet long, and the rolling time has been so short that the iron is still at a bright red heat.

Cutting and Bending

From the rolls it is but a few steps to the hot-saw which cuts the bars to the proper lengths for the links. The hot

* Address: 1 Bailey Avenue, East Saugus, Mass.

saw itself is about 4 feet in diameter and travels with a peripheral speed of 20,000 feet. At a 30-degree angle to the saw is set the table, which is provided with a vise to grip the bar while cutting. The table is set level with the floor, so there is no unnecessary handling of the hot bars. The purpose of cutting the iron bars at a 30-degree angle is to provide for the scarf, so essential to welding. Some idea of the capacity of this saw may be obtained when it is realized that a 30-degree cut through a 2½-inch bar (a cut 5 inches long) is made in 4 seconds.

The two machines shown in Fig. 6 are for bending the links. They are very simple but ingenious machines, and they form the links much better and in a fraction of the time that it would take to do it by hand. Both of these machines were designed by Commander Parmenter and made in the machine shops of the Charlestown Navy Yard under his supervision. The smaller machine is for chain made from 2½-inch stock, while the larger one takes stock from 2¾ inches to 3¼ inches. The action of the machine, which is in reality a press, is very simple and easily understood. The forming

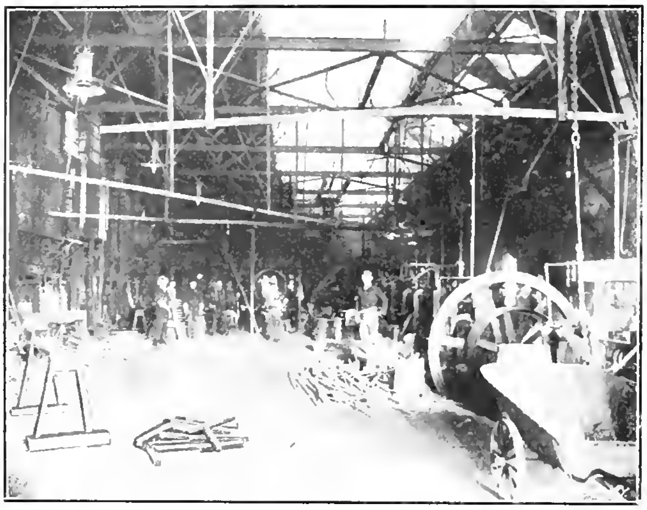

Fig. 2. General View of the Chain Shop

arbor, shaped like the inside of the link, is located just inside of the oval opening at the front of the machine. The groove around this arbor is spiral, so that as the iron is bent to the shape of the link, the ends will be separated enough to allow the links to be connected before welding. On either side of the central opening may be seen the two cam grooves that guide the forming rolls that bend the link. The bar from which the link is to be made is inserted at the left-hand side of the press; the ram descends, carrying the forming rolls (which are mounted in slides to provide for lateral movement)

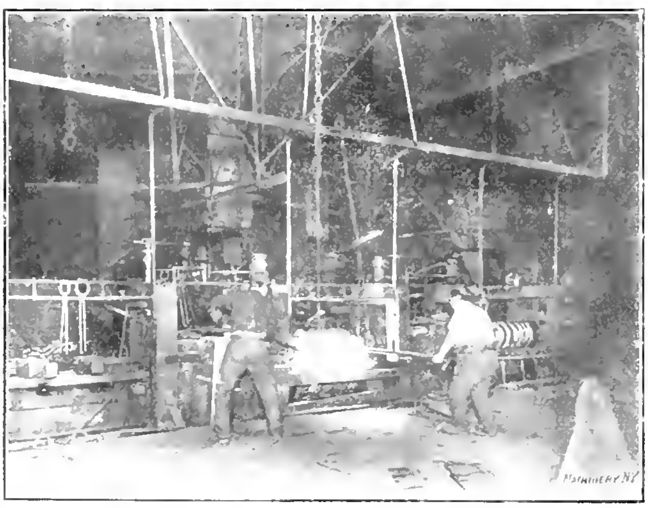

Fig. 3. Starting a White-hot Billet through the Rolls

down the grooves, thus giving the link-shaped motion that does the forming. After the link is bent, the arbor recedes, allowing the link to drop to the opening at the base of the machine. All of these operations of rolling, sawing and bending, from the time the billet leaves the furnace for the first time, are performed in one heat and when the link drops from the bending machine it is still at a good red heat.

Welding and Testing

In the welding department there are about a dozen fires with their "chain-gangs" for welding the links. These fires

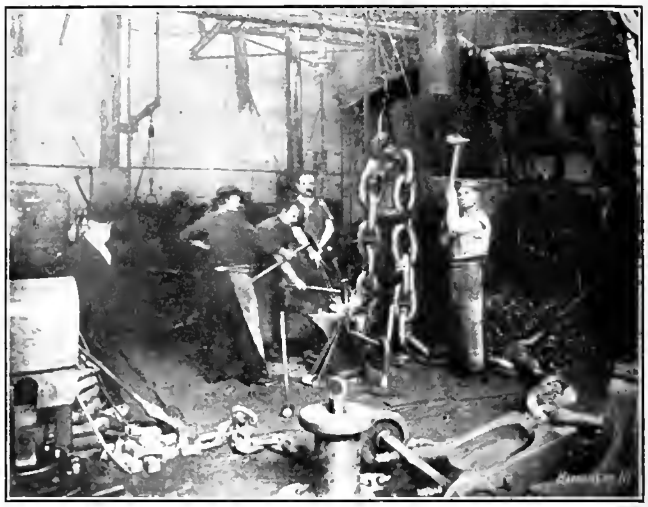

Fig. 4. The Chain Gang at Work Welding a Link

use coke for fuel, and at the side of each one is a constantly growing chain of completed links. Fig. 4 shows one of these fires with its crew at work welding a link. For some of the chain a welding machine is employed, but most of the work is done as shown in the illustration. After connecting the uncompleted link to the rest of the chain, the slack of the finished chain is pulled up out of the way by the hoist shown and the link to be welded is bent together. Next, the joint is placed in the fire and heated without heating the rest of the chain any more than can be helped. When the welding heat

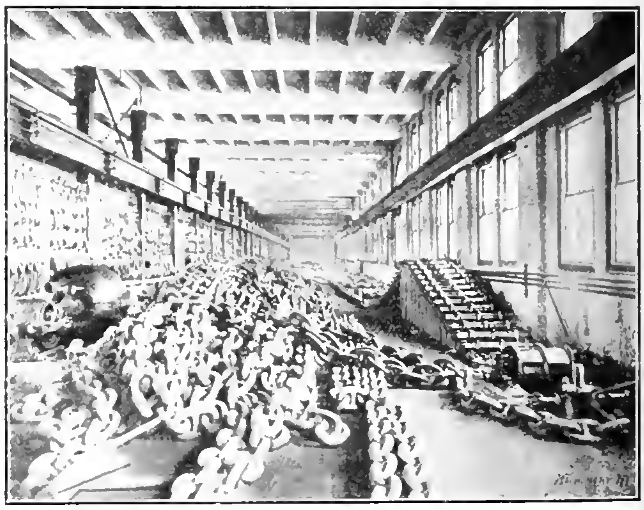

Fig. 5. Chain Painting Apparatus and Chain Ready for Painting

is reached, the link is quickly transferred to the anvil and the strikers send in the blows, under the direction of the smith, who handles the link. The rapidity with which this welding is done is surprising, considering the fact that the chain has "a string tied to it" that makes it awkward to handle. After welding, a drop-forged block is placed in the center of the link and the sides of the link closed in upon it, holding it firmly in place. Each block has the letters "U. S. N." raised upon each of its sides, and while this block does not add to the strength of the chain,* it has a purpose, which is to prevent the chain from kinking and catching while stored away in the hold of the battleship.

* According to Unwin the British Admiralty rule for the proof test of studded cable chain is: Test load in tons (2,240 pounds) = 18 d^2, corresponding to a load of about 11½ tons per square inch of section. For close-link crane chain without studs it is: Test load in tons = 12 d^2. The stud chain thus is subjected to a proof load 50 per cent greater than close-link chain. However, tests made both abroad and by the Boston Navy Yard have shown that the stud does not add to the ultimate strength but rather detracts from it. The function of the stud is essentially to insure the chain running freely from the chain lockers and prevent it becoming rigid under heavy strains. EDITOR.

Testing and Finishing

The testing apparatus used to prove the quality of the chain is very powerful and the result is conclusive. Owing to the location, it was impossible to obtain a good photograph of the apparatus. The chain is placed in a steel-lined pit, 100 feet long, 3 feet wide and 3 feet deep while under test. A length of chain 90 feet long is made fast at one end of the pit and the other end attached to the testing machine. With this machine it is possible to subject the chain to a strain of 80,000 pounds, this being accomplished by using hydraulic pressure. From each length of chain three links (called a triplet) are taken and tested to destruction. This test proves the chain beyond all doubt, and no poor or weak link can possibly "get by."

At the end of the testing pit there is a steel subway that leads to the storehouse on the other side of the street. A thirty horsepower winch furnishes the power for pulling the chain through the subway. Fig. 5 shows a view of one side of the storehouse, with a pile of chain waiting to be painted. At the right-hand side of the engraving may be seen the device that is employed for painting the chain. Just under the drum in the foreground is the paint tank. The paint, which is black asphaltum, is kept hot by the steam pipes running through the tank. The chain is passed through the tank and

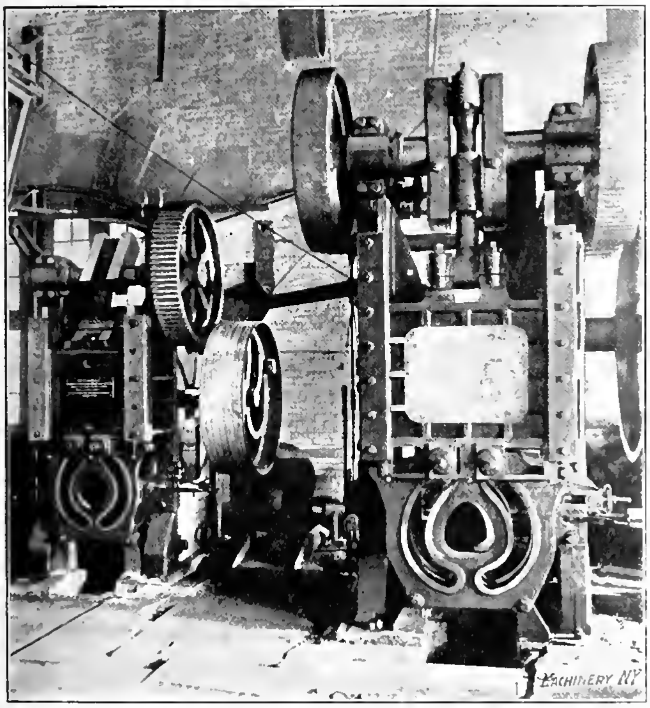

Fig. 6. The Link Forging Machines

under the steel drum and then over the inclined rollers. Another thirty horsepower winch at the farther end of the building is used to draw the chain through the tank and over the rollers. As the paint is applied hot and the chain is drawn over the rollers very slowly, the paint is dry by the time the chain leaves the apparatus. The other side of the chain storehouse is shown in Fig. 1. This view shows more clearly the blocks in the links. Here again the floor is literally lined with chain, and one would think that there was chain enough made to last the navy for years, but when it is remembered that the life of a chain is limited, being scrapped as soon as re-testing proves it to have lost its elasticity or to be otherwise defective, it can be easily seen that Uncle Sam's chain-making industry is an important one.

Anchor Making

The anchor shop of the United States Navy is located in the same large building as the chain shop, and while it is not as large a department, it is fully as important. The work is in charge of Mr. William Paul, whose experience in this line is without a doubt unequaled in this country.

Material and Equipment

In this shop are forged all the anchors for the navy. They vary in size from 400 pounds to 17,500 pounds. The material from which anchors are made is simply the scrap from the process of chain-making—imperfect links, short ends, etc. Fig. 7 shows a pile of this waste chain iron ready to be made into anchors. At the anchor shop it is made into billets of sufficient size to make the various anchor parts. These rough masses of iron are held and worked on huge porter bars, which for the large anchors are 6 inches in diameter and about 12 feet long. The furnaces are of the same type as those

Fig. 7. A Pile of Scrap Chain from which Anchors are made

used in the chain shop, burning soft coal for fuel. Oil furnaces have been tried, but were discontinued for reasons of economy. The steam hammers—and there are six or eight of them—range up to twenty horsepower on the large work.

The Anchor and its Parts

As has been intimated, anchors are built up of several parts, each of which is forged at different fires, according to the size of the work. The parts of an anchor are the two palms, the crown, the shank, the stock and the shackle. The stock and the shackle are not parts of the main anchor forging, though they are very essential to the proper working of the anchor. The stock is to insure the anchor falling in such a position as to grip firmly, and the shackle is the connecting link for attaching the chain. Referring to Fig. 8, *A* is the shank, *B* the crown, *C* the stock, *D* the shackle, and *E E* are the palms. The palms, however, are only called by that name before they are welded to the crown. In the completed anchor, the ends of the crown with the attached palms are known as the flukes.

The System of Forging

In everything that Uncle Sam does there is a common underlying factor that enters into every detail. That factor is system, and it is right at home in the anchor shop as well as in the chain shop. A small model anchor with correct proportions has been made and from that model the weights and measurements for the various sizes of anchors have been computed. Each anchor, then, has its standard size and weight, which is a great aid to the blacksmith. The

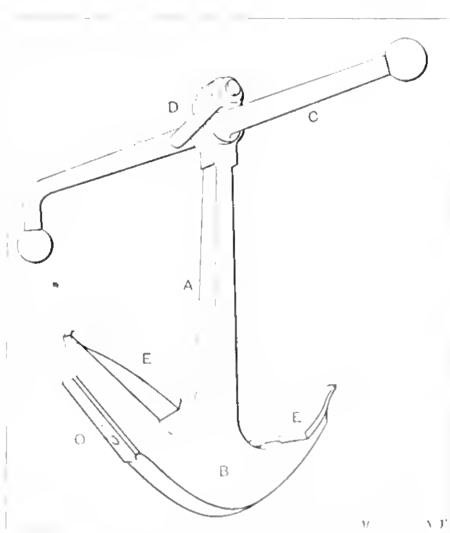

Fig. 8. The Anchor and its Parts

palms, as forged, are merely flat pieces, triangular in shape and quite thin. The shank is forged with a flat end to be welded to the crown, and holes are forged in the top end for the stock and shackle. The crown is forged with a recess to receive the end of the shank when making the box weld. Through the ends of

the crown are two holes which are used to hold it to the porter-bar while it is being shaped and welded to the shank. After the anchor is finished, the holes are extended through the palms and a large rivet put through and headed over. This rivet serves no purpose other than to improve the looks, unless it be to keep the elements from the interior of the iron. A glance at the anchors shown in Fig. 9 illustrates this point. At first thought it is natural to think that the rivet helps to hold the palm to the crown, but as these two parts are united by a weld it is plain that the rivets cannot add to the strength. After the forging of the crown and shank is

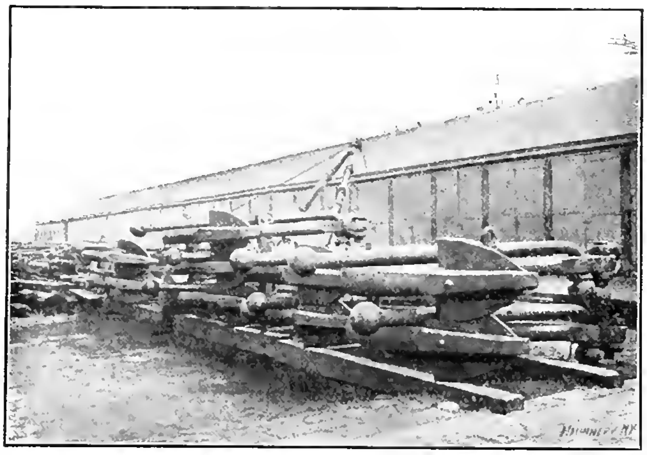

Fig. 9. A Pile of 3- and 5-ton Anchors

finished, they are heated in separate fires and box welded together. The anchor is now complete except for the stock and shackle. These parts are not added until the last thing. The stock is a plain forging and needs no comment. In putting the balls on the ends of the stock, it is, of course, necessary to leave one of the balls off until the stock is put through the anchor, after which the ball may be headed over. The shackles for the small and medium-sized anchors are forged in quantity. These shackles are made from round bars of the size of the body of the shackle, the ends being upset to form the eye. The holes in the eyes and the shaft that enters the

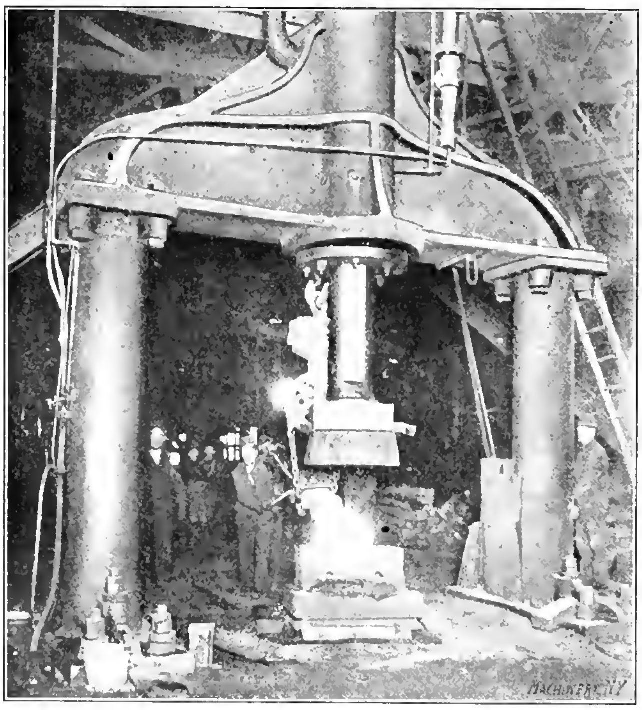

Fig. 10. Forging an Anchor Crown under a 20-ton Steam Hammer

holes are slightly oval so that they may be easily assembled correctly. The shaft is held in place by a taper key, called the fore-lock pin. To bend these shackles and still keep the iron up to its full size, was a problem that Commander Parmenter solved very neatly. The tendency is for the iron to stretch and so flatten out around the bend, thus materially weakening the shackle. He designed a simple and powerful bender that presses the ends of the piece hard up towards the bending point while the shackle is being bent at the same time, thus supplying the extra stock necessary to make a full bend. Fig. 10 shows the 20-ton steam hammer at work putting the finishing touches on one of the flukes of a medium-sized anchor. In this case, as the anchor is not a very heavy one, the crown is being held by the crane and guided by using large tongs instead of the porter-bar used on the larger work.

Costs and Accuracy of Anchor Forging

While the description of anchor forging is not a lengthy one, the work of making a 17,500 pound anchor takes a number of men 27 working days. As the material in the shape of crude iron costs in the neighborhood of eighty dollars a ton and the men receive from three to five dollars a day, it is not hard to realize that the cost of one of these large anchors runs up into four figures.

Fig. 9 shows some finished anchors weighing from 6,000 to 10,000 pounds. The two anchors shown in the upper part of Fig. 1 weigh 17,500 pounds each. As the battleships are constantly increasing in size with every new model, the anchors and chain must keep pace (a 20,000-pound anchor is under consideration at the present time), so it is hard to say when the limit will be reached. Upon each anchor the actual weight is stamped in large figures. A few of these figures were copied off as follows: 17,550, 10,030, 9,080, 10,040, 6,004, 5,975. As these anchors were made for 17,500, 10,000, 10,000, 10,000, 6,000, 6,000 pound anchors, respectively, the figures show how closely the work is done, a fact due to the system of proportional sizes that is so closely adhered to by Uncle Sam's experienced anchorsmiths.

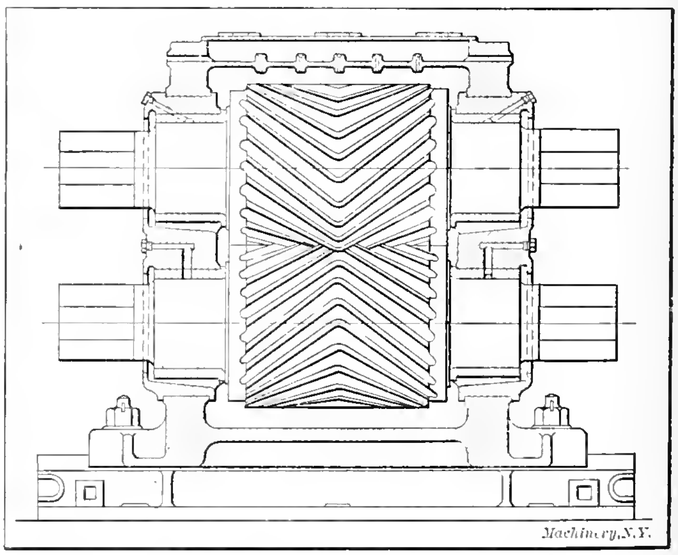
DOUBLE HELICAL CUT PINIONS FOR ROLLING MILLS

JOSEPH G. HORNER*

The steel pinions which drive the rolls of rolling mills have hitherto usually been cast in molds made by tooth-blocks in a gear wheel molding machine. Messrs. P. R. Jackson & Co., Ltd., of Salford, Manchester, England, who are probably the largest manufacturers of cast gears in England, have now constructed a plant for cutting the teeth of rolling mill pinions of double-helical forms, or straight when required. It follows that such gears must be en-



Machine-cut Double Helical Rolling Mill Pinion in Enclosing Housing

closed in an oil box in order to secure the fullest efficiency and durability. They are, therefore, fitted in enclosed housings with oil supply tank above as shown in the accompanying illustration. The advantages of smooth running, reduced blacklash, and greater durability, should more than compensate for the higher first cost of these gears over ordinary cast pinions.

* * *

Blue ink lines on tracings seldom show up clearly on blue-prints, but if a quantity of orange ink is mixed with the blue the line is made opaque.

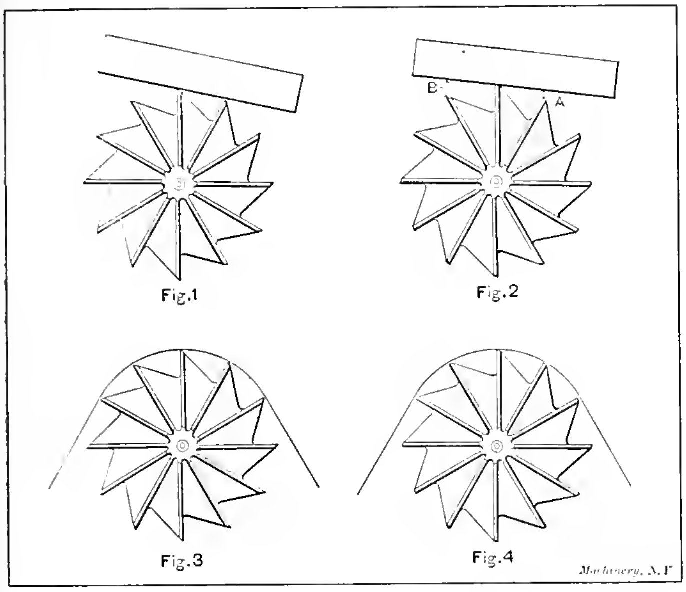
EXPERIENCES OF A YOUNG TOOLMAKER*

T. COVEY

On reporting to his foreman that the surfacing mills were ready to be hardened, Jim was told that his next job would be to grind up the end mills that he had made. Mr. Corbin took him to the grinding room and showed him the machine that he was to use to grind the shanks, and sent him to get the same gage that he used in turning the shanks. On his return Mr. Corbin said, "Whenever you are setting up a grinder for a job like this, you should keep the wheel well away from the work until you are sure that the stops that trip and reverse the traverse feed of the wheel are properly set, as otherwise the wheel is liable to run into a shoulder on the work or the footstock of the machine and either break the wheel, or damage the work or the center; and, *never run a large wheel that has no guard over it.* Now to grind tapers on this machine, loosen the clamps at the end of the table and swing the table around in the proper direction by means of this adjusting screw. This end is graduated to indicate inches per foot, and you will notice that I have set it at ½ inch per foot, which is proper for a Brown & Sharpe taper. You cannot depend on these graduations, however, for more than an approximate setting. The shank should be ground enough so that it is nearly cleaned up and then tested with the gage, first wiping it clean and dry and putting a light chalk mark lengthwise of the shank; then when you try it into the gage and twist it around, if the chalk mark is rubbed off evenly and it seems to stick in the gage, it fits all right. If one end of the chalk line is rubbed off and the other is not it shows that the table should be adjusted to make the end on which the chalk was rubbed off a little smaller. You will note that the gage is marked "Tang to project ⅜ inch"; and when you have ground the shank small enough to let the end project ⅜ inch you have it the right size. You should watch when you are first starting to grind a mill to see if it runs out badly from being sprung in hardening, which frequently happens. When the work is not too badly sprung you can scrape the center in the shank over enough to get the mill to clean up all right, but if it is sprung too much for this, bring the part to me and I will have it hardened over again. When you have the shanks all ground you can grind the teeth on that little universal cutter grinder." And with that he left Jim to himself. He got along all right until he had the first one down nearly to size. As the wheel had not been dressed off, the work was rather rough. Jim noticed it but did not know what was the matter, though he could readily see that the finish was not as good as it was on lots of work he had seen. John Cary was working on a surface grinder nearby, and he asked him if there was not some way to make that machine grind smoother.



Figs. 1 to 4. Testing the Teeth of End Mills for Clearance

"Why! I should say that if the wheel were trued off it would do a better job," said John.

"How do you true it off?" asked Jim.

"Get a diamond from the tool-room and fasten it in the holder; then with the wheel running move it slowly past the diamond—you get the diamond and I'll show you how."

When Jim came back with the diamond John went over to the machine and looked the work over; then as he dressed the wheel off, he said, "I'll tell you how I manage when I have a lot of pieces that are alike, as you have here: I true the wheel off once when I begin the job; then I rough grind all of my work down nearly to size, leaving about 0.0015 stock for finishing. After that I true the wheel off again and finish one piece and note the reading on the dial of the feed handle. By bringing the handle to the same place for each shank you can get them all the same size without taking each one out to try it two or three times. You can also do this when you are roughing them out, only the wheel will wear off more in taking off so much stock and you will have to feed it in a little further each time. When you are roughing off work, it is almost impossible to do a job in reasonable time and have the wheel stay true, and you would have to dress the wheel on each piece to do a good job; but in roughing out, the wheel will stand some crowding and still be true enough to get the stock off rapidly. If you rough all the pieces first, when you come to finish them they will be round and clean, and as you have only one or two thousandths to take off each piece the wheel will easily stay in good shape to finish a dozen shanks. Use plenty of water at all times as it keeps the work cool and helps to keep the wheel clean."

"Thank you," said Jim, "I'll do it that way."

Jim got the shanks ground in reasonably good time, and in the meantime he watched a man that was sharpening some end mills in a machine like the one that Mr. Corbin had told him to use for that purpose, and he saw him take a mill out of the machine after he had ground two or three teeth and hold the mill up to the light with a scale across the teeth. Going over to him he asked him why he did that.

"I do that to see if I have the right clearance," said he.

Jim picked up a mill that he had not ground yet and held it up to the light, using his scale as a straightedge, as he had seen him do. "Oh," said Jim, "you grind the teeth at an angle with the face that will show clearance when the scale rests on the tooth following it." (See Fig. 1.)

"No! I don't! That gives too much clearance. Here try this one," he said, handing him one that he had just ground.

Jim held the scale on that and saw that it looked altogether different; in fact, it did not look to him as if it had any clearance at all.

"Why, on this one the scale does not even touch the following tooth. Surely, that is not clearance enough."

"Yes it is," said he. "As long as the distance from the cutting edge of the following tooth (*A*, Fig. 2) to the scale is less than the distance from the scale to the tooth in front (*B*, Fig. 2), you have clearance."

"But why was this mill ground like this?" said Jim, pointing to the mill he had first picked up.

"Some fellows have a wrong idea as to the amount of clearance needed, and that mill was not inspected after it was ground. It has altogether too much clearance; there is no support to the cutting edge, and the result is that it will get dull before it will do half the work it should. Let me take that flexible scale of yours and I will show you. There!" said he, now you can see the actual clearance it has when at work." (See Fig. 3.)

"Yes," said Jim, "that does look like too much."

"Now try the one here that I have just ground. See the difference? And there is plenty of clearance, too." (See Fig. 4.)

"I see that there is now, but at first I was inclined to think that you were joking with me. I have been sent for left-hand monkey wrenches, and to the blacksmith to get file teeth drawn out, and on other fools' errands, until now when I see or hear something that does not look just right at first, I am like the man from Missouri—I 'have to be shown.' Well, I have got these shanks about ground, and the next thing is to grind the teeth. I suppose that I will have to set that ma-

* Previous installments of this series of articles appeared in the numbers for August and December, 1909.

chine up as you have this one."

"No, I'll be through here in a few minutes and you can have this one. That one is all set up for grinding the teeth on the ends and I will finish my job in that. It will save us both work."

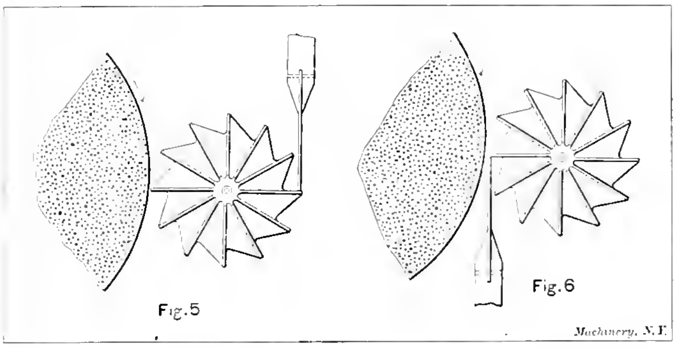
Jim wiped off the grinder and returned the gage and diamond to the tool-room and then started in to grind the teeth. As the machine was all set up he had no trouble at first, and he remarked to his friend on the other machine that "it was not such a very difficult job to grind cutters."

"No, the most important part is to get the clearance right and keep them straight. If they are not straight it is difficult to do accurate work with them."

"What is the best way to tell if they are straight?"

"Oh, just measure each end with your micrometer and keep them within a half a thousandth or so of the same size." Then as his job was finished he gathered up his work and tools and went away.

Jim got a two-inch micrometer and went over the mills he had ground and found that they were pretty straight. He



Figs. 5 and 6. Incorrect and Correct Methods of setting Tooth-rest

had only two more to grind the side teeth on, and one of them was the one that he had made the mistake on when he was milling it up. He put it in and started to grind it when he noticed that on one of the teeth the wheel did not cut at all, while it took a good cut off the others. He saw at once that something was wrong, and as John was still working on the surface grinder he took the mill to him and asked him what was the trouble. John looked at the mill and said, "Your machine is not properly set up."

"Why, it is just as that man who left a few minutes ago was using it, and he seemed to think it was all right."

"Well, I suppose it is all right for mills on which the teeth are evenly spaced, still I would rather have it set differently if I were using it, and not take any chances."

"What is wrong about it?"

"The finger which you use to index with should bear against the same tooth that you are grinding (See Fig. 6) and not on the opposite side, as it is now. (See Fig. 5.) With the finger, or stop, resting against the tooth you are grinding, all the teeth stand in the same position in relation to the wheel while they are being ground; while if it rests against any other tooth any inaccuracy in the spacing of the teeth makes an error in grinding. Of course, ordinarily the teeth of mills are properly indexed and it would make little difference, but you will occasionally find a case like the mill you have here, and also cases where the face of the teeth have been ground free hand, especially saws, etc., where it becomes necessary to grind new teeth because the old ones were worn too short to work good, and in such cases it is impossible to grind the mills or saws so that they will work good unless the tooth that is being ground is the one that rests on the index finger."

"I wonder why that man did not say something about that? He seemed to be a pretty good fellow."

"Probably he did not think that any of your mills had irregular spacing; or it may be that he never took notice of that feature. No one man knows all about this business, you know. We all have our failings and are never too old to learn something new to us and old to the other fellow. I have seen grinding machines put on the market by some of our most reputable machine builders, so designed that it was impossible to get the index finger underneath a cutter in the proper position. Still it is easy to demonstrate that it must be there to do good work."

Jim changed the machine by putting the arm that holds the finger into the binding socket from the bottom, then on re-grinding the mill be found that it acted differently. But on measuring the mill up with his micrometer he found that the tooth that was off in the indexing was apparently small, and he asked John the reason for that.

"That is all right," said John. "It is small because the two teeth you are measuring are not exactly opposite each other. If you had means of measuring the radius of each tooth, you would very likely find them all the same. If you doubt it, put the mill on the lathe centers, clamp an indicator in the tool-post and revolve the mill slowly by hand with the indicator just registering zero as the cutting edge of the tooth passes it and you will probably find that all of the teeth are of the same height."

"I think I understand what you mean," said Jim, and he went back to his machine and finished up his other mill, after which he called John over and asked him if the other machine was properly set up to grind the teeth on the ends. John looked it over and said, "I think it is, but we can tell better by putting a mill in and grinding it. There are two things to look after in grinding the teeth on the end of a mill. One is to get the proper clearance and the other is to be sure that the center of the mill is not higher than the outside. If the center is high it will not leave an even surface when at work; that is, if you were milling a plain surface on which it was necessary to take several cuts side by side you would find that the center of each cut would be low, leaving furrows on your work; while if the center was low this would not occur, so you see it would be better to have the center of a mill a little low, if anything."

"How do you tell when it is low?"

"By holding a straightedge across the two teeth that are opposite each other and noting that there is light underneath

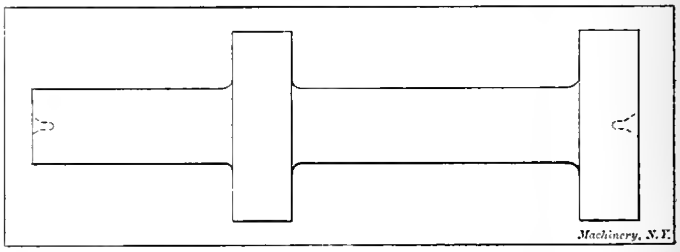


Fig. 7. Test Piece used to set Grinder Table Straight, prior to Internal Grinding

the straightedge in the center of the mill. Or, in case of an odd number of teeth, by rubbing the end of the mill on a plain surface on which you have rubbed a thin coat of prussian blue, then if the mill is properly ground the blue should show on the outer edges of the teeth and very little, if any, in the center. You very seldom find mills with an odd number of teeth, however, as it is difficult to measure the diameter of such mills, and unless it is necessary for some special purpose, they are not made. This machine seems to be all right, but a coarser wheel would be better, as this one is so fine that you are liable to burn the teeth if you are not careful."

"What do you mean by burning the teeth?"

"Why, drawing the temper from them. I don't suppose that it would be possible to burn steel in the way that it could be burned, or overheated, in a blacksmith's fire, by grinding. It is just an expression that machinists and toolmakers have coined for their own use and means heating the steel by grinding until its temper has been drawn. You will be able to notice it by the outer edge of the teeth turning blue."

"It seems queer to me," said Jim, "that this high-speed steel, which will remove chips of a blue color, could be injured by drawing the temper to a blue color."

"Well, to tell the truth, it does to me also, and I am unable to explain why it is so, but I do know that a great many brands of steel will not stand it. There are some brands of high-speed steel that the makers claim cannot be injured by heating on a grindstone or emery wheel, but I never saw any

that was improved by it, and I would much rather be on the safe side because steel on which the temper would not be affected will generally crack and check until the cutting edge would crumble away ,under a cut."

"But why is a coarse wheel less liable to heat a tool or cutter than a fine one?"

"A wheel for grinding metals is built up of numerous particles of abrasive material held together by a bond, or cement, and in a way could be likened to a milling cutter, as it actually cuts chips off, though, of course, they are very small and cannot be recognized as chips except under a strong magnifying glass. Now if you were to use a milling cutter with very fine teeth and force it to take all the cut it could, each tooth would cut until the space in front of it was full of metal when it could cut no more; then if it were not yet free to discharge this metal, or had not passed over its cut, it would have to carry the metal along rubbing hard against the work until it could get rid of it. By this time perhaps the metal is jammed in so hard that it sticks fast, and when the tooth comes around again it is already full and can only rub past the work, causing much more heat than it would if it could cut. On the other hand, take a coarse cutter and there is plenty of room for the chips, and each tooth can cut all the time that it is in contact with the work without crowding the space full of chips. It is the same way with emery, or abrasive, wheels; the coarse ones are adapted to remove metal fast without generating much heat, while the fine ones are more for putting a smooth finish on work, but they must not be crowded or the teeth will become full and the wheel will rub along instead of cutting freely."

Jim finished all the grinding on the mills and took them to Mr. Corbin, who looked them over and pronounced it a good job. "Now," said Mr. Corbin, "your surfacing mills are ready to be ground, and that will finish them. Take them over to the same machine that you used to grind the shanks on the end mills. You will find a chuck over there that will fit on the spindle of the head-stock; put that on instead of the driver, unlock the spindle so that it can turn, and shift the belt onto the pulley that is fixed to the spindle; then you can chuck the mills and grind the inside the same as you would bore them out in a lathe. There is an internal grinding attachment for the machine and you can get some one of the men that is working over there to show you how it is set up, as I have not the time now. I'll be over after a while and see how you are getting on."

Jim carried his work to the machine, put on the chuck and chucked one of the mills; then he asked John about the internal grinding attachment. John pointed it out to him, and told him that to put it on the machine he would have to remove the wheel from the main spindle and mount a pulley, which he showed him, in its stead; then turn the spindle head around and mount the attachment on the support provided for it and connect the spindle of the attachment to the main spindle by a belt. "Did you set the machine straight before you chucked your mill?" asked John

"No," said Jim.

"Well, you will find it a rather difficult job to get it straight unless you do it first."

"I don't know how to get it straight other than to set the graduations at zero."

"Here in this cupboard is a piece of steel that we use for that purpose. (See Fig. 7.) Take your mill out of the chuck and put this in instead, catching it by the small straight end; set it as true as you can and then take a cut off the two disks. When you have the table set so that your cut leaves both disks the same size, using a micrometer to measure with, the machine will be set to grind a straight hole. If you chuck the piece pretty true, you can get it nearly straight by noticing on which disk the wheel throws off the most sparks, and changing the table accordingly. Leave the big wheel on the spindle until you get the table set straight, as it will cut faster than the small one. When you are ready to put on the attachment, let me know and I will help you to get things right."

Jim got the machine straight in a short time and then removed the wheel and made the other changes that John had mentioned; then he called him over and asked him if he had things right.

"Yes, I think so," said John, "but you will have to get a new wheel, as that one is about worn out. Tell the stock-keeper that you want a wheel for internal work, if Mr. Corbin does not specify it on the order. You will probably have to turn it down with a diamond until it is small enough to go in the hole, as the wheels to fit this fixture do not come less than $1\frac{1}{2}$ inch in diameter."

"How would you chuck the mills?" asked Jim; "true with the outside or inside?"

"True with the outside first; then watch when you start grinding and if the hole runs out so that there is danger of it not cleaning up, chuck it so that it will, leaving the outside as true as you can."

"But how can you tell that it is going to clean up before it is finished?"

"Well, until you get enough ground out so that you can measure the diameter of the hole, or until the cut covers more than half of the circumference in some one place, it is simply a matter of judgment; but after that it is a simple matter that is familiar to most lathe hands. Measure the diameter of the hole as the cut leaves it and subtract this size from the finished diameter; the difference is the amount of stock on both sides of the hole. Divide the difference by two and add the result to the size of the hole as it measures; set a pair of common inside calipers to this size, using an outside micrometer to set them to; then if there is no place in the hole that the inside calipers will not touch, the hole will clean up. For instance, suppose you grind out one of the holes so that you can measure the diameter of your cut, and then set a pair of inside calipers so that you can just feel a touch with both legs resting against a ground surface; then set an outside micrometer to the inside caliper so that you can get the same touch as you did in the hole, read the micrometer and find that you have ground the hole to, say, 1.242 inch diameter. The hole is to be 1.250 inch when finished; then $1.250 - 1.242 = 0.008$ inch stock still to be removed. $0.008 \div 2 = 0.004$; $1.242 + 0.004 = 1.246$. Set your outside micrometer to this size and set your inside calipers so that you get a light touch on the micrometer; then with the inside calipers measure the hole, and if you find no spot where the calipers are free, the hole will finish all right. You want to be careful though that the wheel is cutting full size when you take the cut that you measure from, for if it should spring away from its cut for a thousandth or so your measurements would be off. It is best to have apparently a couple of thousandths to come off the lowest spot; then you are sure. You will find that internal grinding is different from outside work, especially in small holes. It is necessarily a much slower job and cannot be crowded if you expect to do good work."

"Do you use water?" asked Jim.

"No. On outside work water washes the grindings away and helps to keep the wheel clean while the reverse is the case with inside work. However, it is a good idea to cool the work with water before trying in a plug or hardened and ground sizer; for if the work was warm and you inserted a cold sizer that would just go in, unless you were pretty quick in pulling it out again, it would be very likely to stick, as the hole would close in and the sizer expand, on coming in contact with each other."

Jim got on pretty well with his work and had a couple of the holes ground when Mr. Corbin came to see how he was getting on. "You seem to be going at it all right," said Mr. Corbin.

"The credit for that is due to Mr. Cary, there, who showed me how to go about it. Where will I grind the ends?" asked Jim.

"On this same machine. There is an expanding arbor that fits the spindle in the place of the center; put that in and loosen the nuts that clamp the headstock and swing it around so that the graduations read 90 degrees, and clamp it fast again. Then slip one of your mills on the arbor and secure it by tightening the screw in the end of the arbor; take off the internal attachment and put the big wheel back on the spindle, then you can back the wheel away until it will clear the mill, set the stops so that one reverses the travel of the

wheel at the center and the other at the outside. Let your cut come on the side of the mill that is traveling upward. The mills should be ground so that they are square across the ends, or if anything a very little concave. When you get the ends ground you can grind the teeth on the cutter grinder that you used to grind the end mills on." With that Mr. Corbin left Jim to himself again.

Jim got the holes all ground out and the machine set up to grind the ends. As he started in to grind, however, he found that the head was not set quite right to get the ends square, and he made several efforts at re-setting it without much better results. John noticed him and coming up said, "Leave the head clamped as it is and make any other adjustment you wish by changing the whole table the same as you would if you were grinding a taper. The screw adjustment on the table is much more sensitive and it is no trouble to move it as little as you like. You want to be sure and keep your wheel clean at all times so that it cuts and does not glaze the work by rubbing. Glazing seems to set up a strain in the metal; sometimes enough to burst the mill lengthwise. I broke two mills myself in this manner before I found out the cause; the tool hardener got the blame for it, and at the time I thought he was to blame, but I have learned since, from experience and observation, that it was my fault. I have seen several mills that broke during the grinding operation or shortly after, and all that I ever saw had a smooth glazed surface and under close examination would show numerous small checks all over the glazed part. I never like to see a smooth glassy surface on hardened and ground work unless it is obtained by lapping, and if such surfaces are afterward lapped they will generally show up more irregular than one obtained with a sharp wheel. In thin work such as saws, templets, etc., if the wheel is allowed to glaze, or even approach that condition, the work is sure to buckle."

"Is it much of a job to grind the spiral teeth on these mills?" asked Jim.

"No," said John, "it is an easy matter. The only difference in grinding straight and spiral teeth is that for spiral teeth the index finger is secured in a fixed position in front of the wheel; then when the mill is pushed by the wheel, the face of the tooth resting on the finger, which does not move, causes the mill to turn just the same as it did when the teeth were cut. The top of the finger should be rounded slightly so that the face of the tooth bears on the center of it. The wheel should be trued off so that that there is only a narrow cutting surface, and the finger should be wide enough to allow the tooth to rest on it before the wheel begins to cut, which should be when the end of the mill approaching the wheel reaches the highest portion of the rounded end of the finger.

"How do you hold the cutter?"

"You can either put in on a solid arbor between centers, or there is a hollow arbor for that machine with stepped collars to fit the standard sized holes in cutters; this arbor slides on a round bar that may be mounted in a fixed position in front of the wheel. This latter method is the best as there is no possibility of getting one end of the mill you are grinding smaller than the other, in fact, nothing but straight mills can be ground in this way. Well; I have got my job over here finished and I'll have to pick up and leave. If you run into anything you can't master, let me know and I'll do my best to help you out."

"Thanks," said Jim. "I think I ought to be able to finish up this job without bothering anyone any more."

* * *

As photographs are becoming more and more commonly used as evidence in legal cases, the *Engineering Record* calls attention to the necessity of having photographs thoroughly identified. Engineers and contractors who make a practice of taking photographs as matters of record would do well to have some independent representative present at the time each photograph is taken, so that he could go on the witness stand and testify that the views were taken in his presence and correctly represent the conditions on the dates when they were taken. Unless some such plan is followed the court may refuse to accept photographs as evidence on the ground that they are not properly authenticated.

TOOLS FOR DRAWING SEAMLESS AUTOMOBILE LAMP HOODS

WILLIAM A. PAINTER*

The drawing dies and punches for drawing a rectangular hood for automobile lamps, in one piece, are illustrated herewith. The advantage of a one-piece hood over the regulation built-up and riveted one is the convenience in cleaning, there being no seams or rivet heads to catch the rouge, cleaning compound or polishing cloth; in addition, the hood has more pleasing lines and greater accuracy can be obtained.

A rectangular shell or drawing is more difficult to produce than a circular one, especially where the corners or angles

Fig. 1. Punches and Dies for Rectangular Lamp-hoods and the Stock Before and After the Drawing Operations

have to be sharp, as the rapid flow of metal to the corners, when reducing from the flat, being out of proportion to the rest of the area, has a tendency to clog and tear the metal. This hood is made of brass, and measures 1 7/8 inch deep and 4¼ inches by 4½ inches across the sides; it is made from a round blank *A* (Fig. 1), the quantity not warranting a special blanking die attached to the drawing die.

The shell is drawn in two operations. Two dies of the same size are used, except that the drawing edges of the first die are rounded, while the second one is sharp. The cast iron shoes or holders are duplicates, and are made for a double-action press. The first drawing operation is made in die *D*, which is set in the holder in place of die *C*, which is the finishing die. The sleeve *B* is used in both operations. The

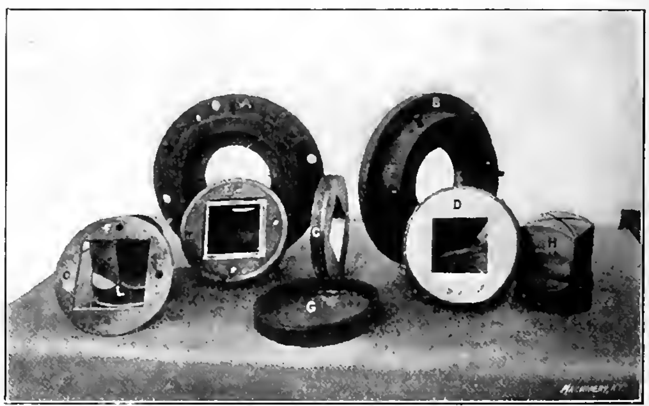

Fig. 2. Protective Shields used for Local Hardening and Dies with Shields in Place

blank *A* is held in place on die *D* by spring gage-pins, different holes being used for different depths of hoods. After the first operation, the flange on the shell is nearly rectangular in form, as shown at *G*. The flow of metal to the corners is also shown, proving that a circular blank is the correct shape, and not a rectangular one, as this shape would not draw at all.

The rounded punch *F* for the first operation and also the one shown at *E* for the second operation are both vented by holes and cross channels; the object of this is to prevent the punch from drawing the finished shell upward by suction on the return stroke of the press. The holes alone would not be of any advantage, as the sheet metal would cling to them and stop the passage of air, but with the channels this is overcome.

The first operation draws the shell to within 3/16 inch of

* Address: 1515 Franklin St., Pittsburg, Pa.

full depth. The shells are then annealed, and the sharp draw-punch *E* and the die *C* are put in the press. The shell enters the die and rests on its flange, and is held by a sleeve while the punch enters. This operation sharpens the edges only, as the drawing of the metal has been accomplished in the first drawing die. The partly completed hood is shown at *H*, while different views of the finished hood are shown at *J* and *K*.

The dies and the sleeve are held in place by six half-inch square-head screws. The cast iron holders are bored straight to fit the dies, which are beveled five degrees in the center of the rim, leaving about 5/16 inch of straight surface at the top and bottom as shown at *C*, Fig. 2. This straight surface is an easy fit in holders *A* and *B* so that the dies can be revolved when the screws are loosened; the object of this is to permit first tightening the punch on the thread of the plunger when setting up tools, without regard to the relative positions of the die and sleeve. When a shell is put in the die and the bed is set to match the screws in the bolster, if the die is free it can be revolved until it matches the punch; the punch is then entered into it and all screws are tightened. This operation is repeated on the sleeve or pad, and it eliminates packing the punch with washers to make it line with the die, as well as the risk of the punch jarring loose and breaking the die or sleeve.

These dies were hardened by my local hardening process, as the shape and angles of the disks would make it a hazardous operation to harden them in the regular way. [For a description of this hardening process see Mr. Painter's article on Local Hardening and Tempering, August, 1908.—Editor.] The dies are 9½ inches in diameter, 1¼ inch thick, and only 1½ inch from the corners of the rectangular hole to the outside, so that the strain in hardening would be at these sharp corners.

The face of the die with one of the steel covers used in the local hardening process in place is shown at *D*. The back of another die when covered to within ½ inch of the square hole is shown at *E*. There are four ½-inch holes in this cover to equalize the cooling. The covers for die *C* are shown at *F* and *G*. These are the same as those shown in place at *D* and *E*. The thickness of the stock from which these covers are made is 0.025 inch. The band *G* is slit with shears and held together with rivets.

These dies were heated in a gas oven and then dipped in clear water. They did not shrink or warp, and have been used for drawing thousands of hoods. The punches *H* and *L* have machine steel bodies and tool steel working ends. The ends are hardened on the outside only, sheet steel being applied to the back of them when hardening. All these covers were put on before heating the parts and were dipped with them. The temper was drawn to a light straw color after the covers were removed.

* * *

At a recent exhibit of gas appliances in New York, certain power-driven machinery was shown, having exposed bevel and sprocket wheels in operation. To prevent accidents to visitors, they were protected with wooden shields, sufficiently to keep the inquisitive sightseer out of harm's way. In regular manufacturing use, however, we infer that these potential instruments of accident are absolutely unguarded, so far as the maker has provided. The extra cost of providing efficient gear guards would perhaps be two or three dollars at the most. What is the use of saving a few cents where the saving may mean the loss of a finger, hand or arm? Even if the humanitarian aspect is ignored, it is poor business policy of the user to let such man-traps exist, and he has a right to expect the manufacturer to supply his machines guarded in all respects where possible. Damage suits are ugly affairs; the defendant is beaten even if he wins because the ill-will and hatred engendered will cost him much in the end.

* * *

The value of the imports of machine tools to Hungary, according to recently published statistics, amounted in 1907 to about $900,000. Machines to a value of about $500,000 were imported from Austria, $325,000 from Germany, and only $58,000 from the United States. Recent developments show that Hungary offers a fair field for the machine tool trade.

YOUNG BRAINS AND OLD

A. S. ATKINSON*

It goes without saying that the young man has a better chance to-day than the old chap who has passed fifty, and when you get past the latter age, woe be unto you if you lose your job. It doesn't seem to matter very much that our grandfathers took more stock in age than in youth and looked upon the man under thirty as of little real account in the business and manufacturing world. Age meant maturity of judgment, and one couldn't be sure of himself much under fifty. So they put out their sign of "Slow and Sure."

Now we have reversed conditions, and every shop and business concern is picking up the young man and dropping the old. Of course some old codgers can't be shelved. They simply bob up smilingly and get there just the same. Nevertheless, the old sign has been reversed, and we read the warning, "Young men wanted; no old men need apply."

Well, of course, that's all right if everybody believes that a man of fifty has lost his usefulness and is chiefly good for holding down cheap jobs that an office boy fresh from school could do as well; but sometimes the "Oslerizing" process may be carried a bit too far. I suppose I am particularly interested in it because of the story about "Old Si Smith," which I related in a recent number of MACHINERY, and of another little experience of "Pop" Lester's, who took his medicine like a man and then got cured of the "old age delusion."

"Pop" was superintendent of the big machine shop whose sooty black smoke can be seen any day clouding the atmosphere up on the Hudson, just far enough beyond the city line to escape the Health Board's edict that nobody shall burn soft coal in the metropolis. This shop is one of the oldest in the country, and it had the reputation of doing some of the finest work on this side of the Atlantic. The old man who built it up had made Pop superintendent way back in the eighties, and under his wise management the profits had been large enough to please anybody except a modern millionaire's son anxious to get the record for fast spending.

Anyhow, when the old man died and the young chap inherited the fortune and the big machine shops, there was bound to be some sort of a change. The youngster came down to look the shops over, and brought an expert with him. They went through the shops, under the guidance of Pop Lester, the superintendent, and the way they commented on the machinery and equipment was enough to drive a good machinist crazy. "Antiquated," "Out of date," "Fit only for the scrap-heap." These were a few of the epithets they used, and Pop winced and bit his lips. He tried to explain that some of the machinery was almost as good as new, and that all of it was doing first class work.

They didn't listen much to these apologies for the machines; they had a reason for their inspection. It didn't come out right away, but after a while it leaked. The young heir wanted to increase his profits, so he could spend a few more dollars on Delmonico dinners and chorus girls, and the machine expert was looking for a good fat job as superintendent and incidentally for some liberal commissions on machinery. They both had their way in time. Pop was kindly and thoughtfully relieved of his position, the young owner explaining plausibly that he wanted the shops run on modern methods, and he thought a young superintendent could do the trick better than an old man. His father had been all right in his day and time, but things had changed a good deal since he was a young man. The shops were in a bad way, and were not making half what they should. He had figures and facts to show it. Here they were, if Pop wished to examine them.

The old superintendent was too surprised and dumbfounded to protest or even to examine the paper shoved toward him. You see he had been the head of the shops so long that he had got into the habit of considering it a life job. It would have been, too, had the old man lived.

Pop wasn't exactly turned loose to shift for himself. That youngster condescendingly said that the deposed superintendent could take a position in the drafting-room, where he

* Address: P. O. Box 1189, New York City.

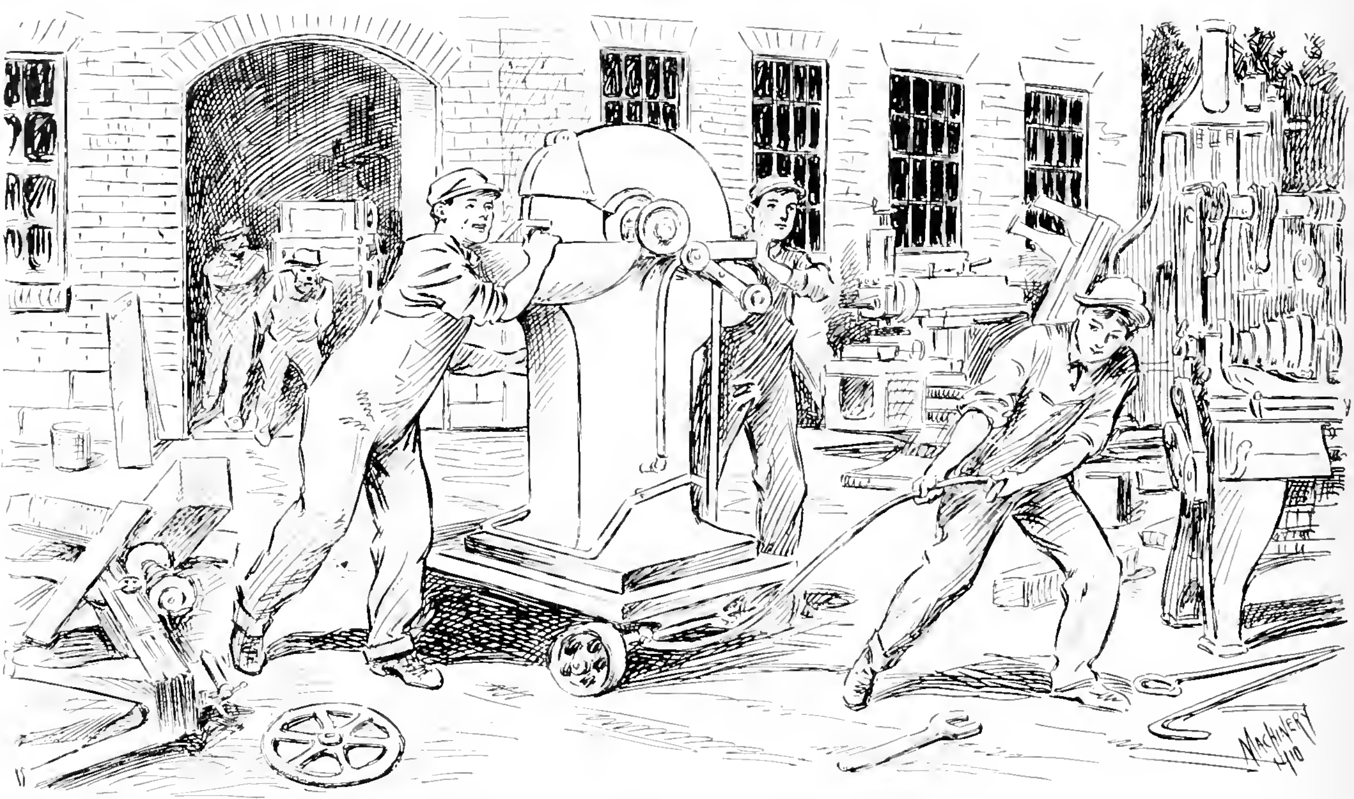
could make himself useful at twenty per week! Think of it!—when his salary had been running into figures that would pay for a first-class automobile once a year!

We felt sorry for the old man, every one of us, but we had too much to think about in holding down our own jobs without openly rebelling for the sake of another. Pop had been kind and considerate to every one of the boys, and we didn't forget it now. We went round in a delegation and asked him what we could do for him. Go on strike? "Good Lord, boys, no!" he said. "We never had a strike in these shops—not since I've been here—and I'm not going to be the cause of one. Go back to your work and hold your own jobs. I'm mighty thankful, however, for your expression of confidence in me—mighty thankful."

The new superintendent was about as boyish-looking as the young owner of the shops, but a little bit shrewder and more experienced. He knew more about machinery than his employer, and possibly more about men and business. At any rate it had all been framed up before he took hold, and the first thing they did was to rip out the old machines. Say, it was a waste of good material, and it gave you a real heartache to see the machines smashed up and carted away. Why, orders ahead had to be cancelled, and others we lost through delay, so the contracting parties threatened to sue the young owner. There was a lot of legal quarreling, and a good deal of trouble all around. The young superintendent, I guess, hadn't figured on the loss of time the big change would make, and neither had the owner.

Well, things finally got started. We had a few new orders, and we started on them. But all that machinery was new to many of the men, and they had to go slow. The young superintendent told the foreman of the shops that he had to make up for lost time, and he tried to push us, but you can't be pushed when you're riding a new horse, and we had a lot of breakdowns and ruined much work. The more the foreman drove us, and the more the superintendent fumed and threatened, the worse we seemed to get, and the new machines showed they were nervous, too, or something like it.

Then pretty soon another trouble followed. Some of the work the shops turned out wasn't satisfactory and didn't come up to specifications, and the buyers refused to pay or threatened to sue the shops for swindling them. Now the old man had earned the reputation for superior work in the past, and his name stood for more than most people's bond. When



"Pop must have felt as if the bottom was tumbling out of everything when he saw those old and new machines ripped out of the shops and new ones put in"

some of them weren't more than a year or two old, and some had done good service for five years and were good for five more. Some of Pop's old pet machines, a big jig-saw and a boring mill he'd had for ten years, were a little out of date and had been patched up some, but they hadn't lost five days for repairs or breakdown in all that time.

Pop had been a little economical in a way; he always hated to turn down an old machine for a new one until he was pretty well satisfied its days of usefulness were gone. I suppose he looked at 'em most as he looked at himself. A machine must wear out in time, and if you keep it long enough it will get out of date. But it isn't good policy to hurry it along to the scrap-heap too fast. Pop must have felt as if the bottom was tumbling out of everything when he saw those old and new machines ripped out of the shops and new ones put in. But he had nothing to say and the machines were sold for scrap and for second-hand machines, just as bidders chose. The new machines came in and were put up by experts. They looked all right, and were all right, and they had many new improvements. Some of 'em could do double the work, and I guess it was only a question of time before the young owner would find his profits increased. But we lost a lot of time making the change. Some of the an article came out of his shops and bore the name of the firm, it was accepted without question everywhere. This reputation meant a lot more to the shops than the young owner realized. At first he told the kickers to go to some hot place, and the others he defied in court and got all he wanted of such proceedings. I suppose he had to have the experience to cool him down and make him understand that even a millionaire isn't the only toad in the big business puddle.

Things went from bad to worse in this way, and by the time we got used to the new machines the shops had a dozen lawsuits on hand and a lot of rejected junk that buyers had shipped back to us. But worse than all this, we'd tarnished the reputation of the old man's shops for first-class work. I guess instead of increasing his income, the new superintendent had cut a pretty big hole in his employer's bank account.

We heard something about this from their talk around the shops, and they put their heads together to find some remedy. The first thing we knew about it was they'd decided to cut wages. That was something that had occurred only twice in the history of the works. Once when hard times hit the business world, the old owner had appealed to us, and said he'd have to cut wages for a time to prevent losses, but he'd restore them within six months or a year. This same thing

happened ten years later, and each time we met the cut with a smile and assured the old man it was all right. He'd stood by us, and we'd stand by him. But now nothing was said about restoring the wages later. Indeed, when our committee spoke about it, they were pretty nearly kicked out of the office, and told to mind their business or they'd be "chucked" out body and soul. Pleasant, wasn't it? Just the sort of "dope" to make self-respecting workmen love their employer. We did, of course, and stood ready to grovel on the ground before him. We talked it over, and decided that for the present no strike would be called. We felt proud of the reputation of the shops, and didn't want to disgrace them. We stood it quietly for six months, and then we asked again if wages would be restored to their old standard pretty soon. We got our reply all right, and it was right in the face. It came in the form of another cut, and a pretty deep one. We couldn't stand for that, and we struck—every mother's son of us. We walked out and let the machines stand idle, and then the most distressed man around the diggings at that time was Pop Lester. He was genuinely sorry and worked up. He went around among us and begged us to refrain from any violence. He tried to excuse and apologize for the young owner and the new superintendent. But there wasn't much to say in their behalf, and Pop had some pretty weak arguments to present.

A big strike in a machine shop isn't an easy proposition for any employer to face, and that kid and his kid superintendent found before they were through they had to do some hustling. You can't pick up five hundred skilled workmen every day in the year, especially when the wages offered were small. So the strike drifted on for several months, and then to six months. The plant was losing orders right along, and it was costing the owner a pile. I guess he had to cut out some of his expensive dinners and chorus girls.

It was the most peaceful strike I ever saw. Pop was around night and day, and we listened to his advice and kept from doing any harm. They managed to get a dozen or two men in the shops, but they ruined more work and machines than anything else. Then one day Pop Lester came around with a more serious look on his face than ever, and when he got enough of us together, he said: "Boys, I want you to go back to work to-morrow—for my sake."

"Too much to ask, Pop," somebody yells out. Then another says: "If you'll be superintendent of the shops, we'll go back at the old wages."

The old man smiled and answered: "That's just what I came to tell you. I've got back my old job, and I want every man here to get his, too."

There were plenty of wild cheers then, and some of them were so noisy that we had to wait a long time for the old superintendent to finish. "You will have to go back at the lower wages," he continued, "for the plant has lost lots of money, but as soon as we get some of it back, we'll restore wages."

Did we go back? You bet! The next morning every man was in his place, and things began to hum. Pop was kept as superintendent after that until he died; and as for that youngster, he learned his lesson, and now before making a big change he always consults with his old reliable guards.

* * *

The use of lava for gas burner tips dates from 1854 when J. von Schwarz discovered its advantages for the purpose. The lava is found in Bavaria at the southeastern point of the Fichtel Mountains, near Bayreuth. It has been used for hundreds of years for musket balls, marbles, fireproof utensils, carved ornaments, etc., being readily turned, sawed and polished. It does not disintegrate with long-continued and repeated heatings, and its smooth non-porous surface prevents carbonization and deposits from the gas.

* * *

The value of the yearly import of machine tools to Spain amounts to about $600,000, and Germany supplies more than one-third of the machine tools imported. Apparently Spain offers an opportunity for the increase of the foreign trade of the United States in machine tools.

JIGS IN A REPAIR SHOP*

A. H. LAVERS†

That jigs are an indispensable factor in economical quantity manufacturing is undisputed. As a necessary element in repair machine shops that are a part of any manufacturing establishment, where the shop is used merely in repairing and building additional equipment, the use of jigs has apparently been neglected to a greater or less extent. This applies particularly to plants in which repairs must be interchangeable and effected at short notice.

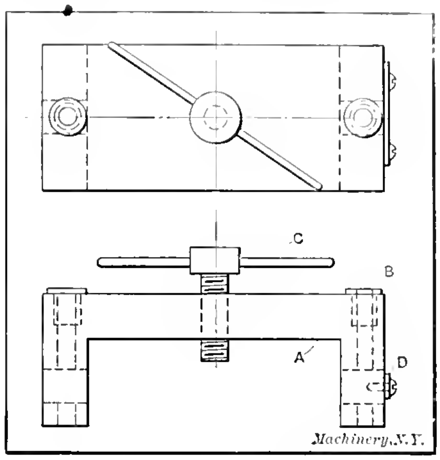


Fig. 1. Simple Form of Jig for Drilling Two Holes in Shaft Ends

In the case of pipe flanges and fittings, or standard parts, it pays to make up fairly expensive jigs, as a standard once established can rarely be altered without causing confusion. The cost of jigs for parts of machinery constantly undergoing changes and improvements, is usually the most important feature, although the time element in duplicating parts must not be lost sight of. Another point that undoubtedly has a bearing on the question is to make the jigs as simple and fool-proof as possible, thereby permitting the employment of unskilled labor in drilling operations and minor lathe jobs.

As a usual thing, repair shops of this character are supplied with drawings of a machine and an order to build one, which, if satisfactory, would necessitate the building of several more. At once the question presents itself: If the machine is satisfactory, what parts will wear out, call for replacement and the use of jigs in repair? This must be decided and then the simplest possible design of a satisfactory jig should be made.

It is good practice to leave the judgment of matters of this kind to some one man who is familiar with the particular shop's practice, but entirely independent, and who, also, has an opportunity to study the machines in operation in both the machine shop and the factory.

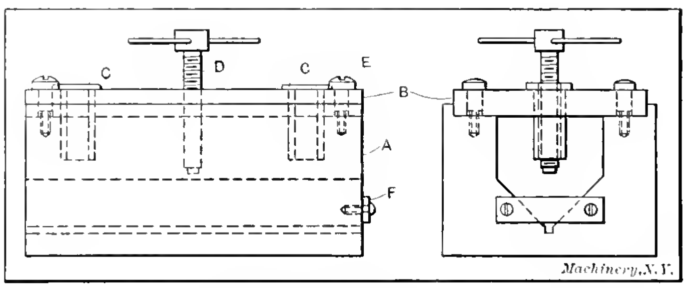

Fig. 2. Jig with Removable Top and V-shaped Locating Surfaces, for Drilling Shaft Ends

A great help in production of work of this kind is to have an equipment of reference gages for press, running fits, etc., standard reamers and tram-rods for bores or parts of large diameters. It sometimes helps to economize by combining several operations on different machines in one jig, and further on some illustrations of this will be presented. Once in a while a job will present itself in which the first number of duplicate parts required will run up in the hundreds, and then a dozen pieces that are duplicates are required at frequent intervals. This, of course, allows the expenditure of a little more money to decrease the first cost of

* For additional information on this subject, see the series of articles on Jigs and Fixtures which began in April, 1908, and other articles referred to in connection with the first installment of this series.

† Address: 534 Canton Ave., Detroit, Mich.

production, thereby giving a little better price to succeeding pieces.

The writer will, in the following illustrations, endeavor to present a number of simple jigs covering various operations. It is not claimed that there is anything strikingly original about these jigs, but simply the adaptation of simple means

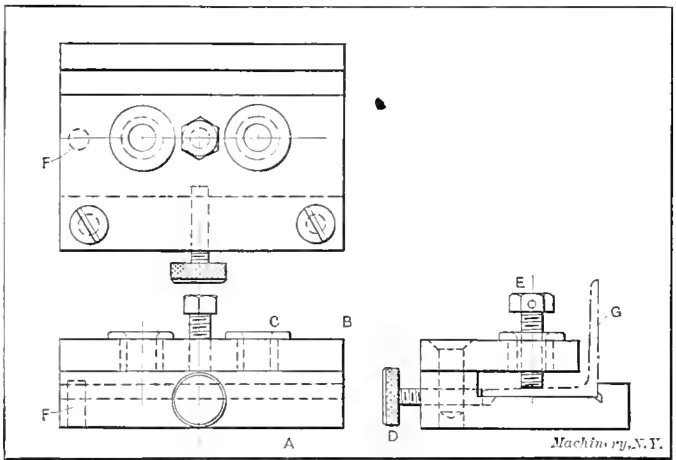

Fig. 3. Simple Jig for Drilling Accurately-spaced Holes in Angle-iron

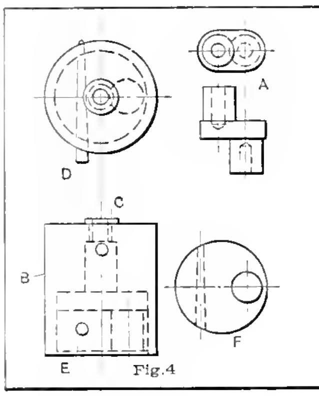
to produce interchangeable work. It is also intended to include in this article some examples of simple lathe and boring mill chucks, which, while they are not, properly



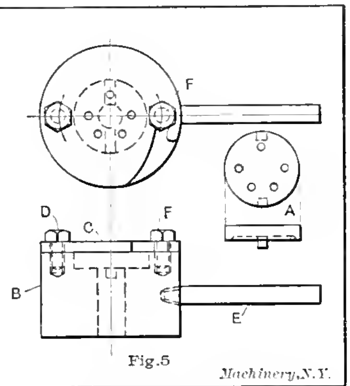


Fig. 4. Ingenious Form of Jig for Drilling Crank A

Fig. 5. Jig with Hardened Plate which guides the Drill and clamps the Work

speaking, jigs, are an important aid to the production of interchangeable parts.

The jig illustrated in Fig. 1 is for drilling two holes at the ends of a piece of shaft, and, as may be seen from the illustration, it is of the simplest construction. The body *A* is of U-section and in it holes are drilled to receive the work. Two holes are drilled at right angles to the shaft openings, and are counterbored to receive the bushings *B*. The shaft is clamped by screw *C*, and located by stop *D*. It may be worth mentioning that the body was made of an old casting which happened to be available, and the same thing is true of several of the other jigs illustrated. It is a distinct advantage to use patterns of machine parts to make jigs of, if possible, and in a fairly large plant with a variety of machines, the number of patterns that are available for such purposes is surprising.

Fig. 2 is a sketch of a jig that was made to accomplish a purpose similar to that of Fig. 1, but it has an advantage that will be noted. The surface against which the work is clamped is V-shaped, and the body *A* is provided with a removable top plate *B* in which the drill bushings *C* are located. This plate may be taken off and another one substituted with a different size and spacing of drill bushings, thus making the jig available for one or more jobs. In this particular case, it was possible, by this method, to use this jig for over twenty-five similar pieces of work. The fitted screws *E*, locate the various plates *B*, while *F* serves as a stop for the work.

The writer is aware that there are various simple adjustable center distance jigs that could be devised, but his experience has been that it is rarely possible to produce duplicate work economically with unskilled labor when using such jigs. It is almost impossible, without the use of precision measuring tools, to adjust a jig twice alike, whereas by the use of the plate *B* in Fig 2, an error made in the plate is not increased in the work, measuring is avoided and there is not the possibility of having the errors one way one time and another way the next.

In Fig. 3, we have another extremely simple jig that serves its purpose excellently. It is used to drill an angle iron in which the holes must be accurately spaced. *A* is the body, *B* is the cover containing the drill bushing *C* and the clamping screw *E*, and *D* is also a clamping screw with a knurled head. The angle iron *G* is placed against stop-pin *F* preparatory to clamping.

In Fig. 4, the extreme simplicity of this jig is its principal charm. It is used to drill a hole in each end of the lubricator crank *A*. The drill bushing *C* is centrally located at the top of body *B*. Beneath this bushing there is an enlarged hole to accommodate one leg of the crank. The other leg is placed in the piece *E*, which is shown in plan at *F*. This piece *E* is held in place by the dowel-pin *D* and it is a neat sliding fit in body *B*. The hole drilled in the body just under the bushing *C* is to allow the chips to escape. Incidentally, it should be noted that this jig represents about three hours' time for its construction; it paid for itself on its first job.

A jig is shown in Fig. 5 that is built on a different principle. It was designed to drill the pneumatic valve shown at *A*, which is a disk having five 1/8 inch eccentric holes and two lugs. It is finished on one face, on the side, and on the small surface shown on the other face. To drill the disk, it is placed in body *B* which is counterbored to fit it and which has corresponding recesses to receive the lugs. The cover *C*, which is hardened, acts both as a series of bushings and as a clamp. This cover is rotated on the screw *D* to permit the removal and replacement of work. The opposite screw *F* clamps the cover securely in position after the work is in place. A half-inch pipe handle *E* is provided simply for the operator's convenience.

As noted in the first part of the article, some jobs call for a considerable number of duplicate parts and permit the construction of a more complicated jig. This is illustrated by Fig. 6. The requirements call for four holes of different sizes to be accurately drilled in a machine steel link. This is a fixture with an eccentric clamping device of original

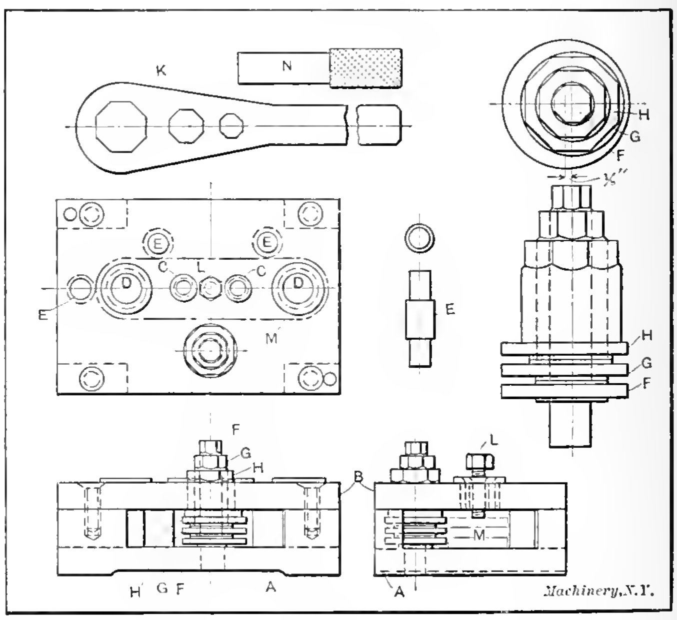

Fig. 6. Jig equipped with Unique Type of Eccentric Clamping Device

features. *A* is the body; *B* the cover; *C* are the smaller drill bushings, and *D* the larger ones. There are three stop-pins *E*, which are light press fits in both cover and body. There are three eccentric clamping disks *F*, *G*, and *H* (see also enlarged detail). Disk *F* rotates on *G*, and *G* on *H*. An extension on *F* rotates in the body *A*, and the larger extension

of H in the cover B. There is an octagon on the end of each disk spindle, and a wrench K with corresponding holes to fit each. The links M to be drilled are shown in position, three being drilled at one time. This arrangement of eccentrics gives an independent side clamp for each link, thus allowing for any irregularity in width. The clamping screw L has an octagon head to fit the smallest hole in wrench K. A plug N is placed in the first of the larger holes drilled, to prevent the pieces from working when drilling the other holes, although the work has been satisfactorily done without it.

In Fig. 7 there is shown a casing for a reversing mechanism and in Figs. 8 and 9 two jigs, the former being a boring mill jig, and the latter a drill jig for drilling the flange holes in line with the bearings. The casing is composed of three parts: A, B, and C. As will be noted, this casing has four bearings in it, two of different sizes in A, one in B of the same size and in line with the smaller bearing in A, and one in C, in line with, and the same diameter as, the larger bearing in A. The holes at X and Y are for fitted bolts, used instead of dowel pins, and the other ten holes shown are clearance holes for through bolts. As will be shown later, the fitted holes serve a double purpose. The casings are made male and female at the joints, and these are turned to close limits, A and C being alike, and B fitting into them.

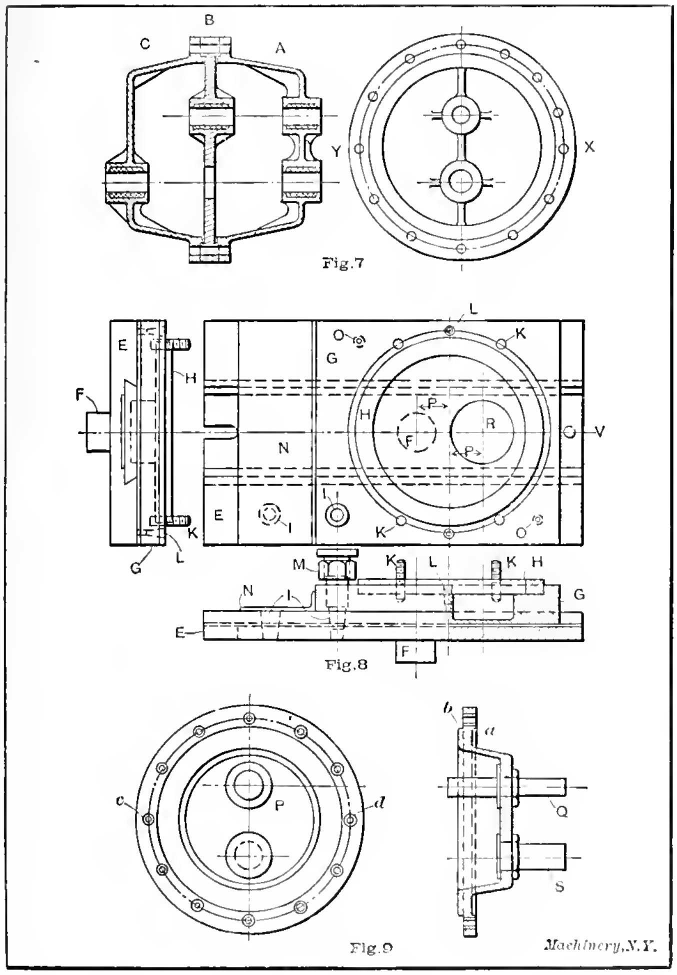

Fig. 7. Casing with Drilled Flanges and Bored Bearings. Fig. 8. Jig in which Bearings are bored. Fig. 9. Jig in which Flanges are drilled

In order to properly set forth the features embodied in these designs, it will be necessary to describe the boring mill jig, then the drill jig, and afterward give a short description of the operations. In Fig. 8 E represents the body of the boring mill jig, in which there is a tapered slide on the top side, and a pin F on the other side to fit the hole in the table of the boring mill, thereby centering the body E. The slide G works in and is closely fitted to E. This slide is counterbored to fit the male part of the joint in casings A and C on the longitudinal center line and midway between the bearings in the casings. The removable ring H is closely fitted to G and projects just enough above G to fit the female joint on part B. By removing H, G becomes the opposite of the joint on A and C.

Two tapered holes I have a center-to-center distance equal to that of the bearings in the casings. Four removal studs K are made somewhat smaller than the bolt holes in the flanges of the casings to hold the latter in position after they are located in the jig. There is a tapered hole L on each side of G, and these serve to center the casings and always bring the bearings in the same relative position. The pins are parallel and closely fitted where they go through the casings, and

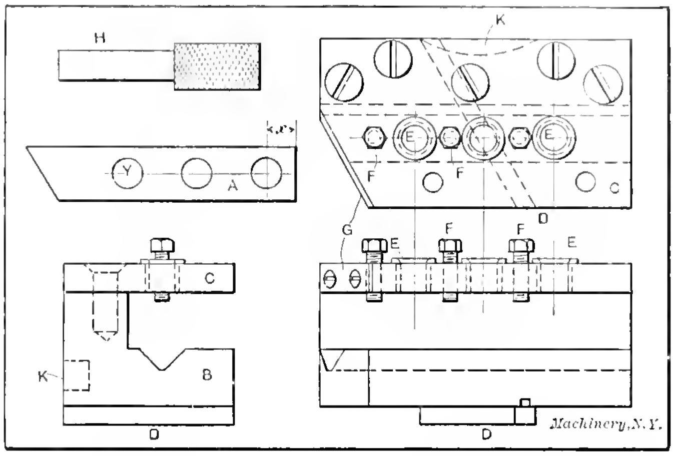

Fig. 10. Combined Drilling and Milling Jig for Part A

tapered below that to fit the holes L. A tapered pin M fits holes I, and is parallel where it goes through G. The nut shown is for the purpose of releasing it; the head is simply a projection to allow M to be securely driven into G. The locating pin that fits the tapered hole L, and also the reamed holes X and Y (see Fig. 7) in the casings, is similar in construction to M, but smaller. A protection strip N prevents chips from getting into hole I, and the working part of the slide E. R is simply a clearance hole in G for the bearings.

In the drill jig shown in Fig. 9, the casing P is the principal part. This casing is recessed at a to correspond to the male part of the joint on casing A and C and at b to fit B. The pin Q on the inside of the jig fits the bearing in B, and on the outside the small bearing in A, while S fits the large bearing in A or C. When drilling C, pin Q is removed. There are twelve holes with bushings shown; the two at c and d are removable to allow smaller bushings to be inserted, in order to first drill and then ream these two holes for the fitted

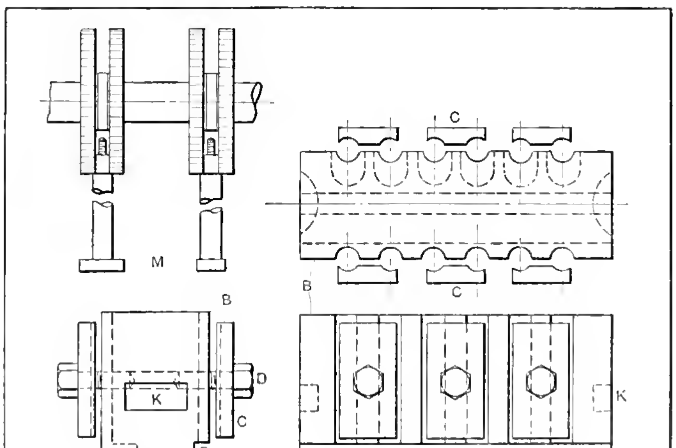

Fig. 11. Fixture for Milling Square X on Bolts A in Correct Relation with Rectangular Heads

bolts previously referred to. A brief description of the boring and drilling operations will make clear some of the uses of various parts of these two jigs.

When machining a new set of casings, the studs K are removed from the boring mill jig, and placed in the tapped

holes O, and the ring H is also removed. The casings A and C are first finished on the faces of the flange and tongue, and the bearings rough babbitted. Either casing A or C, as the case may be, is then placed in the boring jig, and the bearings approximately lined up with the center line V. The casing is then clamped on the jig by means of U-clamps placed over the studs K in the tapped holes O. The bearings are then bored; first the one in line with F, and then the other, after the slide is shifted to the next location by inserting pin M in the other hole I. The drilling jig is now placed on the casing and pins Q and S are inserted in the bearings, thus locating the holes in the flange with reference to the bearings. All the flanged holes are drilled and holes X and Y are reamed. In case of repair to the bearings, the casing A or C is located on the boring jig by the pins that fit into the reamed holes X and Y, and in the tapered holes L in the slide G; the casing is then clamped by means of studs and nuts K in position in the boring mill jig. Thus one jig

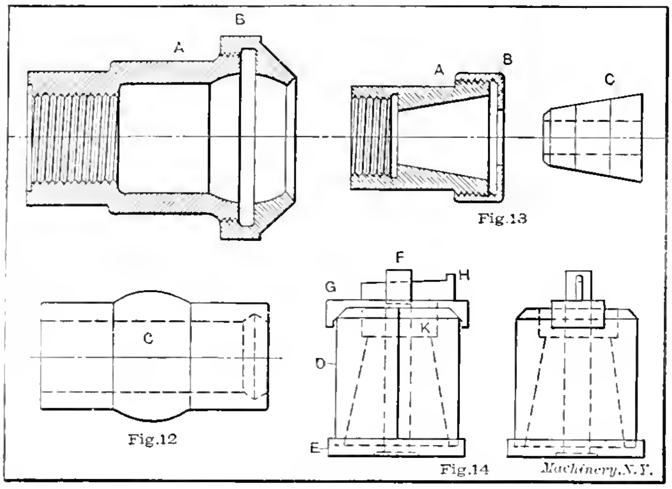

Fig. 12. Simple Chuck in which Bearing C is bored. Fig. 13. Chuck for Boring Part C. Fig. 14. Babbitting Jig in which Part C is cast

is dependent on the other. When casing B is to be bored, the ring H is placed in the position shown in Fig. 8, and then the operation is the same as described for A and C. By the use of these jigs, it is possible to produce new work or repair the bearings in the old casings at any time, and they will be interchangeable. The bearings are, of course, bored to gage.

In Fig. 10 we have an example of a combined milling and drilling jig. The work A consists of a round piece of tool steel, one end of which is to be milled at an angle and accurately spaced from the center lines of three holes to be drilled; the distance x on the work is immaterial within 1/8 inch. B is the body of the jig, having a V-slot cut in it to center the work, and a recess K in the back to clamp it to the table of the machine. A clamp on the other side rests on the jig near the V-groove. In the top-plate C the drill bushings E, and the clamping screws F are located. A removable piece D is recessed into B and made to fit the table slots in the milling machine, thus setting the work at the proper angle; during the drilling operation this piece is removed. The milling cutters are set against a hardened strip G to secure the proper distance from the center line of the first hole and the angle of the cut. After the stock is cut off with a power hack-saw it is clamped in the jig a certain distance from the last hole in the end; this distance is equal to X with an allowable variation of one-eighth inch. The hole Y is first drilled, and then the plug H is inserted to prevent the work from moving. The other holes are then drilled. After the required number of pieces are drilled, the piece D is fastened to the fixture, which is clamped to the milling machine table. The end of A is then milled, plug H locating the holes with reference to the cut.

Fig. 11 shows a milling fixture in which the work A is milled square at X, and at a certain relation to the rectangular head. The body of the fixture is recessed on its sides to a depth equal to half the diameter of the bolt. It is also recessed on the bottom at H to correspond to the longer side of the rectangular head, and at G to fit the shorter side. This is shown plainly at E. The bolts are held by clamps C and clamping screws D. A projection F fits the table of the milling machine. Recesses K on each end of B are used to clamp the fixture to the table. The first and second settings of the bolts are clearly shown by the diagrammatical view at M, making further explanation unnecessary.

A simple chuck is illustrated in Fig. 12 for boring the bearing C. This bearing is first turned all over on the outside by a forming tool and then mounted in the chuck. The body of the chuck A is threaded on one end to fit the spindle of a 16-inch lathe, and it is bored out on the other end to fit the parallel end of C. B is a cap screwed onto A and bored to fit the spherical part of C. Thus when C is placed in chuck A and cap B screwed home, it clamps the work on the spherical part; the parallel part is also effective in centering the work. This chuck is extremely simple, yet very efficient.

The chuck shown in Fig. 13 is similar to that in Fig. 12, except that the work is tapered, C being the work, A the body of the chuck threaded to fit a 16-inch lathe, and B the clamping cap. As the work, in this instance, is of composition, the babbitting jig used will be of interest and is illustrated in Fig. 14. The base E is counterbored on the under side to receive the head of pin F, and on the top to fit shell D. This shell is split through the center and tapered at the top to correspond to the taper on G. Pin F, which acts as a core, is slightly tapered, and has a slot in the top so that by driving the key H in, G, D and E are securely clamped together, making a solid box. By removing H, the box falls apart and F is easily driven out of the work A. The parallel part K of the top is to allow chucking in the lathe for forming.

In summing up, the important points to be observed in repair shop jig design, are: (1) Simplicity; (2) minimum cost; (3) ease of operation consistent with cost; (4) use of machine parts or patterns already made, in designing fixtures, when only slight modifications are necessary; (5) the co-operation of the machine designer to secure simplicity in parts; that is, a number of simple pieces in preference to one complicated piece of mechanism, thus helping the shop side of the question; (6) the combination of a number of different machine operations in one fixture, if this can be done at a minimum cost, as a small loss of time on the machines, due to changing, is not noticeable in comparison to a high fixture cost for a few pieces of work; (7) comparative interchangeability; that is, good enough for the intended work but no more, as going to extremes in this line of work is particularly objectionable.

* * *

It appears that Australia intends to take a prominent place in the development of aerial navigation. A consular report states that Messrs. Walter Thompson and F. A. Boyd of Perth, West Australia, have developed certain designs and models for aerial navigation machines, including, among other inventions, a novel steering apparatus, a "fulcrum" by which an aeroplane floating and soaring in the air will maintain a condition of perfect equilibrium, and a simple and safe design, making it possible to attain speeds with aeroplanes higher than those hitherto attempted. A company has been formed in Australia, and a member of this company has left for England in order to exploit the inventions there. With no other details than those above at hand, it is, of course, impossible to say whether or not the inventions are of practical value and importance.

* * *

Perhaps there is no other feature of marine architecture about which there is so much doubt as the propeller, nor any feature more important to-day in the matter of efficient propulsion. An excellent illustration is the recent improvement made in the Cunard steamship *Mauretania*, by the change in her low-pressure propellers from three blades to four blades. They were made with other changes in design in accordance with a formula deduced by one who made a special study of the subject. The increase in speed is remarkable considering that the *Mauretania* had already exceeded the limit imposed by the contract of the Cunard Co. with the British government.

NEW SPUR GEAR GENERATING MACHINE

JOSEPH G. HORNER

A new spur gear generating machine (the Sunderland patent) is being manufactured by Messrs. J. Parkinson & Sons, of Shipley, Yorkshire, England. There are several bevel gear generators in the field, but few as yet for spur gears, the reason being that the objections to the use of single rotary cutters are not so great when spur gears are cut as when they are applied to bevel gears. Still, the growing demands for teeth of ideal accuracy for high-speed gears includes spur teeth, and the use of the single rotary cutter introduces elements of slight inaccuracy which are inconsistent with the ideal. The Fellows' machine has been familiar for many years, but the greatest impetus to generated spur gear teeth was given about three years ago when German designs of machines for generating these gears by hobbing were introduced. This lead has been followed extensively in England and the United States. The Sunderland spur gear generating machine is designed to avoid the difficulties which have arisen in the operation of the hobbing machines. These were principally the cost of hobs, which is high, due to the difficulties in hardening and grinding them, and to the heat generated in heavy cutting, which results in inaccurate gears. In the Sunderland machine a rack-shaped cutter is employed, containing six teeth hardened and ground. Its cost is only about one-fifth that of a hob, it is easily re-sharpened, and less heat is generated in cutting, while increased output is claimed.

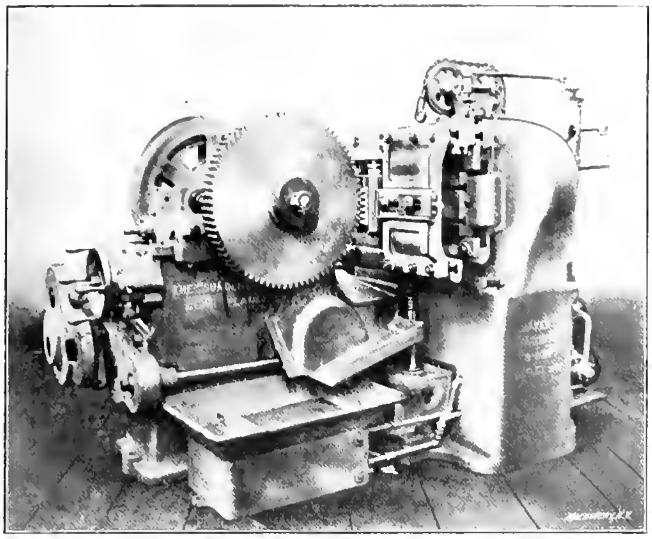

Fig. 1. The Sunderland Patent Spur Gear Generating Machine

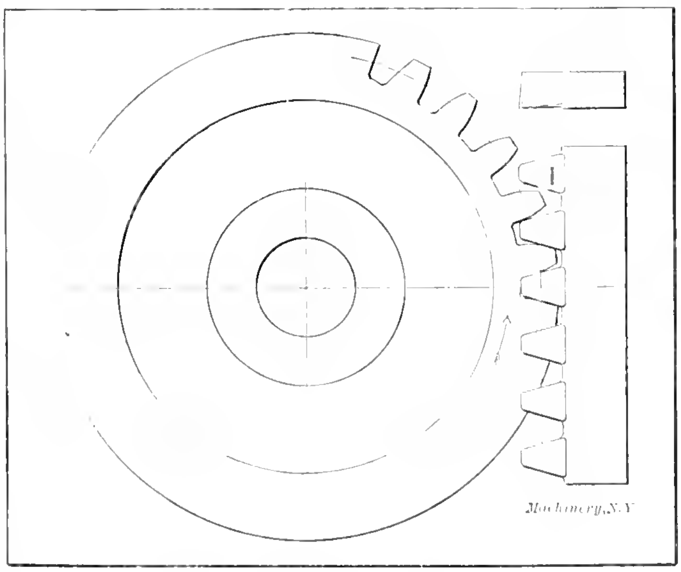

Fig 2. Diagram Showing Action of Rack-cutter in the Sunderland Gear-cutting Machine

* Address: 45 Sydney Buildings, Bath, England

The rack cutter, of involute type cuts, of course, all gears of the same pitch, all meshing accurately with each other and with a rack; and the results are more accurate than those obtained by single rotary cutters, or by planers controlled by a former, while one cutter only is required for one pitch instead of a series of rotary cutters, or a series of formers. The rack cutter is mounted on a slide which imparts a reciprocating motion to it, while the wheel blank, mounted on a horizontal arbor fitted in the spindle of the dividing wheel, rotates in relation to it, in unison with an upward movement of the cutter slide, as in the actual engagement of gears. The rolling movements impart the tooth curves while the reciprocating movements of the rack tool cut the teeth to the correct depth. Several of these operations repeated are required to complete the teeth of the wheel. In the first position the cutter touches the edge of the blank. In the second the blank is fed in to the proper depth, while the spaces are cut by the reciprocating cutter. The heaviest work is done by the leading teeth of the cutter, and as the wheel blank rotates in unison with the upward movement of the cutter the remaining teeth are gradually relieved from strain, and thus retain their keen cutting edges longer for finishing. After as many teeth are cut as can make full contact with the rack cutter through a distance equal to one pitch, the wheel blank is withdrawn clear of the cutter, its rotary motion arrested, and the cutter-slide returns vertically to its original position, that is, to a distance equal to the pitch being cut. The blank is then returned forward to the position for cutting, the rotary motion is re-started simultaneously with the upward movement of the cutter slide, and another cutting cycle repeated. These movements are automatic until the wheel is completed. Only two sets of change-gears have been set up, one for the number of teeth to be cut, and the other for the pitch. Cutting speeds can be varied from about 20 feet to 40 feet per minute. The various speeds are obtained in the machine itself, so that the machine is driven by a constant-speed belt from a line-shaft; or it can be arranged for a motor drive. A pump and circulating pipes are fitted to the machine.

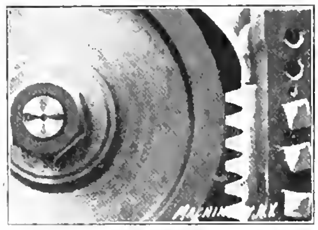

Fig 3. First Position: Cutter just Touching Blank

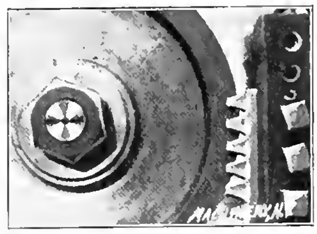

Fig. 4. Second Position: Blank Fed to Proper Depth for Teeth

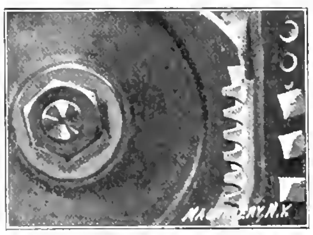

Fig. 5. Third Position: Blank and Cutter having Advanced a Distance equal to the Circular Pitch

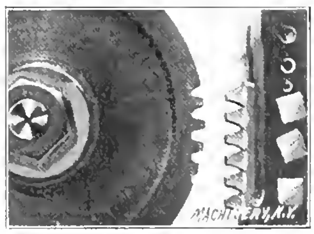

Fig. 6. Fourth Position: Blank withdrawn from the Cutter

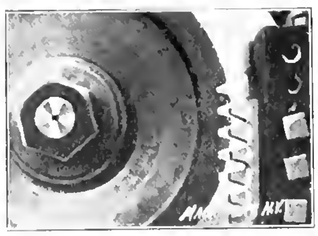

Fig 7. Fifth Position: Cutter returned to Starting Point

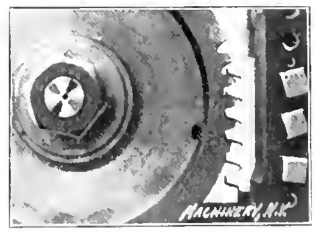

Fig. 8. Sixth Position Blank returned to Cutting Position; beginning of Second Cycle

The machine cuts gears from 3 inches to 24 inches in diameter, and pitches from 8 to 2½ diametral pitch, and widths of faces up to 8½ inches. It weighs 3½ tons.

Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall, Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

FEBRUARY, 1910

PAID CIRCULATION FOR JANUARY, 1910, 25,017 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

GROWTH FROM SMALL BEGINNINGS

The machine tool industry is remarkable in the fact that it is a growth from small beginnings. In mentally reviewing the history of the firms which have been successful in that line, we do not call to mind one which made a flying start with large capital and highly developed organization behind it. These phases have come later. The original start was made from humble beginnings, often by men working at the lathe and the bench.

This hopeful condition is due, possibly, to the high plane of development which machine tool design has reached in this country. The plane is so high that the product which is to meet competition successfully must have behind it a *personality*, brimming with enthusiasm and original ideas. Such personalities are self-selective. They rise to the top like the cream in the milk pitcher. They are not usually attracted by complex organization and powerful resources.

* * *

A DEFECT IN THE SALES DEPARTMENT

Almost every enquiry a manufacturer receives has some value—the actual value depending largely on the way the enquiry is handled. Comparatively few advertisers so handle their enquiries as to get the greatest possible return from them. Some are content with sending a catalogue or circular, and possibly a form letter, which they never follow up, although in many cases a purchase is not made for months after the enquiry is sent in. Other manufacturers, particularly of automobile supplies and office appliances, it is positively dangerous to write to, because the name of the enquirer is immediately placed in a species of mill which proceeds to grind out long follow-up letters, the intent of which is apparently to make life a burden for the unfortunate enquirer, and in time to force him to buy. There must be a reasonable mean between these two methods, and it can be found in the intelligent handling of enquiries by a trained office man who thoroughly understands his business, and not by a typewriter who is handed a list of names to send form letters to.

If the manufacturer considers the amount of money which is often spent in trying to effect a sale, he can quickly figure out that it will pay to handle enquiries intelligently. An instance of the lack of this quality is mentioned by a well-known machine tool dealer who writes us:

A manufacturer will send us prices and quote us discounts, and we take an order and send it in. In the meantime he has made some exclusive agency arrangements with another house covering this territory, and we are politely informed on receipt of the order that they can't fill it on account of these arrangements. Our salesman has lost his time and we have lost ours and we have talked up a deal for the benefit of one of our competitors, as we have to notify our customer that we can't fill the order. There are not so many machine tool dealers in the country but what manufacturers could, without overexertion on their part, keep them posted as to their sales arrangements, and also on their new designs by sending out up-to-date printed matter. The majority of the new catalogues that we receive we have to ask for, although when a manufacturer gets out anything new one day's work in his office would suffice to supply all the machine tool dealers in the country with this information. The greatest assistance we get is through the medium of the trade journals, and this gives us the opportunity of thanking you very much for keeping us posted in the manner you do.

* * *

TECHNICAL LITERATURE

It does not seem to be an exaggerated statement that at least fifty per cent of the technical books brought out to-day in America have been written merely to satisfy the ambition of an author who wants to see his name on the title page of a book, and published simply because the publisher expects to make a profit on the book, and for no other reason. A great many technical books are practically nothing but abstracts and compilations of other books previously published, containing hardly anything that is new and original, not even in the treatment or arrangement of the matter; and in some cases these new books are even inferior to works that have been previously published. Such books have, therefore, no excuse for their existence except the ambition of the author and their money-making possibilities.

Technical books of real merit are few and far between. In this respect a decided difference has been noted by many book reviewers between German and American books. German technical books and English as well, are noted for their thoroughness, logic and originality. The "padding" so common in many American works, is almost always absent from German technical publications. The German mind especially appears to be particularly adapted for arranging the material properly, systematizing it in such a way as to lead the reader or student from subject to subject by easy stages, and provide him, at the end of the journey through the book, with a clear, comprehensive conception of the subject treated.

There have been many reasons advanced for this difference between German and American books. The most plausible is that the "hustling" of American life shows itself in its technical literature. It is produced in haste, and too little attention is given to detail. Perhaps this is because many of our books are not the works of authors with ample time for investigation and study, but of actual workers in the industries who cannot give a large portion of their time to book writing. This last feature is one of the redeeming characteristics of some American technical books. Written by men actually engaged in practical work, with all their faults of illogical arrangement, unbalanced contents and lack of comprehensiveness, they are more practical, more thoroughly in touch with the industrial conditions, and better adapted to the use of the every-day man, than the more thorough-going and comprehensive German works.

The demand for books written in the popular style is perhaps accounted for by the limited educational advantages of a large number of technical book buyers, represented by the workers in every trade; but even this feature presents no excuse for the production of books which are simply "hashed over" from the writings of other authors, because a popularly written book is capable of just as logical arrangement and even more original treatment of the subject than a more scientific treatise.

WHEN TO SAFEGUARD MACHINERY

Machine designers, manufacturers, and others concerned with the production of machinery are slowly awaking to the fact that it is not good design or business policy to put machines on the market having unprotected gears and other danger points. The movement for greater safety in industrial pursuits has already had a marked effect on machine design, but there is still great need of improvement in this respect, in the construction of many classes of machinery. In an editorial in May, 1907, we made a point of the fact that the time to safeguard danger points in machinery is when the design is on the drawing-board. The designer can cheaply and effectively provide guards in the original design of the machine, whereas they might be cumbersome or entirely out of the question after the machine had been built in the ordinary way. We suggested that "safety of operation should be placed on a par with mechanical efficiency, and that our schools of mechanical engineering could do no greater service for the manufacturing interests of the country than to instil this principle in the minds of their students."

Mr. R. C. Bolling, of the United States Steel Corporation, at the recent annual meeting of the Museum of Safety and Sanitation, New York, spoke of the difficulty of providing effective safety devices on machinery that had not been designed for them. He said that the United States Steel Corporation, which is spending about $1,000,000 annually for accident prevention and compensation to injured workmen, has experienced great difficulty in protecting danger points on machines, cranes and other appliances that had been unprovided with these desirable accessories when built. In fact, it was practically impossible in some places to provide railings for runways and protection for gears, because of lack of clearance, etc. Such provision would have made necessary the re-construction of roofs, changes in foundations and in the whole lay-out of the mill, amounting practically to a reconstruction of the plant. Mr. Bolling said that almost all the machines, cranes and other apparatus could have been adequately protected in the original construction with little or no additional cost; but when provided afterward the expense was very heavy.

We reiterate that the time to safeguard machinery is when it is on the drawing-board; and designers should awaken fully to a sense of their responsibility in this respect. They should consider safety as of equal importance with operating efficiency, for if the machines, unprotected, are not safe to work, they are failures, no matter how efficient they may be as producers. Finally, manufacturers and all users of machinery should fully comprehend the significance of the Museum's motto: "Prevention is a benefaction—compensation an apology."

THE AUTOMATIC MACHINE AS A CIVILIZING AGENT

It is the fashion among certain critics of the present social order to cast aspersions on the automatic machine as compared with the hand processes which it has displaced. The old idea that it throws workmen permanently out of employment has been pretty thoroughly exploded; but there still remains a vestige of the ancient superstition that ingenious inventions tend to degrade labor. It is claimed that the workman becomes a part of the machine, performing in unison with it the few movements of feeding or adjustment which it is impracticable for the machine to perform by itself.

With this unfriendly view of the automatic machine we boldly take issue. There are without doubt many instances in which the criticism holds good, but this condition is only a passing phase of development. The application of automatic feeds, for instance, has relieved and will continue to relieve the operator of tiresome routine work. We shall eventually change our belief that the only mechanisms which can successfully be made self-acting are those which may be operated by unskilled labor. The time is approaching when mechanisms will be found profitable which require the attention of mechanics of the very greatest skill and experience. As the field thus broadens, mechanics of all grades of ability will become more and more engaged in the work of supervision, instead of being bound to the monotonous repetition of manual movements required for hand work or machine feeding.

The continued development of the automatic machine holds out hope to the workman for relief from much that constitutes the drudgery of labor.

SALARIES VS. PROFITS

A STUDY IN SHOP AND OFFICE MANAGEMENT

POLYCON

The draftsman, usually, has an excellent opportunity to study methods of shop management and general business systems. Except in some of the largest establishments, he has free access to the shop, and usually avails himself with more or less freedom of the opportunity to study shop methods and, incidentally, to break up the monotony of close confinement to the drawing-board. His work, too, brings him more or less into contact with foremen and workmen, and he is thus in a position to learn the shop view of matters with some degree of accuracy. In addition to this, the drafting-room being a sort of neutral ground between shop and office, he is often able to get something of an insight into office methods, more particularly as regards the ordering and cost-keeping departments. It has been the writer's fortune, good or bad, to have wandered considerably, and to have been employed in establishments doing a wide variety of business, from pure manufacturing to pure engineering, including various admixtures of these two extremes. Although making no pretensions to speak authoritatively on the subject, I have always been rather a close observer of shop management, and a comparative description of some of the systems I have seen might be of interest.

Cost Systems

Shop *A* was engaged in the manufacture of gas and steam engines and boilers for use in the oil fields, besides making general oil-well supplies and attending to repair work. The shops were modern and employed about four hundred men, and the output was limited to a few standard sizes. The cost system was handled by one clerk, and there was one foreman to each of the usual departments, machine, forge, foundry, pattern, and boiler shops. The stock was kept by a young man, and was delivered to the workmen as required, on an order from the foreman.

Shop *B*, where I was employed immediately after leaving *A*, was engaged in exactly the same line of work, with the addition of a general line of plate work, such as tanks and pen-stocks, and the development of a line of larger sizes of gas engines. On account of these latter branches a large force of draftsmen was maintained, while in the previous position I was alone in my glory. The number of men employed was but inconsiderably greater than in the case of *A*, but the cost department included three or four clerks, all of whom appeared to have enough to do, and each foreman had a clerk. In order to get a piece of drill steel or a machine screw from the stock-room, it was necessary for the workman to get an order from the foreman, take it upstairs to the cost department to have it signed, and then get the material from the stock-keeper, who, by the way, also had an assistant.

Now it is significant that while the *A* company was paying a good dividend to the stockholders and was also able to give its employes, as a Christmas present, a substantial bonus based on their wages, the *B* company not only was not paying dividends on the stock, but was in actual financial difficulties. I do not say that the elaborate cost system was the sole cause of the trouble with *B*, but I do believe that a simpler system would have been sufficiently accurate for the purpose, and would have saved thousands of dollars yearly.

Office Systems

The first establishment under this heading, *C*, was engaged principally in the manufacture of mining and ore-handling machinery, and had modern and well equipped shops employing five or six hundred men. Having a well-established business, the selling was done chiefly by correspondence and by one or two supply houses in the mining districts, beside which the general manager and engineers

took occasional trips when something "big" was in the air. The business of this company was handled by the president, general manager, treasurer, and purchasing agent, with a staff of clerks and stenographers not exceeding five. All of the above officials, as well as the superintendent and some of the engineers, were stockholders in the company, were receiving satisfactory salaries, and there was a spirit of hearty cooperation evident among them.

Company D was also engaged in manufacturing, mining and ore-handling machinery. The office building was a handsome four-story structure, and the shops, employing about the same number of men as C, were well built and equipped with the most modern tools and appliances. This company had a president, general manager, works manager, secretary, treasurer, purchasing agent, auditor, sales manager, two vice-presidents and a chairman of the board of directors, most of whom were relatives of the original members of the firm and drew large salaries, their assistants, in some cases, doing the work.

It is not difficult to understand that while C was paying dividends, D was not, and further, was in serious financial difficulties. Both companies maintained large and efficient engineering staffs, had well-equipped shops and an established reputation in their lines of business, and it could not but be patent to the most casual observer that the profits in the case of D went to pay large salaries to supernumeraries.

Shop Systems

The next shop to be considered, designated as E, was one which had grown from a jobbing shop and, at the time that I worked there, employed about four hundred men, building steam engines, boilers, mining machinery, saw-mill and pulp-mill machinery, and general plate work. The buildings were frame structures, inadequate for the work, and the tools were—some of them—fit only for the scrap heap. However, there were some good, heavy machines, and, with good management, the plant should have been capable of producing a fair output. As stated, the shops had grown from small beginnings at a time when business was plentiful and prices good, and the company had always been able to pay good dividends. Being a close corporation, practically owned by three men actively engaged in the management, one of whom was the general manager, a sharp eye was kept on the balance sheet. This being so, it seems strange that the shops were not maintained in a more efficient state, but, on the contrary, the manager's sole idea of economy seemed to lie in the reduction of expenditures. In order to get the work out cheaply, all sorts of patchwork was done on the patterns, metal was skimped to the limit, an excess of scrap and a low grade of pig was used, and the machinery was often shipped out only half finished. All through the shops an excessive number of apprentices was employed, and laborers were doing work which should have been done by skilled mechanics; in the office, the highest salaried man outside of the general manager and the treasurer received $150 a month. At the same time, the cost system was only used to obtain the total cost of a new size or design of machine; it gave no idea of where the loss or profit occurred, and was not followed up for duplicate machines. The natural result of these methods was that this concern was losing more in bad castings and mistakes than was saved by the false economies, and continually the few good workmen employed would leave because the firm was not willing to pay them as much as someone else would pay.

In sharp contrast to this was plant F. Here the spirit was to do the kind of work best suited to the requirements, to improve the equipment as fast as financial conditions would warrant, to pay such wages as would attract and keep the best men, and to keep down costs by finding out exactly where losses occurred and then rectifying the conditions causing the loss. Each month an accurate and complete statement was made up, showing the number of men employed and their wages, the cost of material consumed and the output, with a comparison with previous months. The foundry had to make a daily report of all castings, giving the names of the molders whose castings were spoiled and the cause thereof, and every foreman was made to feel that he was there to improve the output in quality and reduce the cost.

Conclusions

And now to point the moral! Not that it is necessary to do so, for it seems as if the conclusions were self-evident. However, the officers of any corporation owe it to the stockholders to so conduct the business as to pay a reasonable profit in the form of dividends. Too many corporations are like D: they pay large salaries to the officers and provide remunerative and not-too-laborious employment for sons and sons-in-law. Others, with perfectly honest intentions, are overburdened with systems or are swamped by an overweening vanity on the part of the officers, manifesting itself in elaborately-fitted offices and lavish but ineffective advertising. Still others are being wrecked by incompetent or too daring engineers, who undertake unusual contracts without sufficient investigation of the conditions and requirements, with the result that the work as finally designed over-runs the estimate excessively.

The best results, however, would be obtained if the order and cost systems were kept in the simplest possible form consistent with obtaining accurate and reliable results; the same rule should apply to the business management. In the shop it is good economy to pay fair wages and to insist on a fair return of work therefor. System is a good thing, but, like most good things, it is possible to have too much of it and, therefore, "be temperate in all things" is good advice in the business world, as elsewhere.

* * *

THE POWER OF LARGE GUNS

A gun may properly be considered as a prime mover, and its output may be expressed in terms of horsepower. As, however, the period of time during which energy is exerted is very short, the horsepower expressed in figures becomes rather startling. A calculation involving the horsepower of the large 16-inch gun mounted at Sandy Hook, for instance, will reveal more than anything else the enormous size and power of this gun. The projectile weighs 2,370 pounds and has a muzzle velocity of 2,300 feet per second. The energy developed at the muzzle is about 88,000 foot-tons. If we assume that the projectile moves through a distance of 33 feet within the gun while acquiring the given velocity, and that the acceleration of the projectile is uniform until the muzzle is reached, the mean velocity of the projectile while within the bore would be $\frac{2,300}{2} = 1,150$ feet per second, and the period of time during which the energy of 88,000 foot-tons is developed would be $\frac{33}{1,150} = \frac{1}{35}$ of a second. This corresponds to a total of $88,000 \times 35 \times 60 = 184,800,000$ foot-tons per minute. Since the horsepower = 33,000 foot-pounds, or 14.7 foot-tons per minute, we have $\frac{184,800,000}{14.7} = 12,600,000$ horsepower, as the power developed by the gun during the period and conditions mentioned.

* * *

In accordance with the factory and work-shop act of Great Britain, the British Government has issued regulations relating to safety arrangements to be used in dry grinding and finishing processes. According to these rules all grinding wheels must be provided with a hood or other appliance so constructed and arranged as to take care of practically all dust created. A duct of adequate size arranged to carry away the dust must be provided, and a fan or other effective means for extracting the dust must be installed. Suitable respirators must also be provided for all persons employed in grinding, whether working in a room or in the open air. No person is permitted to do any work other than grinding in a room where grinding is carried on, except work required for cleaning purposes. Provisions are also made for effective cleaning of rooms in which grinding is carried on, at least once a week. The employer is required to furnish all safety apparatus, respirators, etc., and every person employed is required to make full and proper use of the appliances provided.

LAYING-OUT AND ALIGNING OPERATIONS ON MACHINE TOOLS—1*

ALFRED SPANGENBERG†

In general, laying out is the process of placing such lines on castings, forgings, or partially finished surfaces, as will designate the exact location and nature of the operations specified on the drawing; an aligning operation, as its name implies, consists in lining-up a shaft bearing, bracket, or other similar machine element, in its proper place relative to other members. The first-named operation usually is associated with the process of machining, while the last-mentioned is generally included in the work of assembling. Laying-out and aligning operations may be divided into two parts: the preliminary and the final. The preliminary operation consists in approximately locating a machine element in place for the purpose of marking the clamping bolt holes on its supporting member; in the final alignment, the exact location is ascertained for the purpose of drilling the dowel pin holes, the work being held by its clamping bolts. Clearance in the bolt holes permits of this adjustment.

As the ultimate results obtained in assembling are controlled to a large extent by the accuracy of these operations, it is of the utmost importance that means be provided for insuring the refinement that the nature of the case demands. Jigs and fixtures have, of course, been a dominant factor in dispensing with much of the ingenuity and skill required in this work, but owing to special considerations a preclusion of these valuable adjuncts to manufacturing work may be advisable. In this case a simple gage or templet, or even a wooden jig provided with steel bushings, will greatly facilitate the operation of laying out or aligning, and, in fact, when proper care is exercised in using these comparatively crude devices, work may be produced on an interchangeable basis as good as with more expensive tools; although it is to be expected that more skilled labor will be required.

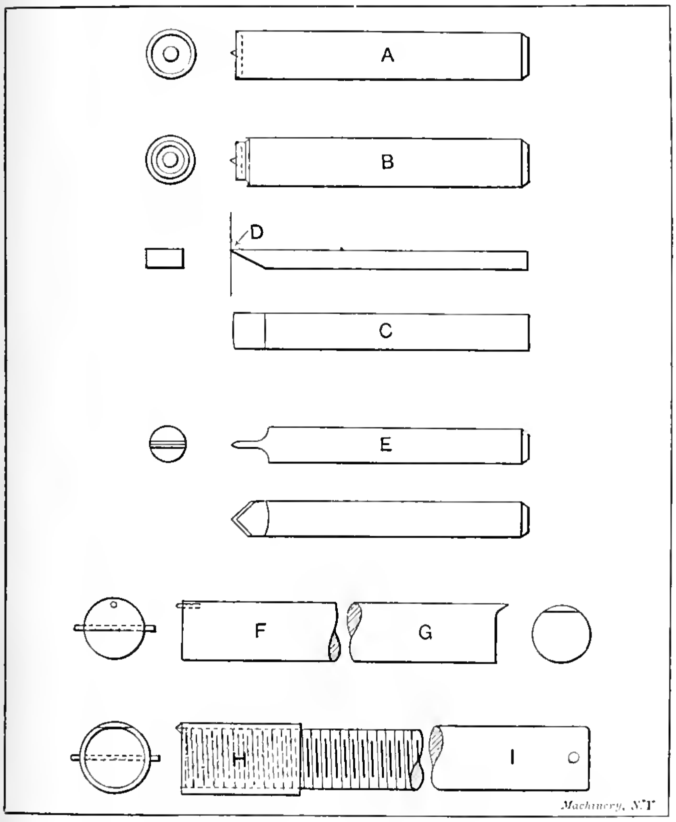

Fig. 1. Special Tools used in Laying-out Operations

As regards the different methods of laying out and aligning, no definite rules can be given. The machinist must consider the means at hand and the nature of the job; he must then use his ingenuity and be guided by his practical experience. A few special cases are illustrated in the accompanying line-engravings; the methods and processes shown and the remarks made in regard to them are intended only as suggestions of how the work may be accomplished without the employment of drill jigs. It is not to be inferred that the way shown is, in each instance, the best method possible and the only one applicable. Circumstances alter cases; while the methods shown may be eminently suitable for one set of conditions, they may either be too refined or not refined enough for other conditions and requirements.

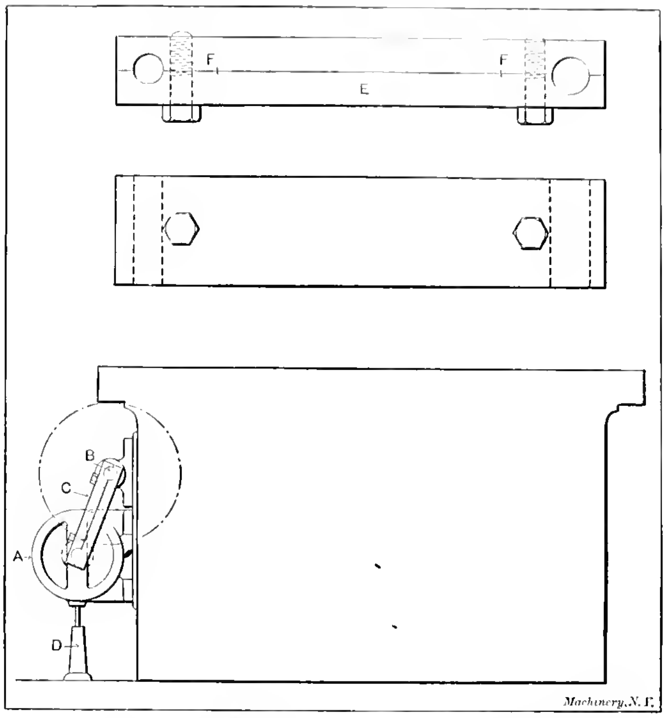

Fig. 2. Locating a Small Motor by the Use of a Link

Special Tools and Appliances

Aside from the more common laying-out tools such as the dividers, surface gage, steel scale, etc., there are a number of tools of a special form used for laying-out operations, some of which are shown in Fig. 1. The form of center punch shown at *A* will greatly facilitate marking off holes through brack-

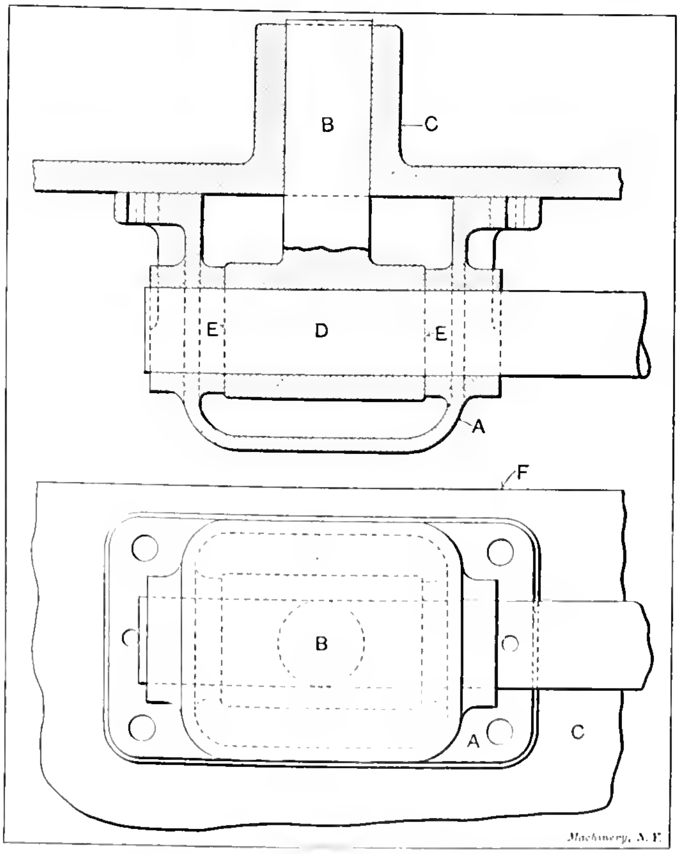

Fig. 3. T-jig for Locating a Bevel Gear Bracket

* For additional information on this and kindred subjects see "Assembling a 48-Inch Motor-Driven Planer," in the December, 1909, issue of MACHINERY, and other articles there referred to.

† Address: 951 W. Fifth St., Plainfield, N. J.

ets and templets, or in laying off pin holes for cams. It is necessary to provide a number of different sized center punches of this type, as the body of the punch must fit the clearance hole in the work. For obtaining a circle, the diameter of the tap drill, the punch or marker may take the form shown at *B*, while a combination of the two will provide a guard circle.

A flat scriber *C* is very useful for marking a line on a plane surface at right angles to another plane surface when the corner is rounded as shown at *D*. The form of marker illustrated at *E* is for giving permanence to lines intersecting on surfaces at right angles, as for instance, in marking the relative position of a gear on a shaft. At *F* is shown a special marker for laying out a circle, the center of which must coincide with a hole already bored. The body of the marker fits the bored hole and a circle is scribed in the piece to be marked off by rotating the marker when the point is in contact with the work. Two methods of making the scribing point are clearly indicated in the engraving, the one shown at end *G* producing a circle the diameter of the body. In marking off a hole in alignment with a threaded hole, a bushing *H* having a scribing point is made to fit the threaded arbor *I*. This arbor fits the threaded hole, and the bushing is rotated to mark the circle.

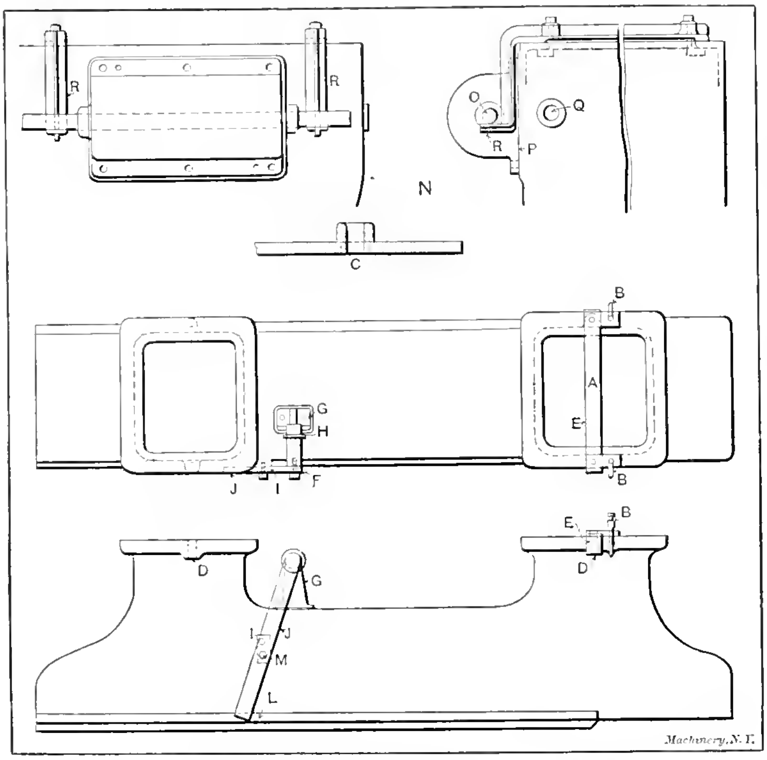

Fig. 4. Special Gages and Templets for Laying-out and Aligning Operations on a Turret Lathe Bed

One of the most convenient and accurate methods of locating gear centers is by the use of links. For drilling or boring operations the link may take the form of a casting provided with hardened steel bushings to guide the cutting tools. Again, a link may be used for cases similar to the one shown in Fig. 2, which illustrates the method of accurately setting a small motor *A* so that its pinion will mesh properly with a gear on shaft *B*. The work is accomplished as follows: With the link *C* and the motor in position as shown, the jack-screw *D* is adjusted until the motor frame just touches the finished seat on the bed. This adjustment is determined by means of tissue paper placed between the motor and bed, after which the bolt holes are marked off on the bed; the special marker *B*, Fig. 1, is used for the purpose. The construction of the link is clearly shown at *E*, Fig. 2; this form, being made of two pieces bolted together, permits of ready application to a shaft supported between bearings, without removing the shaft. Such a case is frequently met with in applying a geared pump to a machine already built. For ordinary cases, however, the link may be made in one casting or forging, as the circumstances require, and provision for clamping may be made by sawing through the ends as far as indicated at *F*.

In Fig. 3 is shown a T-jig for locating a bearing bracket *A* relative to the hole *B* in the main casting *C*. The requirements are that the axes of hole *B* and shaft *D* must intersect, and the faces of hubs *E* must be equidistant from the axis of *B*. It is evident, however, that the T-jig will not take care of the alignment of the shaft *D* with reference to its being parallel with the surface *F*. This may be accomplished by measuring down from surface *F* with either a combination square or surface gage or, in case the adjacent bearing for shaft *D* is already located, bracket *A* will find its own alignment by using this bearing to support the shaft.

The Use of Templets

When a number of pieces are to be made interchangeable without the use of jigs or fixtures, this can be accomplished by the employment of templets for laying out the work. While these devices greatly simplify laying-out and aligning operations, they are not intended for guiding the cutting tools. Templets are particularly well adapted for work where the holes to be laid out lie in the same horizontal plane, and, owing to this condition, the templet usually takes the form of a flat plate of sheet iron, or a wooden piece, having the same general outline as the work to be laid out. Again, many irregular forms are drawn on work from accurately filed templets, after which permanence is given the lines by dotting them with prick-punch marks placed directly on the line.

In making a templet for the first-mentioned class of work, holes are drilled in the templet to conform to the drawing of the piece to be laid out. In use, the templet is laid on the work and is then clamped to it by suitable and convenient means, so that its outline coincides with that of the work. The layout may be transferred to the work by means of a marker as already explained, or, in the case of comparatively large holes, an ordinary scriber is used to mark the circles, and after the templet is removed from the work, the center of each circle is laid out with dividers, permanence being given the lines by a prick punch. Witness circles are often placed on the work to make sure that the original lines were closely followed in drilling, *i. e.*, a circle is drawn in each case 1/32 inch larger in diameter than the one worked to; then, if the hole is correctly drilled, it will be concentric with this circle.

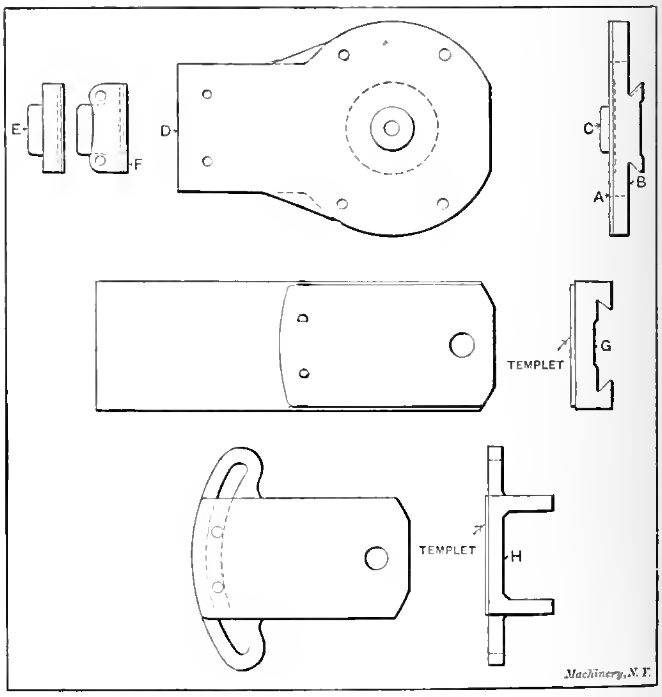

Fig. 5. Sheet Iron Templets for Laying out Planer Crossrail Members

For a certain class of work where great accuracy is not required, templets may be made provided with hardened steel

bushings for guiding the cutting tools independently of the skill of the operator, in which case, however, the templet takes the form of a jig. Owing to the lack of rigidity due to the thin material of which such jigs or templets are constructed, no attempt is made to provide clamping arrangements. The templet may be clamped to the work by means of ordinary C-clamps, or with machinists' clamps. Very frequently, however, it is desirable to provide locating points which may consist of pins extending from one or both sides of the templet, as the case may require, or the locating points may be formed by bending the edges of the metal to a right angle.

The application of a jig such as just described is illustrated in Fig. 4, which shows the method of drilling foundation bolt holes in a turret lathe bed, the holes being drilled from the bottom. As will be seen, the jig or templet *A* consists of three pieces of flat iron riveted together and clamped to the bed by means of clamps *B*. The method of inserting the drill bushings is shown in detail at *C*. To facilitate setting the jig with reference to the bosses *D* on the under side of the bed casting drilling the tap holes in the lathe bed, not shown. Steel lining bushings *E* are provided for the drill bushings. The jig and work are clamped to the drill press table by straps and bolts. The frame consists of four pieces of ash fastened at the corners with blue and wood-screws, the joints being made as shown. Ash is the best wood for the purpose, since, if well seasoned, it is less likely to warp than any other, but where this wood is not available, maple is a good substitute.

A slightly more expensive, but more durable jig, for the same purpose is shown at *F* in the same engraving. This jig is made of flat bar steel riveted together, and is of the same general construction as the wooden one.

Gages for Aligning Operations

A gage may briefly be defined as any standard of comparison; as here used, the term gage will have reference to special devices for aligning work without the employment of ordinary tools such as a combination square, surface gage, etc. Besides greatly facilitating aligning operations, the particular

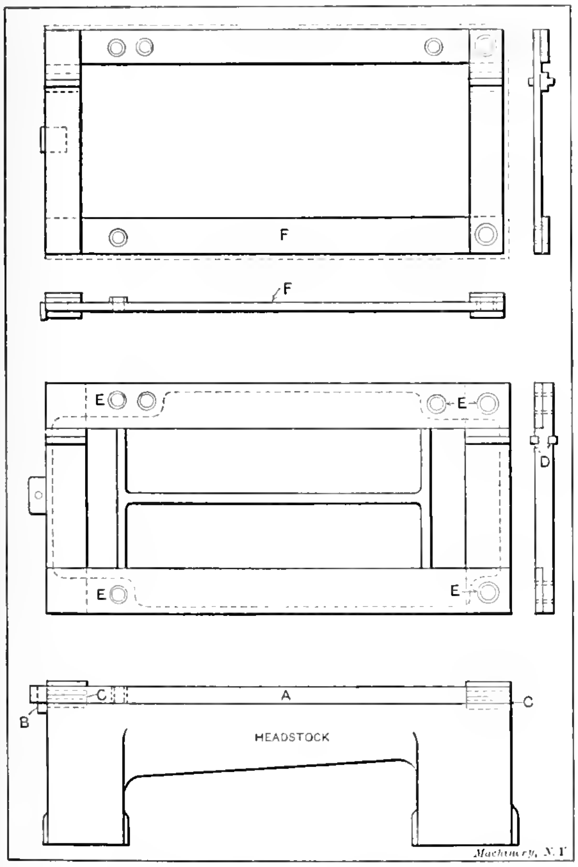

Fig. 6. Application of a Wooden Jig for Drilling a Lathe Headstock. At F is shown a Similar Jig constructed of Flat Bar Steel

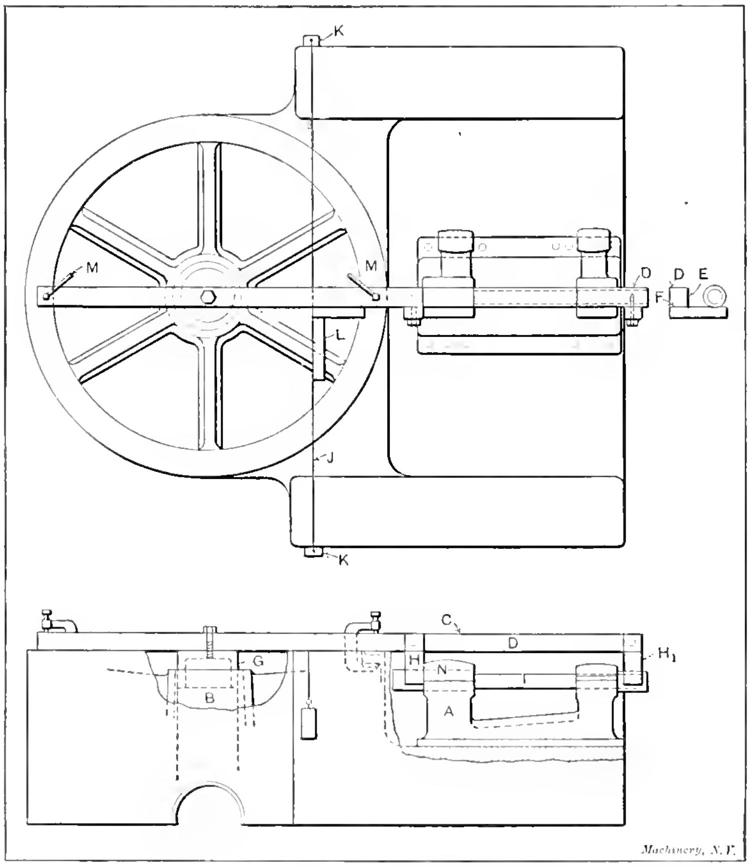

Fig 7. Gage for Aligning the Driving Shaft Bracket on a Vertical Boring Mill of the Bevel Gear Driven Type

so that the holes when drilled will be concentric with these bosses, jig member *E* is bent to a right angle at each end so as to extend down the casting; the location is determined by matching these ears with the bosses on the bed.

In Fig. 5 is shown the application of sheet iron templets for laying out cross-rail members for large planers. Templet *A* for swivel member *B* is located by the hub *C*, and is lined up to match the end *D*. A separate templet is provided for laying out the swivel clamp *E*; edge *F* of the templet is bent over to form a locating point. But one templet is required for laying out slide *G* and its clapper-box *H*. This is lined up on each member as shown. It is obvious that these templets are more advantageous than cast iron jigs for this class of work, since very large and heavy jigs would be required, and furthermore, no great accuracy is necessary, as the bolt holes have 1/16 inch clearance.

As already stated, a very cheap and serviceable jig for certain classes of work can be constructed of wood. At *A*, Fig. 6, is shown a jig of this character for drilling the clamping bolt holes in an engine lathe headstock—in this case for a 30-inch lathe. The jig is located by pin *B* and keys *C*, the latter fitting a keyway in the headstock; having these keys on both sides of the jig as shown at *D*, it is also used for

advantage of using gages is that the possibility of error due to carelessness in transferring scale measurements is avoided. It is assumed, however, that the gages here shown are intended only for duplicate work; it would not be economy to make gages for aligning only a few pieces.

Turning back to Fig. 4, *F* represents a simple gage for aligning bracket *G* on the bottom of a turret lathe bed. The requirements are that face *H* of the bracket must be a certain definite distance from seat *I* on the bed, but the alignment in a longitudinal direction is non-essential. The gage merely consists of two pieces: a straightedge *J*, planed only on one side and one end, and a gage which is fastened to the end of the straightedge as shown. As surface *L* on the bed lies in the same plane with seat *I*, the straightedge is made long enough to reach this surface, thereby obtaining greater accuracy in the alignment. Bolt hole *M*, already tapped, is utilized for clamping the gage. In aligning the bracket, its face is brought into contact with the gage, and the bracket is then set longitudinally to match its seat on the bed.

Another gage, or more properly speaking, a pair of gages, for aligning a feed box on the turret lathe bed shown in the lower part of the same engraving, is shown at *N*. The requirement of the present case is simply that the feed-box shaft

hole O be located a certain definite distance from the top of the bed; seat P on the bed takes care of the center distance from hole Q. It is obvious then, that the gage castings R should only provide a positive locating surface with reference to the top of the bed; this is accomplished in the manner shown. The location endwise is determined by scale measurement from the end of the bed.

An aligning operation on a vertical boring mill bed, and the gage used, is illustrated in Fig. 7. This boring mill is of the bevel gear driven type, in which the pinion meshing into the table bevel gear is carried on the driving shaft in bracket A. The problem of aligning this driving shaft bracket with reference to the spindle hole B in the bed, is easily solved by using gage C. As will be seen, this gage consists of a bar D planed on two sides, E and F; a bushing G fitting the spindle hole; and two gage pieces H and H_1. A special arbor I, having both its ends ground to the same diameter, fits bracket A.

When in use, a line wire J is stretched across the bed by means of weights K. This wire lies in a small groove or mark planed in the bed for the double purpose of squaring the gage and setting the housings. Square L is used in setting the gage before it is clamped by means of clamps M, so that when the bed members are assembled, the driving shaft will be approximately square with the housing faces. With the gage in this position, bracket A is set so that its arbor just touches the gage blocks H and H_1. The location with reference to the distance from spindle hole B in the bed is determined by simply bringing the hub face N on bracket A into contact with the side of gage block H. After the operation of marking off the tap holes in the bed is accomplished, and the holes are drilled and tapped, bracket A is reset in the same manner and clamped by its bolts, for drilling and reaming the dowel pin holes.

* * *

A few years ago mahogany was regarded as a very precious wood and was employed only for the interior finish of the finest houses and in the manufacture of high-priced furniture. During the past few years, however, there has been a wonderful development in mahogany importation and use. The total quantity of mahogany imported in 1908 was nearly forty-two million board feet. It is one of the most valuable woods known for other than decorative purposes. As a pattern material it is unsurpassed, being strong, light and not as much affected by rough usage as pine. It takes glue remarkably well and is also superior to pine in that it is not affected as much by dampness.

DERIVATION OF BEVEL GEAR FORMULAS*†

RALPH E. FLANDERS‡

In the present article are given the derivations of the formulas used for calculating the dimensions of bevel gearing for all conditions of shaft angles and types of gears, including bevel gears with shafts at right angles, miter gearing, bevel gears with shafts at acute or obtuse angles, crown gears, and internal bevel gears.

In Fig. 1 is shown an axial section of a bevel gear, the pitch lines showing the location of the imaginary pitch cone. The pitch cone angle is the angle which the pitch line makes with the axis of the gear. The pitch diameter is measured across the gear drawing at the point where the pitch lines intersect the outer edge of the teeth. In speaking of the pitch of a bevel gear we always mean the pitch of the larger or outer ends of the teeth. Diametral and circular pitch have the same meaning as in the case of spur gears, the diametral pitch being the number of teeth per inch of the pitch diameter, while the circular pitch is the distance from the center of one tooth to the center of the next, measured along the pitch diameter at the back faces of the teeth. The addendum is the height of the tooth above the pitch line at the large end. The dedendum (the depth of the tooth space below the pitch line), and the whole depth of the tooth are also measured at the large end.

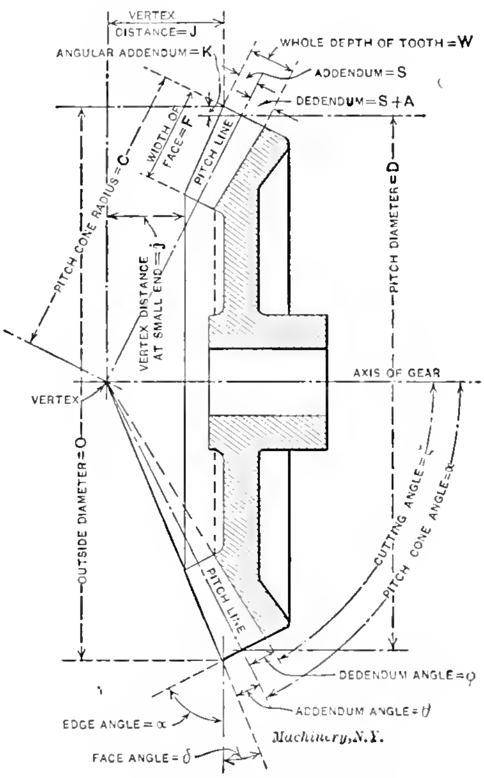

Fig. 1. Dimensions, Definitions and Reference Letters for Ordinary Bevel Gear

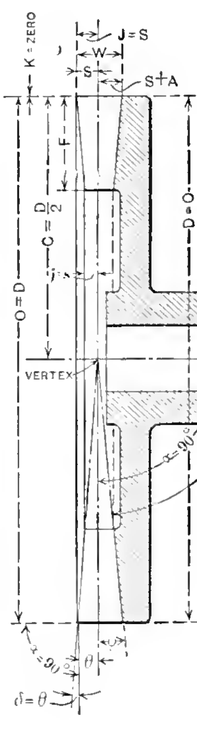

Fig. 2. Dimensions for Crown Gear

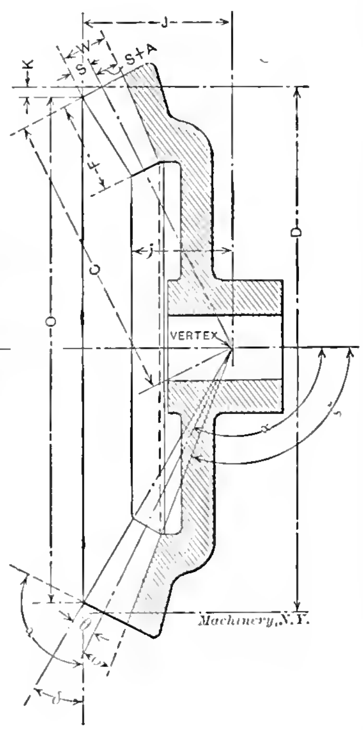

Fig. 3. Dimensions for Internal Bevel Gear

The pitch cone radius is the distance measured on the pitch line from the vertex of the pitch cone to the outer edge of the teeth. The width of the face of the teeth, as shown in Fig. 1, is measured on a line parallel to the pitch line. The addendum, whole depth and thickness of the teeth at the

See also MACHINERY'S Data Sheet No. 36, September, 1904, Proportions of Bevel Gears; No. 37, October, 1904, Dimensions of Miter Gears; No. 64, December, 1906, Strength of Bevel Gears; No. 69, May, 1907, Bevel Gear Formulas and Diagrams; No. 102, Extra Data Sheet, October, 1908, Table for Determining the Outside Diameter of Bevel Gears; MACHINERY'S Reference Series No. 37, Bevel Gearing.

‡ Associate Editor of MACHINERY.

small or inner end may be derived from the corresponding dimensions at the outer end, by calculations depending on the ratio of width of face to the pitch cone radius. (See s, w and t in Fig. 4.)

The addendum angle is the angle between the top of the tooth and the pitch line. The dedendum angle is the angle between the bottom of the tooth space and the pitch line. The face angle is the angle between the top of the tooth and a perpendicular to the axis of the gear. The edge angle (which equals the pitch cone angle) is the angle between the outer edge and the perpendicular to the axis of the gear. The latter two angles are measured from the perpendicular instead of from the axis for the convenience of the workman in making measurements with the protractor when turning the blanks. The cutting angle is the angle between the bottom of the tooth space and the axis of the gear.

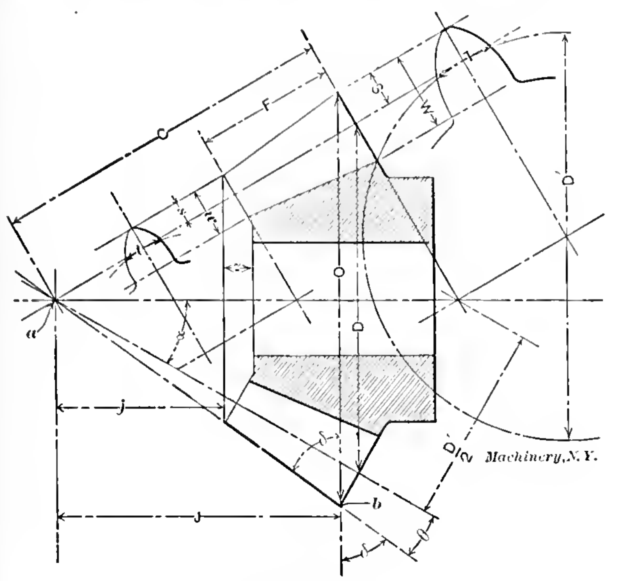

Fig. 4. Diagram Explaining Certain Calculations Relating to Bevel Gears

The angular addendum is the height of tooth at the large end above the pitch diameter, measured in a direction perpendicular to the axis of the gear. The outside diameter is measured over the corners of the teeth at the large end. The vertex distance is the distance measured in the direction of the axis of the gear from the corner of the teeth at the large end to the vertex of the pitch cone. The vertex distance at the small end of the tooth is similarly measured.

The shape of the teeth of a bevel gear may be considered as being the same as for teeth in a spur gear of the same pitch and style of tooth, having a radius equal to the distance from the pitch line at the back edge of the tooth to the axis of the gear, measured in a direction perpendicular to the pitch line.

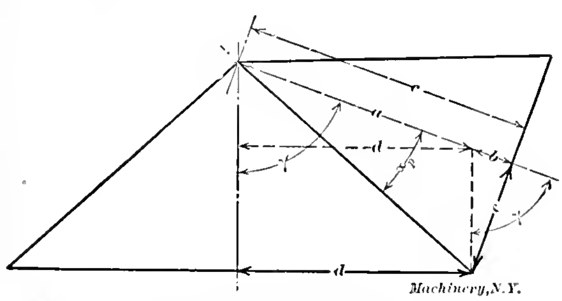

Fig. 5. Diagram for Obtaining Pitch Cone Angle of Acute Angle Gearing

This distance is dimensioned $\frac{D'}{2}$ in Fig. 4. The number of teeth which such a spur gear would have, as determined by diameter D' thus obtained, may be called the "number of teeth in equivalent spur gear," and is used in selecting the cutter for forming the teeth of bevel gears by the formed cutter process.

In two special forms of gears, the crown gear, Fig. 2, and the internal bevel gear, Fig. 3, the same dimensions and definitions apply as in regular bevel gears, though in a modified form in some cases. In the crown gear, for instance, the pitch diameter and the outside diameter are the same, and the pitch cone radius is equal to one-half the pitch diameter. The addendum angle and the face angle are also the same. The angular addendum becomes zero, and the vertex distance is equal to the addendum. The number of teeth in the equivalent spur gear becomes infinite, or in other words, the teeth are shaped like those of a rack.

When the pitch cone angle is greater than 90 degrees, so that the gear becomes an internal bevel gear, as in Fig. 3, the outside diameter (or edge diameter as it is better called in the case of internal gears) becomes less than the pitch diameter. Otherwise the conditions are the same, although many of the dimensions are reversed in direction.

Rules and formulas for calculating the dimensions of bevel gears are given in the accompanying Data Sheet Supplement. The following reference letters are used:

N = number of teeth,
P = diametral pitch,
P' = circular pitch,
π = 3.1416,
a = pitch cone angle and edge angle,
γ = center angle (angle between axes of two meshing gears),
D = pitch diameter,
S = addendum,
$S + A$ = dedendum (A = clearance),
W = whole depth of tooth space,
T = thickness of tooth at pitch line,
C = pitch cone radius,
F = width of face,
s = addendum at small end of tooth,
t = thickness of tooth at pitch line at small end,
θ = addendum angle,
ϕ = dedendum angle,
δ = face angle,
ζ = cutting angle,
K = angular addendum,

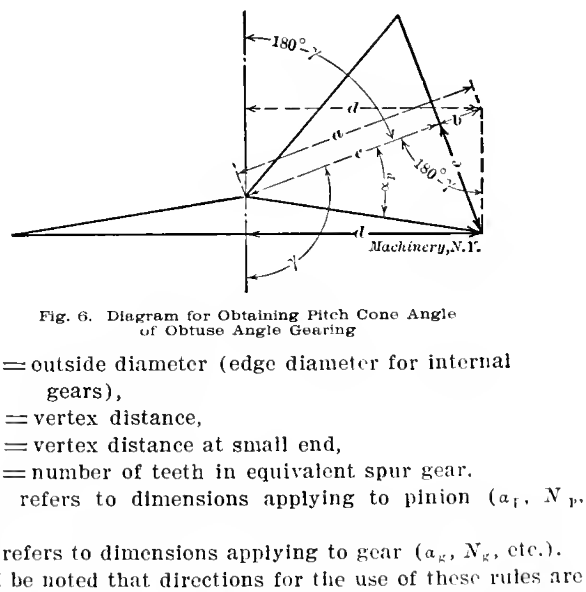

Fig. 6. Diagram for Obtaining Pitch Cone Angle of Obtuse Angle Gearing

O = outside diameter (edge diameter for internal gears),
J = vertex distance,
j = vertex distance at small end,
N' = number of teeth in equivalent spur gear.

Sub $_p$ refers to dimensions applying to pinion (a_p, N_p, etc.).

Sub $_g$ refers to dimensions applying to gear (a_g, N_g, etc.).

It will be noted that directions for the use of these rules are given for each of the six cases of right angle bevel gearing, miter bevel gearing, acute angle and obtuse angle bevel gearing, and crown and internal bevel gears.

Rules and Formulas for Bevel Gear Calculations

The derivation of most of these formulas is evident on inspection of Figs. 1 to 4, inclusive, for anyone who has a knowledge of elementary trigonometry. It is not necessary to know how they were derived to use them, however, as all that is needed is the ability to read a table of sines and tangents.

Formulas 5, 6, 7 and 8 are the same as for Brown & Sharpe standard gears. The dimensions at the small end of the tooth given by Formulas 10, 11 and 19 obviously are to the corresponding dimensions at the large end, as the distance from the small end of the tooth to the vertex of the pitch cone is to the pitch cone radius. This relation is expressed by these formulas. The derivation of Formula 20 may be understood by reference to Fig. 4:

$$D' = \frac{D}{\cos\alpha} = \frac{N}{P \times \cos\alpha}, \text{ also } D' = \frac{N'}{P}$$

$$\text{therefore } \frac{N'}{P} = \frac{N}{P \times \cos\alpha}, \text{ or } N' = \frac{N}{\cos\alpha}$$

Formula 21, for checking the calculations, will also be understood from Fig. 4, where it will be seen that

$$O = 2\,ab \times \cos\delta, \text{ also that } ab = \frac{C}{\cos\theta}$$

$$\text{therefore } O = \frac{2\,C \times \cos\delta}{\cos\theta}$$

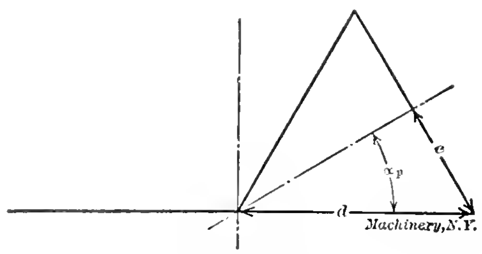

Fig. 7. Diagram for Obtaining Pitch Cone Angle of Pinion to mesh with Crown Gear

Formulas 22 to 27 inclusive are simply the corresponding Formulas 1, 9, 14, 15, 16 and 20 when $\alpha = 45$ degrees.

Formula 28 is derived as shown in Fig. 5.

$$c = \frac{e}{\tan\alpha_p}, \text{ also } c = a + b = \frac{d}{\sin\gamma} + \frac{e}{\tan\gamma}$$

$$\text{therefore, } \frac{e}{\tan\alpha_p} = \frac{d}{\sin\gamma} + \frac{e}{\tan\gamma}$$

Solving for $\tan\alpha_p$, we have: $\tan\alpha_p = \dfrac{e\,(\sin\gamma \times \tan\gamma)}{d\tan\gamma + e\sin\gamma}$

Dividing both numerator and denominator by $e\tan\gamma$, we have:

$$\tan\alpha_p = \frac{\sin\gamma}{\dfrac{d}{e} + \dfrac{\sin\gamma}{\tan\gamma}}$$

Since $d = \dfrac{N_g}{2P}$ and $e = \dfrac{N_p}{2P}$, and since $\dfrac{\sin}{\tan} = \cos$, we have:

$$\tan\alpha_p = \frac{\sin\gamma}{\dfrac{N_g}{N_p} + \cos\gamma}$$

Formula 29 is derived by the same process for the other gear. Formula 31 (and likewise 33) is derived from Fig. 6, using the following fundamental equation:

$$\frac{e}{\tan\alpha_p} = \frac{d}{\sin(180^\circ - \gamma)} - \frac{e}{\tan(180^\circ - \gamma)}$$

When solved for $\tan\alpha_p$, this gives formula 31.

Rule 32, of course, simply expresses the operation of finding out whether the pitch cone angle of the gear is less, equal to, or greater than 90 degrees. The derivation of Formula 34 is shown in Fig. 7:

$$\sin\alpha_p = \frac{e}{d} = \frac{N_p}{N_g}$$

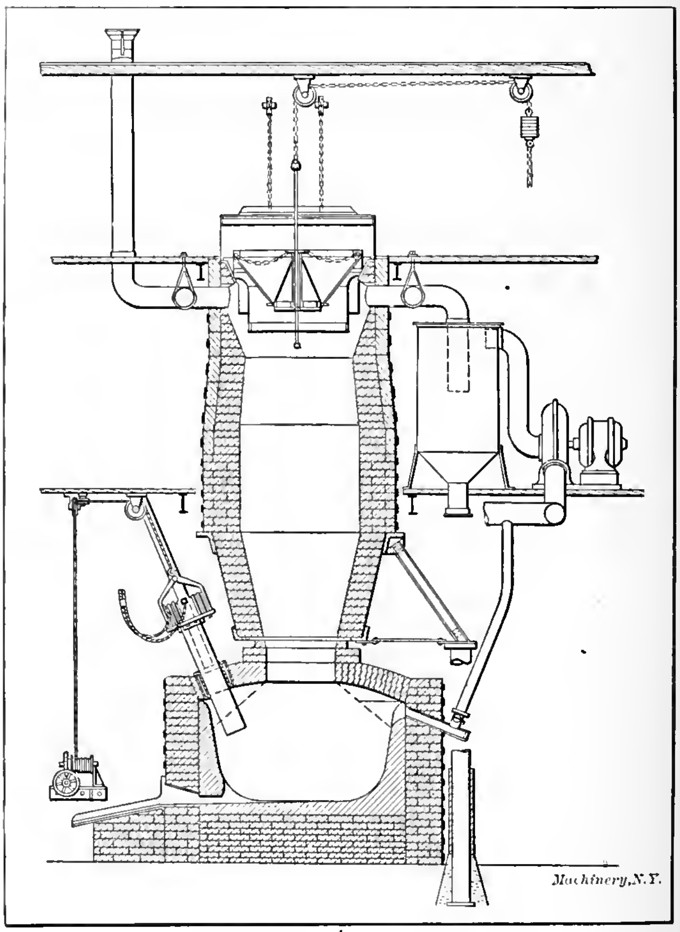
Since in a crown gear the dimension $\dfrac{D'}{2}$ in Fig. 4 is to be measured parallel to the axis, and will therefore be of infinite length, the form of the teeth will correspond to those of a spur gear having a radius of infinite length, that is to say, to a rack. This accounts for Formula 38.

Formulas 39, 40, 42 and 44 are simply the corresponding Formulas 33, 9, 16 and 20 changed to avoid the use of negative cosines, etc., which occur with angles greater than 90 degrees. These negative functions might possibly confuse readers whose knowledge of trigonometry is elementary. The other formulas for internal gears are readily comprehensible from an inspection of Fig. 3.

ELECTRIC SMELTING OF IRON AND STEEL*

At Gysinge, in Sweden, in one of the works belonging to the Stora Kopparbergs Bergslags Aktiebolag, a furnace as shown in the accompanying engraving is installed. This furnace is similar to a common blast furnace, but is provided with three electrodes fed by three-phase alternating current at about 40 volts, 60 cycles and 9,500 amperes, 674 H. P. The electrodes take the place of the tuyeres. This furnace has been running for 1,903 hours and 28 tons of iron, containing from 0.95 to 3.09 per cent of carbon has been produced. The temperature of the escaping gases from the furnaces is generally very low, and they contain on an average about 22 per cent of carbon dioxide. The gases contain practically no nitrogen, but considerable steam from the water in the ore, lime, coke or charcoal is present. No air whatever is used in the process, and the gases are produced from the carbon in the charcoal and coke, and the oxygen in the ores ($FeO + C = Fe + CO$). Either charcoal or coke may be used, but the consumption of fuel will be practically the same in either case.

The line engraving shows a vertical section through the furnace which consists of a lower portion or smelting chamber, corresponding to the hearth of a blast furnace, and a top section or blast. The latter is supported on columns, which prevent any weight from bearing on the arch of the smelting



Electric Blast Furnace built at Gysinge, Sweden

chamber. The latter is so proportioned as to provide a considerable amount of free space between the charge and the arched roof through which the carbon electrodes project into the charge. The brickwork is thus protected against any very high temperature, and remains a non-conductor of electricity. This is an important feature of this furnace, since experiments have shown that if the electrodes enter the chamber at the point where the charge touches the walls, a very high temperature is generated at this point; the brickwork is destroyed and becomes a conductor of electricity, giving rise to a more or less complete short-circuit. The charge is made up of ore, lime, coke and charcoal. The ore and fuel are crushed to a suitable size, and are fed into the top of the furnace through the bell hopper in the usual way.

* Abstract of paper by Mr. E. J. Ljungberg, of Falun, Sweden, read before the Iron and Steel Institute of Great Britain.

THREAD ROLLING*

J. F. SPRINGER†

Of the several methods used for producing threads on screws, the one least understood or known by mechanics in general is the process of thread rolling. When threads are produced by means of this process, the blank, which is held in a machine made for this purpose, is rolled between two dies or blocks, provided on their faces with grooves of the right pitch, form and angle of lead, as shown in Fig. 1. The thread

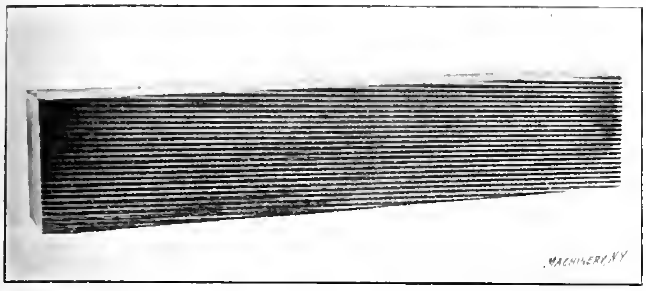


Fig. 1. A Thread Rolling Die for Rolling United States Standard Threads

is formed by the displacement of the metal, some part of which is forced up to form the top of the thread. The finished screw, therefore, is larger in diameter than the blank.

That it is possible to form or roll a perfect thread by means of straight grooves or threads cut into a flat block or die, will be understood by imagining the thread helix as unrolled upon a flat surface. In Fig. 2, for instance, the line AB indicates

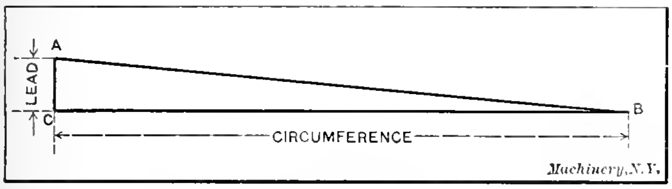

Fig. 2. Diagram for Determining Angle of Threads in Thread Rolling Dies

the helix of a thread thus developed on a flat surface; the line AC is the lead of the thread, and the line BC is the developed circumference of the screw. It is necessary, of course, that the angle of the thread cut on the flat thread rolling die be the same as the helix angle of the thread, which, in turn, is the same as the angle ABC in Fig. 2. The tangent of this angle, of course, equals

$$\frac{AC}{BC} = \frac{\text{Lead}}{\text{Circumference}} = \frac{\text{Lead}}{\text{Diameter} \times 3.1416}$$

These general remarks indicate the main principles involved in the process of thread rolling. In the following some of the elementary matters to be considered in this connection will be treated.

Methods Used for Thread Rolling

There have been a number of methods proposed for carrying out the mechanical operation of rolling threads. As far back as 1851 a machine was built for this purpose. In this machine the blank was rolled between dies or blocks with their faces vertical, one of the dies having a reciprocating motion in a direction at right angles to the axis of the blank. This fundamental idea of construction has been retained in some of the most modern thread rolling machines. Flat dies with their faces placed horizontally have also been used, but there is, as far as the writer knows, no machine of this type now on the market. In another type of thread rolling machine a cylindrical die rotating on its axis and provided with thread grooves on the outside, is set horizontally within a hollow cylindrical die provided with threads on the inside. This thread rolling machine, known as the rotary machine, is at the present time on the market. It has the merit of continuity of production; when one bolt has just been rolled, another is fed in immediately without the necessity of the reversal of the movement which in reciprocating machines causes a period of idleness. The disadvantage of the lost time in reciprocating machines, however, is partially removed by introducing a return movement which is more rapid than the advance; but the continuity of action of the rotary thread roller is, no doubt, an item of importance. A single revolution of the convex die produces, in fact, four bolts.

Automatic Feed for Screw Blanks

There are, however, other things to consider besides continuity of action. An important question is the feeding of the blanks, and the machine having flat dies of the type shown in Fig. 1, set with their faces vertical, lends itself best to automatic methods of supplying the blanks. In such feeding mechanisms the greatest problem probably is that of getting the blanks into the required position for the operation to be performed upon them. A device for this purpose is illustrated in Fig. 3. The blanks for the screws are placed in a hopper A of generous size located at the top of the machine. There is a long slot in the bottom of the hopper through which a flat plate B, called the center-board, is vertically reciprocated. This center-board has a vertical slot whose width is just a trifle in excess of the diameter of the body of the blank. When this slotted center-board rises through the slot in the bottom of the hopper—the motion being actuated by a cam and gearing as shown—one or more blanks are likely to drop, under the influence of their weight, into the slot in the plate. These blanks then hang suspended by their heads as shown. Sometimes, however, the center-board will rise through the mass of blanks in the hopper without any blank being properly located to come into the required position; but the mass of blanks will be disturbed and the next time the board rises some blanks may be caught in the manner necessary for feeding to the machine, and sooner or later one or more bolts will be suspended by their heads. To get a sufficient number to supply the machine, all that is necessary is to proportion the mechanism properly and to operate it at a suitable rate of speed.

Sometimes the blanks will be picked up crosswise or get into other unfavorable positions across the edge of the slotted center-board. An auxiliary device may then be employed to throw off such blanks. In Fig. 3 several blanks are shown

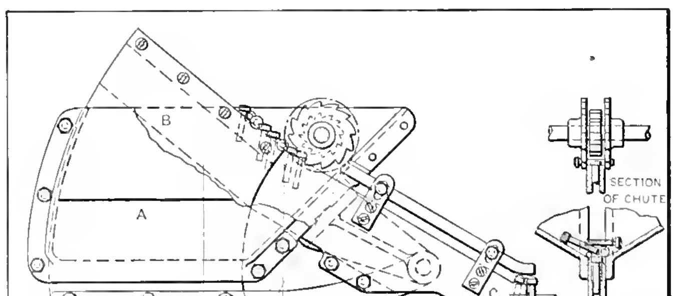

Fig. 3. Automatic Feeding or Hopper Mechanism for Screw Blanks in Thread Rolling Machines

in the proper position in the slot and two others are already delivered to the fixed portion C of the chute, while a number are in unsuitable positions for feeding. As the blanks in or on the center-board move outward to the fixed part of the chute, they pass under and between a rotating system of three toothed wheels of the ratchet-wheel type. The outside wheels pass close to the outer edges of the board, while the inner wheel passes close above the heads of the blanks which are properly caught. This is indicated in the upper sectional

* See MACHINERY, November, 1909, engineering edition: Calculating the Size of Blank for Rolling Screw Threads.

† Address: 625 W. 135th St., New York City.

view to the right in Fig. 3. If a blank is in the correct position in the chute it will not be disturbed by the wheels, but if not, it will be thrown off. The lower sectional view to the right shows a typical situation of the blanks when the center-plate rises through the slot at the bottom of the hopper.

It will be seen in Fig. 3 that as the blanks pass down the inclined chute they are prevented from subsequent displacement by an adjustable guide or keeper passing over their heads. At the end of the chute the direction of the blanks becomes vertical and they are then caught between the dies and the thread rolled. Of course, all thread rolling machines are not fed with automatic hoppers of this type. Conditions decide when and when not to employ devices of this kind.

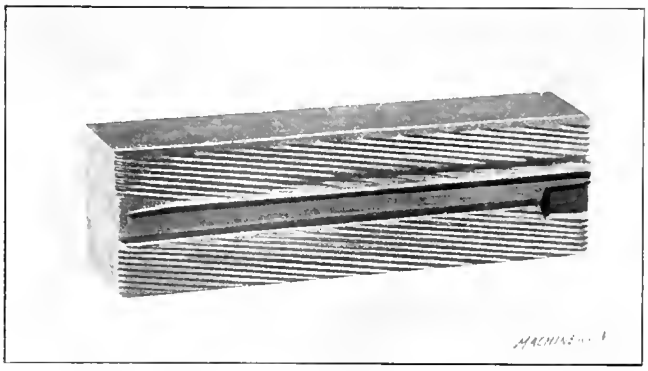

Fig. 4. A Reversible Thread Rolling Die for Wood-screws

The Thread Rolling Process

One of the thread-rolling dies is stationary while the other has a reciprocating movement. Both dies are exactly the same otherwise except for length. The thread-rolling die shown in Fig. 1 is for a right-hand thread, the grooves inclining downward toward the right. For a left-hand thread, the threads on the dies incline downward toward the left. In Fig. 4 is shown a reversible die. In this die when the upper portion is worn down the lower portion may be brought into service by reversing the die. This die is for rolling wood-screw threads. On account of the gimlet point required, the surface of the die is not flat. In rolling screw threads using one stationary and one reciprocating die, the working stroke of the moving die must be at least twice the length of the fixed die, otherwise the screw blank would not be rolled over the full face of the fixed die, but would be carried back at the return of the movable die. While a good thread might be rolled that way, it would obviously be impracticable to have the screw blank return, if for no other reason than because it would interfere with the blank just fed into the dies.

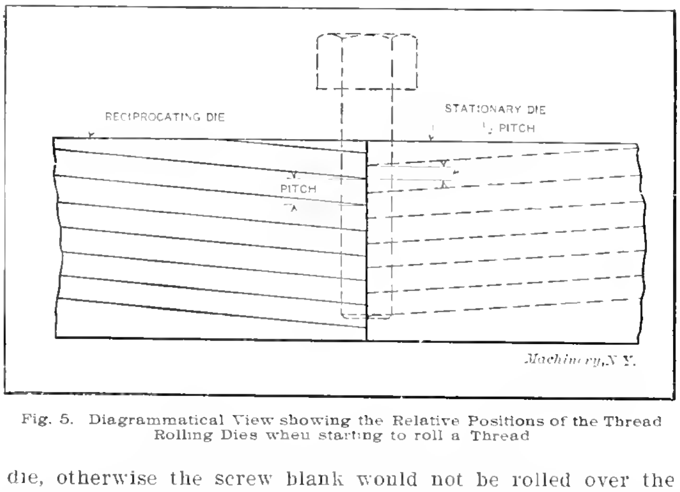

Fig. 5. Diagrammatical View showing the Relative Positions of the Thread Rolling Dies when starting to roll a Thread

When calculating the angle of the threads on the die face, the circumference of the die blank should be taken as the length of the side *BC* in Fig. 2. For example, suppose that we wish to roll an ordinary V-thread having a finished diameter of ¾ inch, and 10 threads per inch. The diameter of the blank is found by Formula (11), on page 181 of MACHINERY, engineering edition, November, 1909. This diameter is 0.689 inch, and the circumference of the blank, consequently, 2.165 inches. The screw having 10 threads per inch, the lead is 0.100 inch and hence the tangent of the angle of the thread on the die face $= \frac{0.100}{2.165} = 0.046$, giving an angle for the thread of 2 degrees 40 minutes.

A little thought will easily convince one that when starting to roll the thread it is necessary that the grooves in one die be in a given relation to the grooves in the other. The two dies work on the screw on parts separated one-half turn, and as one-half turn of the screw corresponds to one-half of the pitch, the ridges and grooves of points exactly opposite each other must be one-half of the pitch above or below the corresponding ridges and grooves in the other die. (See Fig. 5.) In rolling threads this relative adjustment must be secured, otherwise the thread rolled by one die would not coincide with that formed by the other. It is, therefore, necessary to have vertical adjustment in the slides in which the dies are mounted.

It will be understood from what has been said that not only is it important that the two die faces be adjusted exactly in relation to each other, but also that the blank be started exactly at the time when points on opposite faces of the dies are in the correct relation to each other. It is, therefore, necessary to have means of adjustment for timing the start of the operation of rolling the blank. For this purpose a starting rod is used. The blank stands with its head pointing upward at the proper level and close to the right-hand edge of the fixed die. The die is cut away at this point so that as long as the blank remains there, no work will be accomplished by the movement of the reciprocating die. The starting rod then forces the blank between the dies at the precise moment when the threads are in the proper relation to each other. The starting rod is usually referred to as the "starter." It is, of course, important that the blank pass through in a perfectly upright position. If it is started vertically there is ordinarily no difficulty in maintaining it so. At the moment of starting, the starter forces it against the vertical edge of the fixed die, which is sufficient for usual requirements. If the blank is very long, it may need support at its upper end; this support in most cases may be given by the hand of the operator.

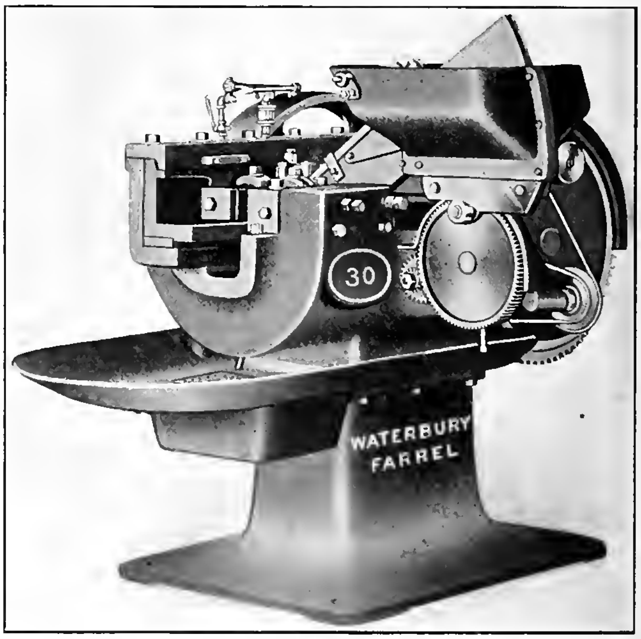

Fig. 6. A Waterbury Farrel Foundry & Machine Co.'s Thread Rolling Machine with Automatic Hopper Mechanism

At the first part of the stroke the bolt is only partially penetrated by the threads in the dies. The dies, therefore, are not mounted exactly parallel, but so that they are further apart from each other at the point where the rolling process commences. When the bolt has rolled all the way through to the left-hand edge of the fixed die the operation is complete and the movable die begins to return. It has been found desirable to provide a means of preventing the bolt from getting

caught and carried back between the dies. Gravity alone cannot be depended upon because of the possibility of the thread on the screw clinging to the moving die. One method for throwing off the work is by the use of a flat spring. One arm of a rather obtuse V protrudes over the upper edge of the movable die. When the bolt comes along its head or upper part strikes this arm of the V, forcing it back; when the work has passed, the arm returns to its normal position, so that it prevents the work from following the die back. The spring

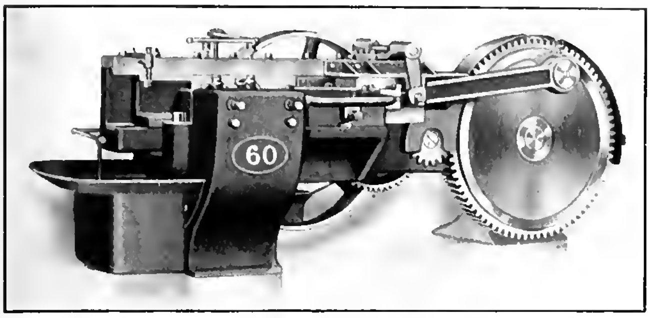

Fig 7. Large Thread Rolling Machine

will not be pressed back on the return stroke, as the work is not held very firmly to the die.

Advantages of Thread Rolling

As already mentioned, the rolling of threads increases the outside diameter; thus in the example previously given, a blank 0.689 inch in diameter produces a thread of 0.750 inch in diameter, or an increase of 0.061 inch—over 8 per cent. It will be seen, then, that if the diameter of that part of the bolt which is not threaded and the threaded portion are desired to be the same, blanks must be used having a smaller

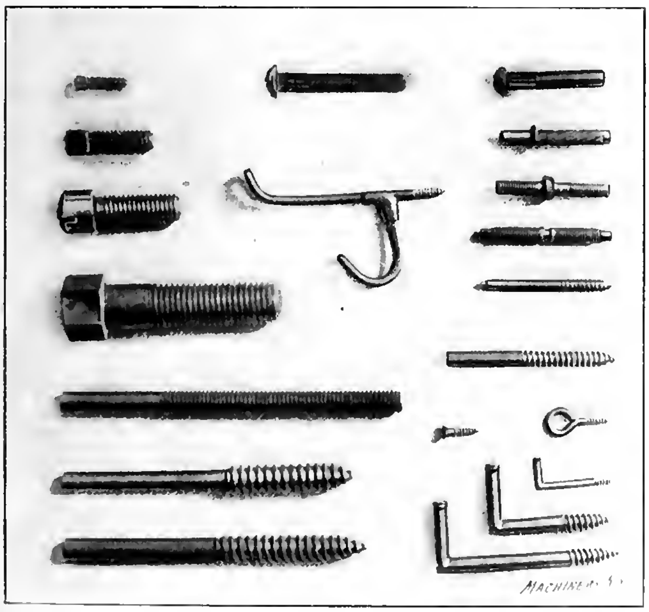

Fig. 8 Examples of Work performed in Thread Rolling Machines

diameter where the thread is to be formed.

The fact that thread rolling is accomplished without waste is perhaps a consideration worth taking into account.* Suppose that we are threading ¾-inch bolts, the threaded part being 4 inches long. When cutting the threads in a lathe or with dies we use full size stock, but when rolling them we can use stock 0.689 inch in diameter. The saving is expressed by the formula:

$$S = \frac{\pi}{4} (G^2 - g^2)\, l$$

in which G is the diameter of the finished thread, g the diameter of the blank, and l the length of the thread. For the example above, we find:

$$S = 0.7854\ (0.750^2 - 0.689^2) \times 4 = 0.276 \text{ cubic inch.}$$

For 10,000 bolts we would have a saving of 2,760 cubic inches, or about 770 pounds of steel.

* The bolts for holding together the cast iron sections of the Hudson tunnel tube are all provided with rolled thread.

Quite aside from the question of economy of material is that of the quality of the product. A bolt or screw whose threads have been rolled may not be suited to applications where microscopic accuracy of the threads is essential; no one would think of using a rolled thread for a micrometer screw. The strength of the thread, however, appears to be fully that of cut threads, although the writer is not aware of any extended comparative tests having been made between cut and rolled threads. It seems reasonable to expect even greater strength from these threads for the reason that the rolling process, executed on cold metal, may be expected to impart firmness to the thread and adjacent parts.

One of the greatest advantages of the manufacture of bolts and screws by the rolling process is the rapidity with which the work can be carried out. The smallest machine manufactured by the Waterbury Farrel Foundry & Machine Company, for instance, having a capacity of stock up to 3/16 inch in diameter, will roll screws at the rate of one every 4/5 of a second. If the thread is short, this speed, it is claimed, can be increased. The largest machine, having a maximum capacity of blanks 1½ inch in diameter, is said to be capable of rolling threads at a rate of one every three seconds. In Fig. 6 is shown a medium-sized thread rolling machine provided with the automatic feeding device illustrated in Fig. 3. As shown in the half-tone, the center-plate is at the highest point. The toothed wheel arrangement for removing blanks improperly caught by the center-plate is barely visible over the edge of the hopper. The fixed die is on the side toward the observer, the movable die being mounted in a slide having guides at top and bottom as indicated. In Fig. 7 is shown a larger machine which is not provided with an automatic feeder.

In Fig. 8 are shown a number of screws and other pieces of work having threads produced by rolling. Among these samples is a wood-screw with tapering thread and gimlet point. In other samples the thread is straight until near the end, where a gimlet form is produced. Attention may be directed to the longitudinal grooves on two of the pieces at the top of the illustration. While these are not threads in the ordinary sense, although they might be regarded as groups of multiple threads with an infinite lead, they may be readily formed by a rolling operation. Another sample shows a thread with a very steep lead. Pieces with a threaded portion at each end, one right-hand and the other left-hand, are also shown. That it is practicable to thread very close up to the head may be seen from some of the samples to the left.

THE "NEW MECHANICS"

In an address before the French Association for the Advancement of Science, Mons. Henrie Poincaré recently pointed out the contrast between the so called "new mechanics" and the old mechanics based upon Newton's laws of motion. The conceptions of the new science of motion are not easily presented in a popular form, because of their entire novelty. In a word, the modern idea is that a constant force acting upon a moving body does not impart equal increments of velocity in each successive second, but that the accelerative effect decreases as the velocity of the body becomes greater, and finally reaches a limit which it cannot pass. This limit is the velocity of light. In other words, the inertia of matter increases with its velocity of translation, and becomes infinite when the velocity is equal to that of light. Another form of statement is that the mass of a material body increases with its velocity of movement, and that there can be no motion swifter than that of light, that is, about 186,330 miles per second.—*Youth's Companion.*

* * *

CORRECTION

In the articles "Machining Cylinders and Pistons for Automobile Engines" and "Automobile Factory Practice," January number, engineering edition, it was stated that in the Nordyke & Marmon shops pistons are lapped in dummy cylinders, using oil and emery. This is an error as regards the abrasive. Powdered glass is used instead of emery on account of the well-known tendency of emery to embed in cast iron and cause destructive wear in use.

MACHINE SHOP PRACTICE*

THE VERNIER SCALE—ITS PRINCIPLE AND METHOD OF READING

Every machinist knows how confusing it is to take measurements with a scale that is graduated in hundredths or even sixty-fourths of an inch, owing to the multiplicity of lines. If it were possible to graduate a scale to thousandths, that is, so that every inch would be divided into a thousand equal parts, it would, of course, be useless, owing to the extreme fineness of the lines and the minute distances between them. Such fine divisions on a scale are not, however, necessary, for by means of a special auxiliary scale called a vernier (after its inventor), graduations which are comparatively large can be divided so that fine measurements may be taken. For example, the true or regular scale of the caliper-square shown in Fig. 1, is graduated in fortieths of an inch; but by means of the vernier scale *V*, which is attached to the sliding head of the instrument, measurements within one-thousandths of an inch may be taken. In other words, the vernier, in this case, makes it possible to divide each fortieth of an inch on the true scale into twenty-five parts. The vernier may be defined, then, as an auxiliary scale that is attached to caliper squares, protractors, etc., for obtaining fractional parts of the sub-divisions of the true scale of the instrument.

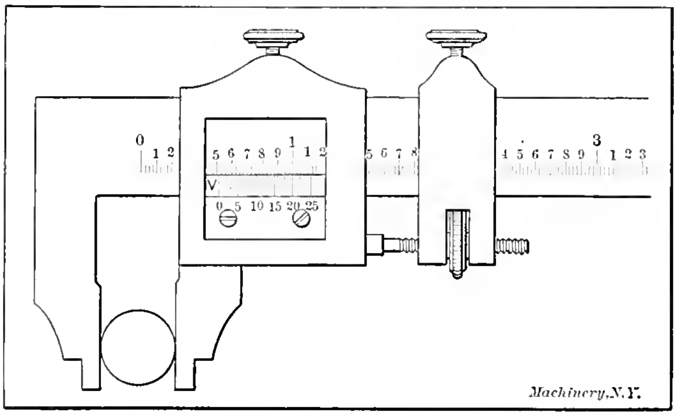

Fig. 1. Caliper Square with Vernier reading to Thousandths

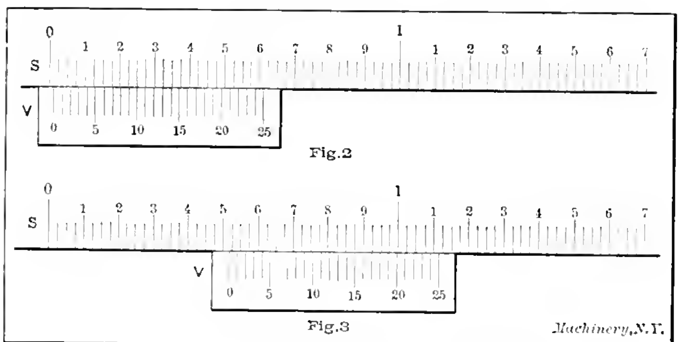

Figs. 2 and 3. Scales with Verniers set to Different Positions

By referring to the enlarged scales shown in Figs. 2 and 3, the principle of the vernier can be more easily understood. Here each inch of the true scale *S* is divided into ten parts, and each tenth into four parts, so that the finest divisions are fortieths of an inch. The vernier scale *V* has twenty-five divisions, and its total length is equal to twenty-four divisions on the true scale, or 24/40 of an inch; therefore, each division on the vernier equals 1/25 of 24/40 or 24/1000 inch. Now, as 1/40 equals 25/1000, we see that the vernier divisions are 1/1000 inch shorter than those on the true scale. If, then, the zero marks of both scales were exactly in line, the two first lines to the right would be 1/1000 inch apart; the next two 2/1000; etc. It is evident then that if the vernier be moved to the right until, say, the tenth line from the zero mark exactly coincides with one on the true scale, as shown in Fig. 2, the movement will be equal to 0.010 inch, since this line was 0.010 inch to the left of the mark with which it now coincides, when the zero lines of both scales were together. Similarly, if the fifteenth line were exactly opposite a line on the true scale the movement of the vernier would be equal to 0.015, etc.; so we see that the number of thousandths that the vernier zero has moved past a graduation on the true scale, is determined simply by counting the number of spaces between the zero of the vernier, and that line on it which is exactly in line with one on the true scale. If the vernier were moved along to the position shown in Fig. 3, the true scale would indicate directly that the reading was slightly over 0.500 inch, and the coincidence of the graduation line 15 on the vernier with a line on the true scale, would show the exact reading to be $0.500 + 0.015 = 0.515$ inch; that is, the exact amount (in thousandths with this particular vernier) that the vernier zero has moved past the 0.500 division, is determined, as before stated, by counting the spaces between vernier zero line and that line of the vernier which coincides with one on the true scale.

In Fig. 4 a true scale *S* is shown that is graduated into sixteenths of an inch, and the vernier *V* has eight divisions with a total length equal to seven divisions on the true scale, or 7/16 of an inch; therefore each division on the vernier is 1/8 of 1/16, or 1/128 inch shorter than the divisions on the true scale; so we see that in this case the vernier enables readings to be taken within one-hundred and twenty-eighths of an inch instead of in thousandths as with the one described in the preceding paragraph. The divisions then that may be obtained by a vernier depend altogether on the way the true and vernier scales are graduated. In order to determine the fractional part of an inch that may be obtained by any vernier, multiply the denominator of the finest sub-division of an inch given on the true scale, by the total number of divisions on the vernier. For example, if as in Figs. 2 and 3, the true scale is divided into fortieths and the vernier into twenty-five parts, the vernier will read to thousandths, as twenty-five times forty equals one-thousand. If there are sixteen divisions to the inch on the true scale and a total of eight on the vernier (as in Fig. 4) the latter will enable readings within one-hundred twenty-eighth of an inch to be taken, as eight times sixteen equals one hundred twenty-eight. It will be seen then that each sub-division on the true scale is divided into as many parts as there are divisions on the vernier. If, for example, the vernier of a protractor has, in all, say twelve divisions, evidently each degree may be divided by it into twelve parts or one-twelfth degree. As there are sixty minutes in one degree, the protractor would indicate angles within five minutes.

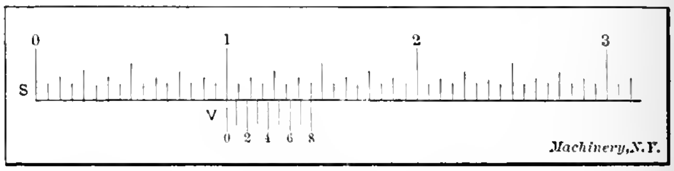

Fig. 4. Scale with Vernier Reading to One-hundred Twenty-eighths of an Inch

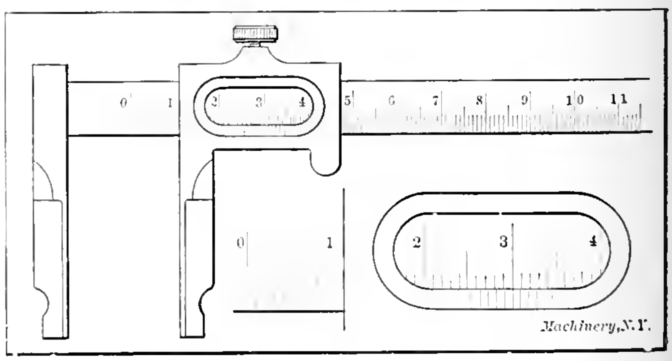

Fig. 5. Caliper Square Graduated on the Metric System

The following is a general rule for taking readings with a vernier: Note the number of inches and whole divisions of an inch that the vernier zero has moved along the true scale, and then add to this number as many thousandths, or hundredths, or whatever fractional part of an inch the vernier reads to, as there are spaces between the vernier zero and that line on it which coincides with one on the true scale.

* With Shop Operation Sheet Supplement.

For example, the zero line of the vernier shown in Fig. 1 is slightly beyond the 0.500 division, and graduation line 15 on the vernier coincides with one on the true scale; hence, the reading is 0.500 + 0.015 equals 0.515 inch. If the vernier is attached to a protractor, note the whole number of degrees passed by the vernier zero mark, and count the spaces on the vernier as before. If the vernier indicates angles within five minutes the number of spaces times 5 will, of course, give the number of minutes to be added to the whole number of degrees.

The application of the vernier to a "Columbia" caliper-square graduated on the metric system, is illustrated in Fig. 5. Here we have, instead of inches, centimeters which are sub-divided into ten parts called millimeters. By the aid of the vernier, each millimeter is again divided into ten parts so that readings can be taken to within 1/10 of a millimeter or 1/100 of a centimeter (0.0039 of an inch). The reading with the caliper set as shown in the illustration is 2 55/100 centimeters, or, as commonly expressed, 25 5/10 millimeters. This particular instrument has on the opposite side of the beam two series of inch graduations which, with the verniers, enable measurements within 1/100 and 1/128 of an inch to be taken. It will be seen that inches may be converted into metric measurement, and *vice versa*, by taking the reading first on one side of the beam and then on the other.

Further information on reading verniers when applied to a micrometer or bevel protractor is given in the Shop Operation Sheet accompanying this number, to which the reader is referred.

The education of apprentices at the United Shoe Machinery Co., Beverly, Mass., has been arranged along lines similar to those in vogue in Worcester and Fitchburg, and which have previously been mentioned in MACHINERY. The company has organized two classes of twenty-five boys each, recruited from the machine tool department. The city has a technical school supported by the town and the state board of industrial education, and the two classes of boys work alternate weeks in the shop and in the school. These boys are paid half the piece rates that the regular factory employes are paid, and earn at an average of $3 per week, although a few of them earn $5 weekly. Besides these small earnings, of course, they get a thorough knowledge of the use of machinists' tools and, in fact, learn the entire machinist's trade. The class when instructed in the school is taught such subjects as drawing, elementary machine design, mathematics and other practical subjects. They do not receive any pay while attending the school. There is no effort made to educate the students to be superintendents or foremen, but they are fitted to earn a livelihood, and, as one of the men in charge at the Beverly factory says, "If they have the right stuff in them they will get there."

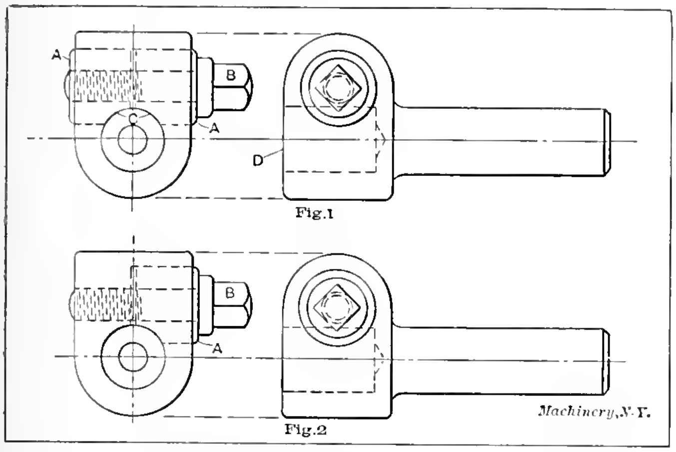
TOOL-HOLDER DESIGNS

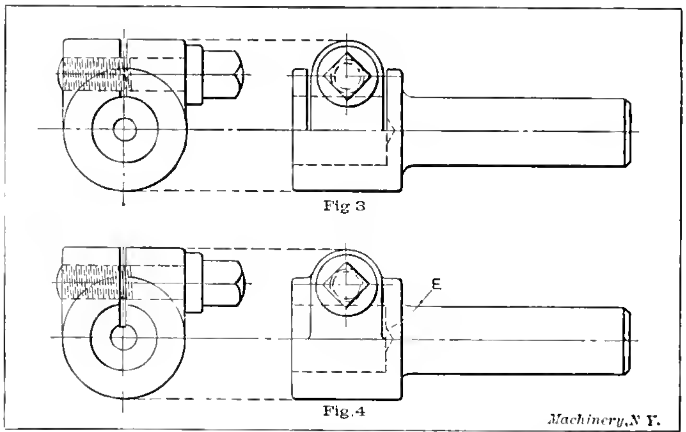
F. P. CROSBY*

A number of tool-holders of different designs for turret lathe and automatic screw machine work are shown in the accompanying illustrations. As many of the types illustrated are widely used and represent standard practice, they are presented herewith for the guidance of tool-makers, designers, or others interested in such equipment.

The binder type of turret lathe tool-holder is shown in Figs. 1 and 2. Fig. 1 illustrates a holder of the double binder type. The hardened cylindrical parts *A*, which should be fitted accurately to the body of the holder, serve to clamp the tool in place. These parts are turned away at *C* to conform to the hole in which the tool is inserted. As may be seen, one of these parts is tapped to fit the screw *B*, which has a collar head bearing against the other part. The clamping action is effected by turning screw *B*, which draws the two parts *A* together, thus binding them firmly against the cutter which is inserted in the bore *D*. The holder shown in Fig. 2 is of the single binder type. The screw *B* is tapped into the body of the holder and only one binding piece *A* is used. These holders are considered to be the best of their class and they can, of course, be made in any size that may be desired. The construction is clearly shown in the engraving.

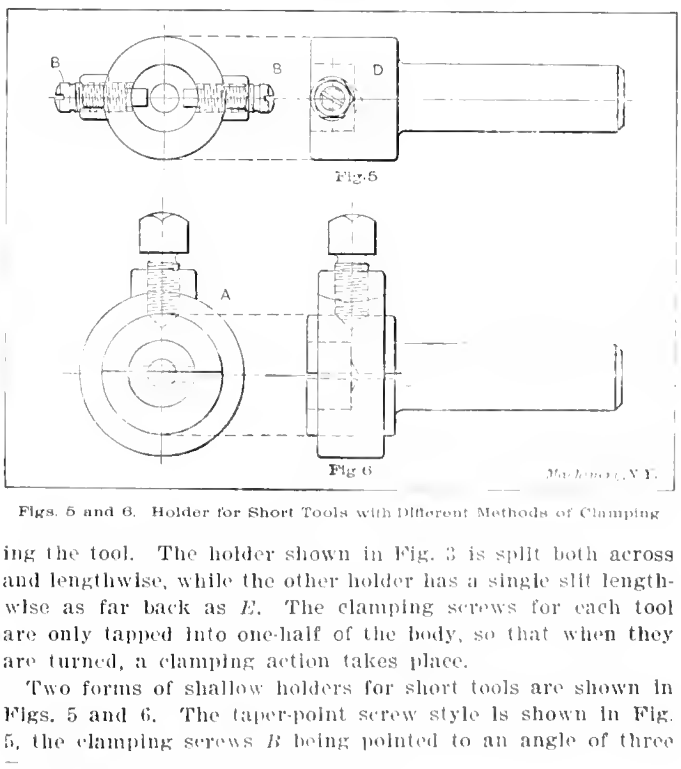


Figs. 1 and 2. Turret Lathe Tool-holders of the Double and Single Binder Type



Figs. 3 and 4. Two Tool-holders of the Compression Type

Figs. 3 and 4 show two holders of the compression type, which for some classes of work is the best. These two holders are practically the same, differing only in the way they are split to obtain the required amount of elasticity for clamping the tool. The holder shown in Fig. 3 is split both across and lengthwise, while the other holder has a single slit lengthwise as far back as *E*. The clamping screws for each tool are only tapped into one-half of the body, so that when they are turned, a clamping action takes place.



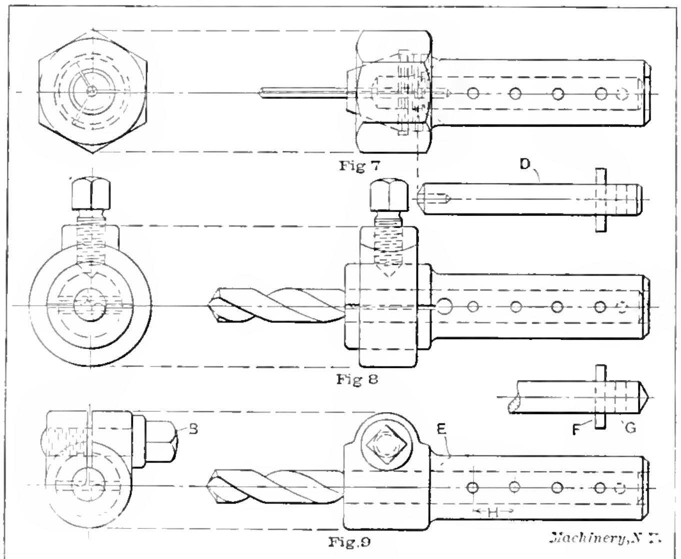
Figs. 5 and 6. Holder for Short Tools with Different Methods of Clamping

Two forms of shallow holders for short tools are shown in Figs. 5 and 6. The taper-point screw style is shown in Fig. 5, the clamping screws *B* being pointed to an angle of three

* Address, 113 North State St., Chicago, Ill.

degrees and fitting into holes drilled in the tool shank. These holes are located at the right distance from the end so that the screws bind the end of the tool shank against the holder. The holder shown in Fig. 6 is of the compression type, the split end being tightened on the tool shank by the collar *A* and pointed screw shown.

Drill holders of the compression type are shown in Figs. 7, 8 and 9. Fig. 7 shows a compression holder of the chuck type which is used for holding small drills. The shank of the drill is soldered to a larger shank, which has a retaining pin engaging the holes in the holder. This enlarged shank, that the small drill is soldered to, is shown in detail at *D*. The small hole in the end for the reception of the drill is plainly indicated by the dotted lines. The holder shown in Fig. 8 is provided with a collar and pointed screw for clamping the drill. With the exception of the method of clamping, this tool is similar in other respects to the one shown in



Figs. 7, 8 and 9. Three Types of Drill Holders

Fig. 9. The latter is slotted lengthwise as far back as *E*, and the drill is held in position by the collar-head clamping screw *B* which is tapped into one side of the holder. The shank of this holder has drilled into it a number of holes in regular order as shown. The shank of the drill is fitted with the pin *F*, which prevents the crowding back or turning of the drill in the holder. An extra hole *G* is provided for the pin,

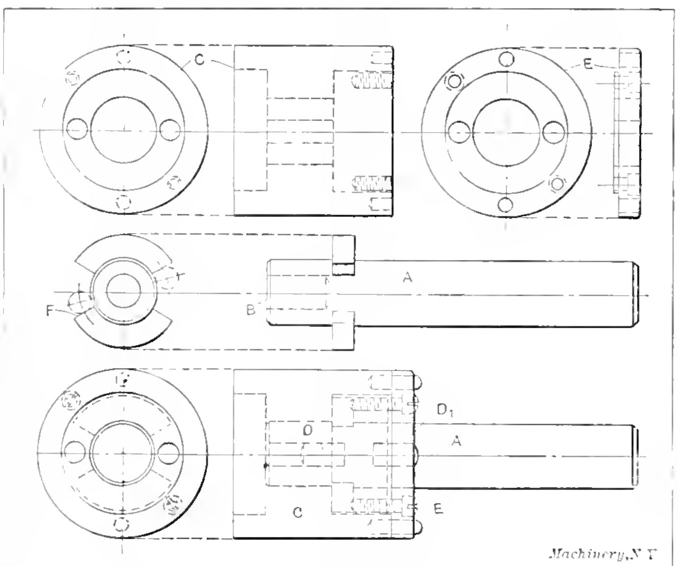


Fig 10. Assembled and Detail Views of a Die-holder

and the distance between the two pin holes is equal to one-half the dimension *H*. The clamping screw on a holder of this type needs only to be tightened enough to bring the tool in line.

Fig. 10 shows both assembled and detail views of a solid shank die-holder. The reference letters used in the detail views are the same for the corresponding parts in the assembled view. The shank and the clutch *A* is made in one piece from tool steel, and it is tempered and ground. In the end of this shank there is a clearance hole *B*, the depth and diameter of which is sufficient to give the required clearance for the work. The sleeve *C*, which is accurately fitted to the shank,

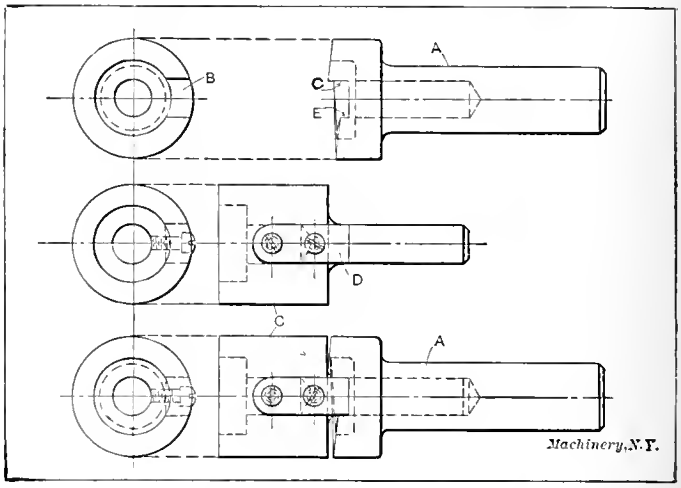

Fig. 11. Another Type of Die-holder

has attached to it the die, two of the contact pins *D* for driving the die, and the backing-off plate *E* with its contact pins D_1. The way in which the backing-off plate is held in place by screws and dowels is clearly shown in the illustration. The contact points at *F*, in case the shank should become worn, can be trued by grinding. The contact pins in case of wear can be removed and turned one-quarter way round.

A die-holder of the semi-hollow shank order is shown in Fig. 11. The shank *A* of this holder should be made of tool steel tempered and ground. On the enlarged end of the shank is shown a left-hand helix which is cut from the slot *B*. If the holder is to be used for cutting a left-hand thread, a right-hand helix has to be provided. The die is held in the

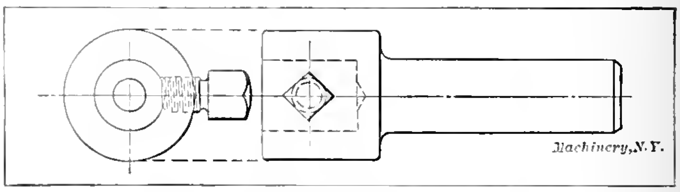

Fig. 12. Tool-holder of Objectionable Design

swiveling part, *C*, which is fitted to the shank as shown. In operation, when the turret comes to a stop, the clutch *D* disengages with the point *E*, and in backing off it is in contact with the point *C*. The clutch is made of tool steel, and is tempered and fitted to the die-holder in a manner clearly indicated in the illustration.

The tool-holder shown in Fig. 12 is one in common use, but the best place to put it is in the scrap pile, as it is simply impossible for any workman to adjust a tool in it that will be lined up properly. It is supposed that the reason for using this type of holder is to save a little on the cost. Such a tool, however, will prove to be a very poor investment.

* * *

According to the provisions of the new custom tariff of Norway, machines, motors and apparatus not manufactured in the country will be admitted free of duty. As the machine industry in Norway is comparatively undeveloped, there are a great many machines and machine parts which are thus placed on the free list, among which may be mentioned band saw blades, circular saw blades, steam hammers, pneumatic drills, steam turbines, ball bearings, link belts, etc. The complete list of the machinery admitted free of duty may be found in the November 19, 1909, issue of the *Daily Consular and Trade Reports*, published by the Department of Commerce and Labor, Washington, D. C.

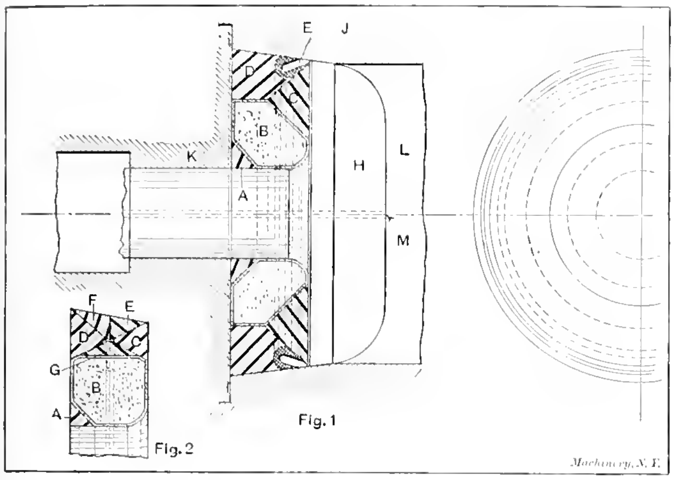
Don't forget that the top of a work-bench should slant back toward the wall.

A GAS CHECK FOR BIG GUNS

ROBERT O'NEAL*

In the large guns in use by the government, as in most other things, it is the little parts that make the great engines of war of real value. This is clearly illustrated by the fact that a fifty-thousand dollar implement of modern warfare may be temporarily put out of commission by the catching on fire of a small pad used in the construction of what is known as the gas check. This little pad which is made of canvas, hair, tallow, beeswax, etc., is worth about thirty cents, which is an insignificant sum when compared with the cost of the gun, complete; but the gun without it is about as dangerous at one end as at the other.

In Fig. 1 of the accompanying engraving is shown, in cross-section, the interior of that part of a large gun with which this little pad has to do, and in Fig. 2 the present method of



Sectional View of Gas Check for Big Guns

the construction of the rings of a gas check is illustrated. The difference between the two checks is clearly perceptible, and the advantage of that shown in Fig. 1 over that of Fig. 2 will, I think, be readily seen when the matter is fully explained.

In order to show as clearly as possible the use of the rings and the pad, it will be necessary to go into the matter somewhat in detail. In Fig. 1, *H*, *J*, *K*, and *L* represent the mushroom, the gun, the breech-plug and the powder or combustion chamber, respectively. When the charge is rammed home, the breech-plug—the face of which is shown in contact with the rear face of the rings *A*, *D*, and the pad *B*—is swung into position and turned through an arc of 40 degrees, it having entered an interrupted thread of sixty one-hundredths inch lead; this brings the mushroom *H* firmly against the wall of the gun *J*, through the contact of the rings *A*, *C*, *D*, and the pad *B*. Now, the powder charge in the chamber *L* is ignited through the vent *M*, and a pressure ranging anywhere from forty to fifty thousand pounds per square inch is generated within the chamber. Against this pressure it has been found impracticable to devise a method of holding the mushroom *H* sufficiently hard against the wall of the gun to prevent the escape of gas; therefore the gas check is necessary, as the mechanism must be free-working to allow of easy manipulation by the gun crew.

As the mushroom moves back, the pad *B* is caught between the members *A* and *C*, and as *C* is held rigid, the tendency is to reduce the thickness of the pad *B* and increase its diameter. This directly increases the diameters of the rings *C*, *D*, *E*, *F* and *G* when they are constructed as in Fig. 2, and brings them up against the wall of the gun with a pressure directly in proportion to the pressure of the gases in the combustion chamber, according to the laws of force as applied to the wedge; but this increased diameter is accompanied by a proportionate increase in the opening where the ring has been cut. The opening necessary for this expansion, though small (about 0.006 of an inch), like most little things, plays an important part, in that it allows the gas to escape through it to the pad *B*. As the temperature of this gas is that of a white heat, and acting under a pressure sufficient to throw a five-hundred-pound projectile about twelve miles in something less than half a minute, it is safe to say that this little mass of combustible substance can not long resist the onslaught of such a potential factor of destruction. Quite often only one charge is fired, when it is found necessary to renew the pad, and rarely can over three or four shots be made without renewal. While this does not require any great amount of time, nevertheless, it requires the removal of the firing lock (not shown here), the mushroom, and the dismantling of the rings; in addition the danger of fire in the turret is incurred while removing the burning pad.

It will be seen at a glance that the difference between the two gas checks illustrated lies principally in the construction of the ring *E*. In Fig. 2 this ring is of triangular cross-section and of solid metal, necessitating its being cut in order to increase its diameter when the gun is fired. In Fig. 1 ring *E* is of a U-shape in cross-section, which will allow of its being opened out to fill the space between the angular face of the ring *C*, and the wall of the gun, without cutting it, for, when the mushroom *H* recedes, the ring *C*, being solid, is carried back with it; the pad *B*, in either case, is pressed thinner and consequently larger in diameter, thus forcing the ring *D* out and hard against the wall of the gun. The gas, passing between the mushroom *H* and the wall of the gun *J*, is caught between the legs of the U-shaped ring *E*, which is being firmly supported on its inner side by the face of the ring *C* and on the outer side by the wall of the gun, while the round portion is sustained by the concave surface of the ring *D*. The pressure of the gas forces the legs outward against these three surfaces with a pressure equal to that within the chamber, and a joint is made between these surfaces through which the gas cannot possibly escape.

This design of check could be constructed to take the place of the one now in use without in any way altering the standard parts of the gun, as the set of rings shown in Fig. 1 could be made to fill the space occupied by the set shown in Fig. 2; and, if constructed with care, I see no reason why they would not last as long as the gun, or, at least, until general repairs are needed, which is usually after approximately fifty shots have been fired.

* * *

KINDLINESS AN ASSET IN MANUFACTURING

It may seem a long step from machine construction to the sentimentalism of smiles and kind words, but nevertheless these two items play an important part in many successful manufacturing plants. The object sought by a manufacturer is efficiency—efficiency on the part of the individual members of the organization as well as on the part of the machinery employed. A great deal of time and thought is expended on making the machinery efficient. Experiments are made, careful records are kept, and the best results utilized; but little thought is usually given to increasing the efficiency of the "man who works with his hands," and that often lacks system and appreciation of the final effect. Sometimes attempts are made to increase the efficiency of the men making up the organizations by methods entirely erroneous, not to say culpable, and which in the long-run prove as costly as they are ineffective.

There is, however, an inexpensive method of increasing the efficiency of the personnel in any organization. While fair compensation, and what is generally considered fair treatment are absolute essentials, a great deal can be both lost or gained by the general attitude of the employers and men in charge of the various departments. A kind word, an appreciative smile, a commendation for work well done, for instance, will often increase the efficiency, and are more effective in eliminating friction, than a so-called welfare department planned on an elaborate scale.

The efficiency of the mechanical element of the industries has been raised to a high standard, and the efficiency of the human element should be raised to an equal height by methods which will be of lasting effect both in a factory and without. If you never use smiles and kind words, try them, and you will find that the effect will be immediate, not only on those around you, but on yourself.

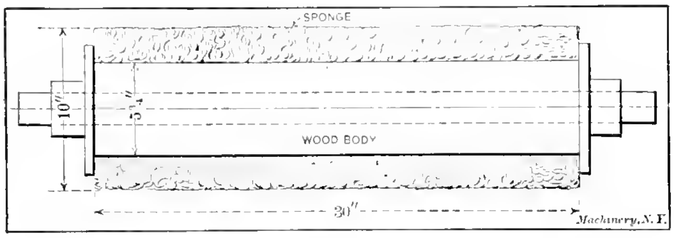
INGENIOUS METHOD OF TURNING A SPONGE-COVERED ROLL

A roll formed of strips of sponge and a wooden body, had to be turned true, and the writer was asked to do the job, which was wanted in a hurry. You can bet that there was



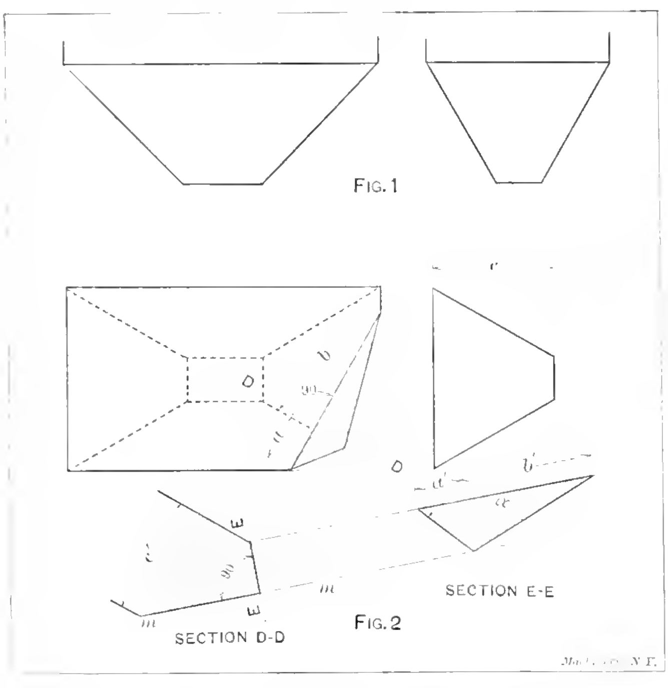
Wooden Roll with Sponge Covering which had to be turned true

some question as to how it was to be done. The sponge strips were fastened by brass tacks to the wooden body. These tacks were placed as near together as possible, there being about sixteen of them to each block of sponge. After the roll was built up in this way, the method of getting it to the required diameter proveu to be a sticker. There were enough suggestions offered to fill a book, but finally the following method was tried with considerable success. As the temperature out-of-doors was near the zero mark, the roll was placed outside on two woodeu horses with blocks arranged on either side of the shaft so that it could be turned. With the aiu of a dog on one end of the shaft, the roll was then revolved, while a fine spray of water from a hose was turned on it. In about twenty minutes the roll was frozen solid; it was then placed in the lathe and two cuts were taken over it, which completed the job. After the ice melted, the sponge covering was found true.

Lewiston, N. Y. CHARLES H. LAKE.

ANGLES OF HOPPER SIDE INTERSECTIONS

In building a steel hopper of the form shown in Fig. 1, it becomes necessary to know what angle the sides of the



Graphical Method of obtaining the Angle formed by the Tapered Sides of a Hopper

tapered portion make with each other, in order to properly bend the flange or splice plate, for the corner, as the case may be. This angle can be obtained graphically, as shown in Fig. 2. For clearness of demonstration, consider a block of the same shape as the lower portion of the hopper, with a corner cut off in a plane perpendicular to the corner *D-D*, as shown. To obtain the angle, first lay out a plan of the outline of the block as it would be before the corner was cut off; then draw section *D-D*, making c' equal to c. Draw any line *E-E*, perpendicular to *m-m*, and then projecting upward, obtain a plan view of the surface *E-E*, or a view representing the block as it would appear from above, with the corner cut off. Now draw section *E-E* making a' equal to a and b' equal to b. Then a will be the required angle. CHAS. E. EVANS.

Aurora, Ill.

[The diagrams of the Data Sheet for April, 1908, will be found very convenient for obtaining the angle formed by hopper sides.—Editor.]

MILLING A CORRECT BEVEL GEAR

In this article a method of cutting bevel gears is described which has been in use now for about two and a-half years, in a number of shops in this vicinity.

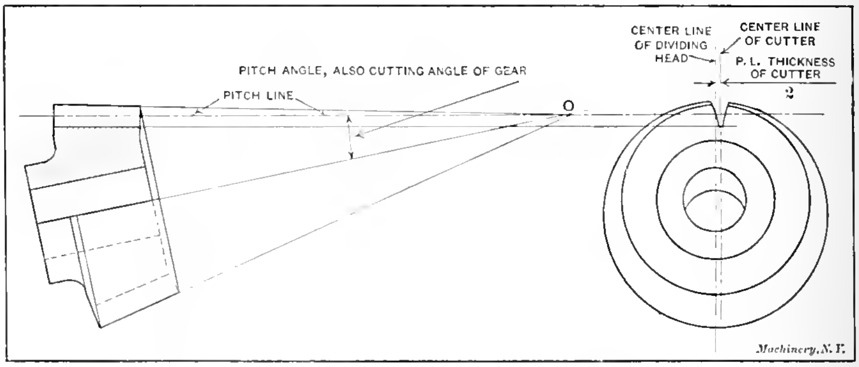


Illustration showing Method of Setting Gear Blank with Relation to Cutter

While the method is perhaps a trifle difficult to understand, as it was to work out, the results are so satisfactory as to more than make it pay. It is applicable to all cases excepting miters of very coarse pitch and few teeth and where strength is an essential feature. There is a slight excess depth at the small end of the tooth which, ordinarily, is entirely negligible and only in unusual cases is so objectionable as to make this process impracticable.

The advantages sought for and gained are these: A smooth-running bevel gear milled scientifically without "cut-and-try"; a pair of bevel gears which mesh perfectly at the pitch-line; a bevel gear which requires no filing at the small end of the tooth to make it run smoothly; and, as important

PITCH LINE THICKNESS OF B. & S. BEVEL GEAR CUTTERS

Diam. Pitch	2	3	4	5	6	7	8	10	12	14	16	20
Thickness	.513	.334	.257	.204	.169	.145	.126	.100	.082	.070	.060	.047

as anything, a method that saves a large amount of time and does away with uncertainties in bevel gear cutting.

These results are accomplished as follows: The regular bevel gear cutter is used. The gear to be cut is mounted as usual in the dividing head, but it is set up so that the working or pitch angle of the gear is the cutting angle; in other words, so that the pitch line of the tooth running to the common center *O* of the gears is parallel with the bottom of the cut, as shown in the accompanying illustration. The milling machine table is not swivelled in any case.

The cutter is set for depth, as usual, from the high point on the gear to be cut. The saddle of the machine is moved so that the vertical center of the cutter is to one side of the vertical center of the gear, a distance equal to half the pitch line thickness of the cutter. A cut is then taken all around, for each tooth. This finishes, one side of the tooth. The

other side of the tooth is finished by moving the saddle in the opposite direction, so that the vertical center of the cutter is on the opposite side of the vertical center of the gear, a distance equal to half the pitch line thickness of the cutter as before. Before the cut is taken the dividing head spindle is rotated so that the amount taken off this opposite side of the space is such as to leave a tooth of the correct thickness at the back, which may be easily determined by trying a spur gear cutter of the same pitch and number of teeth, or tooth gage, or spur gear tooth of the same pitch, or otherwise. This being done, the cut is taken all around, which finishes the gear.

On examination, by actual test, careful measurements or analysis of the method, it will be found that the results sought have been secured and the gears will run proudly, as self-respecting bevel gears ought to run.

Muskegon, Mich. Chas. A. Kelley.

INTERESTING WORK IN AN EXPERIMENTAL SHOP

No one class in society has a corner on inventive genius; to-day, the doctor conceives the "best thing yet," while on

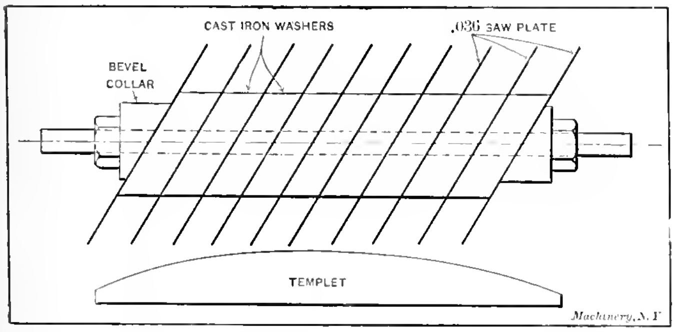

Fig. 1. Steel Disks which were turned to conform to the Templet

the morrow the chances are that it will be the laborer who is propounding something that will bring him fame and fortune. The machine shop has been and will continue to be the mecca of inventors, and a shop catering to experimental work is brought face to face with constructions and schemes as diversified as are the stations in life of their sponsors. To save the inventor from being "stung" for special tools and fixtures which he is sure will be needed when he gets to the manufacturing stage, the shop man may have to use diplomacy, and then, on his own side, resort to some homely short cuts to get the work through without these special tools.

Figs. 1 and 2 show pieces of work turned out for different

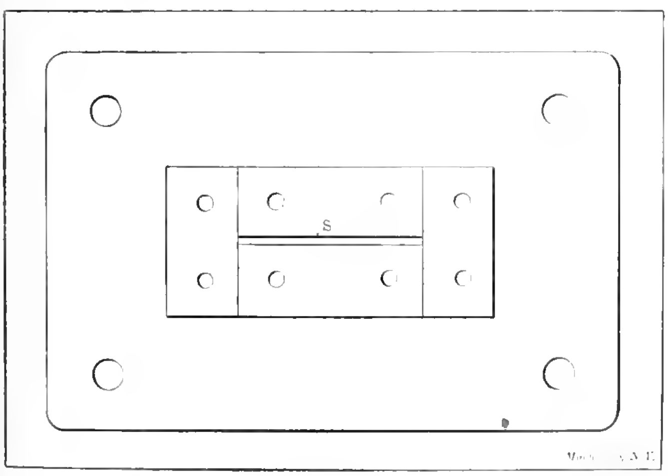

Fig. 2. Four-piece Die for Experimental Work

inventors (each with plenty of money to spend) at a fraction of the outlay that might have been put upon them. The mandrel in Fig. 1 was loaded with carbon steel disks that had to be turned to fit a templet. These disks, instead of being at right angles to the center line of the mandrel, were at an angle as shown, an effect produced by using a beveled collar on each end and loose fitting spacers between the disks. It can readily be seen that to turn these disks, projecting beyond the spacers from 3 to 5 inches, was impossible by ordinary means unless a rigging was made to follow in and out and back and forth as each one was cut separately—all of which was practically out of the question. The short way out of it was to slip on each end of the mandrel a board the size of the largest disk blank and to wrap about the whole several thicknesses of heavy manilla paper and tack it securely to the boards. After filling the disks with lead both the lead filler and the disks were turned off to the shape of the templet in quick time.

Fig. 2 shows a die and block that were substituted for the inventor's specifications for a solid tool steel die with a slot *S* 3/32 by 3 inches and absolutely to size. The four-piece die illustrated was simple to make as compared with the solid one, had ample security against spreading when set into the block, could be sharpened as often as necessary, maintained its size, and presented no risk in hardening.

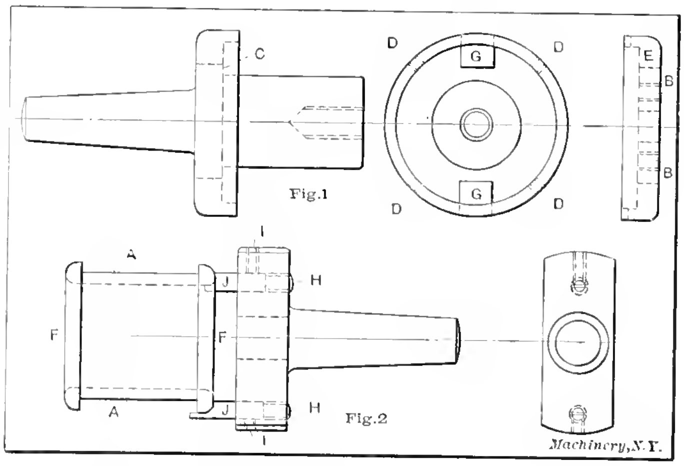
And like so many that have gone before, neither of the above pieces was ever used long enough to keep the rust off and neither produced dividends on the investment.

Middletown, N. Y. Donald A. Hampson.

MACHINING SPLIT BEARINGS

An interesting problem in the machine shop is to bore and and turn split bearings accurately. The success obtained by the use of the following methods, leads me to sumbit them to the readers of Machinery. The bearings are made of brass; when received from the foundry, they are placed in a shaper and planed on the faces *F-F* to a certain height from the back. After this operation, they are taken to the forge and sweated together. While this is not absolutely necessary, it facilitates handling the work in the next operation of chucking and boring.

The brasses are held by a pair of false jaws, which were cast



Mandrel on which Bearings are turned, and Special Tool used for Rounding Corners

for the turret lathe, and which are turned and recessed so as to clear the flange of the brass and bear on the faces *A*. The boring is done with a bar and fly-cutter, the bar being supported by a bushing in the spindle of the machine. The front face and flange are next squared and turned off before the work is removed from the chuck. It was to shorten the time required and facilitate the operation of turning the brasses that the mandrel shown in Fig. 1 was designed. The shank was made to fit in the headstock; and as the mandrel is very rigid, it is not necessary to support it by the tailcenter; consequently, high speeds can be used and there is no danger of a center becoming heated. The brasses are placed on the mandrel with the end previously finished in the turret lathe against the finished face *C*. They are locked in place by four set-screws *D*. A C-clamp is placed on the outer end of the brasses and is left there until that end and flange are finished. The cap *E* is then placed over the outer end of the brasses and the clamp is removed. This cap is fastened to the mandrel by a bolt in the center. Set-screws are provided in holes *B* to aid in removing the cap, as it is made a snug fit over the work, to prevent the latter from spreading during the process of turning. The over-all measurements are taken

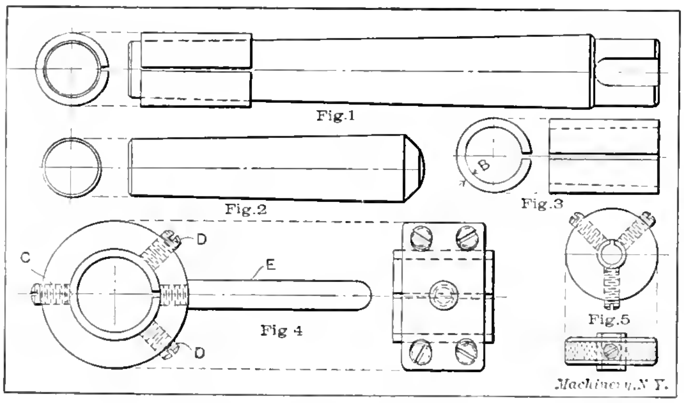
through the port-holes *G*, which are cut in the mandrel for this purpose.

After the trial lot of brasses had been completed, the radius- and fillet-turning tool, shown in Fig. 2, was designed. This tool is held by a shank in the tailstock and with it the corners of the bore and flange are rounded with a greater degree of accuracy than is ordinarily obtained when the shape of these surfaces is left to the judgment of the workman. The cutters *J* are made of drill rod, and they may be adjusted by the screw *H* and locked by the screw *I*. Direct evidence as to the time-saving qualities of the foregoing method, was given when the cost clerk made inquiry about the shortness of the time listed on the daily time cards for the lot of work which was machined by these tools.

Salem, Mass. JOHN F. WINCHESTER.

LAPS AND POINTS ON LAPPING

The laps which are shown in the accompanying illustration are excellent designs for both the outside and inside lapping of cylindrical parts Fig. 1 shows an inside lap with the arbor in place. The included angle of the taper of this arbor should be about 2 degrees; this is considered great enough for any kind of work. The lap proper, or the part that is in contact with the work, is made of bolt copper, and is shown in detail in Fig. 3. Cast iron and lead are sometimes used, but copper is the best metal for hardened work. The lap is split as shown, to allow it to expand as it becomes worn. The length of the lap should be somewhat greater than the length of the hole to be operated on, and the thickness *B* should not be more than 1/6 or less than 1/8 of the diameter of the work.



Laps for Inside and Outside Work

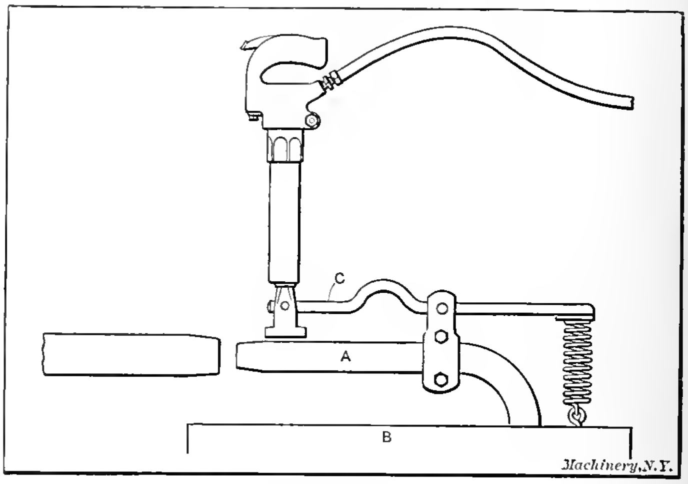
When making these laps, especially small ones, a hardened swedging plug, (Fig. 2) that is ground to the same taper as the arbor, can be used to advantage for tapering the hole through the lap before it is turned and slotted. If in the operation of lapping, the hole becomes "bell-mouthed," that is, enlarged at the ends, this is caused by the introduction of sharp emery from time to time as the hole is being lapped. To obviate this, the lap should be cleaned of all loose emery and expanded by driving the arbor farther into it. The hole is then dry lapped by using only the emery that sticks or is charged in the lap. This process must be repeated occasionally until the proper size is obtained. If the operator is careful to see that the emery used is not too coarse, and the lap is kept expanded to fit the work at all times, the result will be a perfectly straight hole. It takes considerable practice before one can use a lap and keep it from getting lumpy. If this occurs, the high spots must be removed with a file, and the lap kept a close fit to the work. The work should always be finished to size with the lap dry and well fitted to it.

Fig. 4 shows an outside lap. The proportions of the lap proper should be the same as were given for inside laps. The same method of procedure described for inside work should also be followed, *viz.*, the lap must be freed from oil and loose emery from time to time as the work progresses. The pointed screw *C* keeps the lap from slipping out of place, and the adjusting screws *D* compress it to fit the work. A handle *E* should be used on all laps of large size, as it will be found much more convenient than a lathe dog, which some workmen use for moving the lap. Fig. 5 illustrates an outside lap and holder for small work, say less than ½ inch in diameter. Laps of this size are not provided with a handle, but are knurled on the outside as shown. F. P. CROSBY.

Chicago, Ill.

PNEUMATIC FLUE WELDER

An inexpensive flue-welding device that was designed to handle a large repair job that came in unexpectedly is shown in the accompanying illustration. It consists of a mandrel *A*, which is attached to a cast iron block *B*, and a pneumatic hammer (equipped with a swage), which is mounted on a lever *C*. As the illustration shows, this arm is fulcrumed to a bracket on the mandrel and is spring supported. The ends of the long pieces were first scarfed by lowering the back end of the tube until it was about six inches below the level of the mandrel. This gave a taper of approximately ¼ inch to the inch. After all the long pieces were scarfed, short pieces about 8 inches long were placed in the furnace and heated on one end so that they could be drawn to a feather edge. This was also done under the pneumatic hammer. After all the flues were scarfed and the short ends made ready for welding, the horse upon which the outer ends of the flues had rested, was raised to bring the work level with the mandrel. All short pieces were then put on the flues while hot so they would shrink tightly in place, thus insuring a good clean weld by preventing any dirt from getting between the surfaces to be welded. After all flues were treated in this way the furnace was cleaned, and the welding done at a speed which would make many of the costly flue-welding machines hustle to keep up with. T. O. MARTIN.

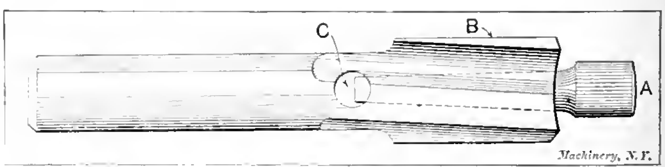


Inexpensive Tool for Flue Welding

Jackson, Tenn.

COUNTERBORES WITH REMOVABLE PILOTS

By making a counterbore with a removable taper-shank pilot the value and efficiency of the tool is increased fully 100 per cent. Once in a great while a toolmaker is found who makes them this way, but it is not the general practice. The illustration shows very plainly the design we use, excepting for very small sizes. A hole drilled at right angles to, and at the end of the taper, makes the removal of the pilot easy by inserting a drift. Standard taper pin reamers are generally used for reaming the pilot seats, thereby making the different pilots interchangeable within certain limits.



Counterbore equipped with Removable Interchangeable Pilot

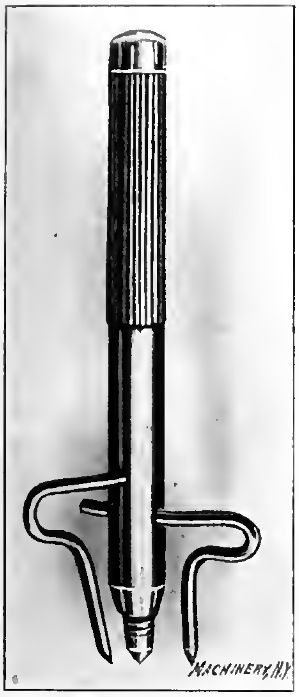
When the matter is carefully considered it is easily seen that a great combination of sizes can be made with but a few counterbores and pilots. Then again, if a pilot breaks when being used (which very often happens with the solid variety), it is but a moment's work to remove the broken part

and replace it with a new one. Last, but not least, is the convenience offered, when sharpening on a grinder, by removing the pilot. The counterbore may be held in a taper collet, if it has a taper shank, or if straight, in a simple form of chuck, fitted to the spindle of the grinder and made straight inside to fit the shank of the tool. The extra cost of the taper hole in the body and turning the pilot, is very slight when compared with the usefulness and long life of counterbores made in this way. A. DANE.

Buffalo, N. Y.

SPACING AND OUTLINING PRICK-PUNCH

By the use of the prick-punch shown in the accompanying illustration, the centers for holes to be drilled within any outline can be located, no matter what the shape, without making extra lines for guiding the point of the punch. For example, if the central part of a die is to be drilled out with, say, a 1/4-inch drill, the drill spacer on the punch is set to 1/4 inch and the guide point to 1/8 inch full; then no matter what shape is followed the centers will be 1/4 inch apart, and 1/8 inch from the line, or a distance equal to the radii of the holes to be drilled. This punch, which is 3 1/2 inches long, is made of 5/16-inch drill rod. The end is drilled and tapped for a threaded center point made from No. 12 drill rod. Care should be taken to see that the threaded end bears against the bottom of the hole so that the shock of the hammer blow will come on the end of the pin and not on the threads, as would be the case if the point were not screwed home. The thread that is exposed is flattened on opposite sides so that the point can be tightened or removed with a pair of pliers or a small wrench. Several points can be made at once by threading a piece of drill rod and pointing and cutting off pieces to the required length while holding the rod in a chuck. These points should be hardened all over and drawn to a light straw color. Both the spacing and the guide points are made of No. 42 drill rod; they are hardened in oil and given a spring temper. These points slide through the body and are adjusted to any length desired. They are held in place by a small screw which is tapped through half of the punch body. The bow or crook in the wires is to give them sufficient spring to adjust themselves. This is a laying-out tool, and is not intended for heavy work. For large drilling, it should be followed by a heavy punch to deepen the marks. WILLIAM A. PAINTER.



Prick-punch with Spacing and Guide Points

Pittsburg, Pa.

INSIDE CALIPER WITH INDICATOR ATTACHMENT

An ordinary 6-inch inside caliper that has been changed somewhat in form to adapt it to precision work, is shown in Fig. 1. One of the legs of the caliper was hammered or upset to make it thick enough to be slotted for an indicator arm, and the other side was cut off to the correct length. This indicator or registering arm is 3 1/2 inches long, and it has a travel of one inch at the point. It is 1/32 inch thick, and the graduated blade (shown more clearly in Fig. 2) is of the same thickness. The latter is recessed in the caliper leg and is fastened with two rivets. A travel of 0.025 inch on the caliper end is equivalent to 1/2 inch travel on the graduated leg, the pivot or axis multiplying twenty times. The working point *A*, Fig. 2, is made of drill rod and is hardened and rounded on the end. The smallest diameter of the point is 0.050 inch and it projects about 0.065 inch when pushed out against its shoulder. Normally this working point is held against its shoulder by a flat spring *B*. In use, the caliper is adjusted until the pointer stands at zero or at the center of the graduation. As shown, the limit of travel is 0.025 inch in either direction which is sufficient for ordinary work. The caliper is set to the required size, for close fits, with a micrometer, and allowance is then made from the indicator. This tool is especially useful when boring, to test the truth or varations of the work or in making an allowance for driving or running fits. The attachment is, so far as I know, original, as I have never seen anything like it in use, or in catalogues. WILLIAM A. PAINTER.

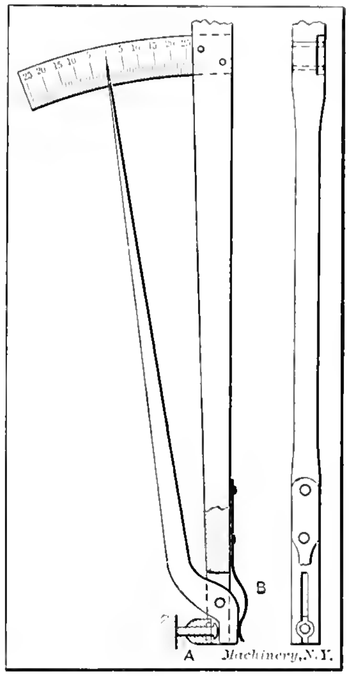

Fig. 2. Detail of the Inside Caliper Indicator Attachment

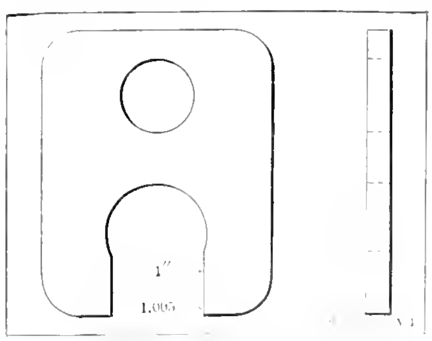
Pittsburg, Pa.

SNAP-GAGE WITH TAPER TO ALLOW FOR FINISH

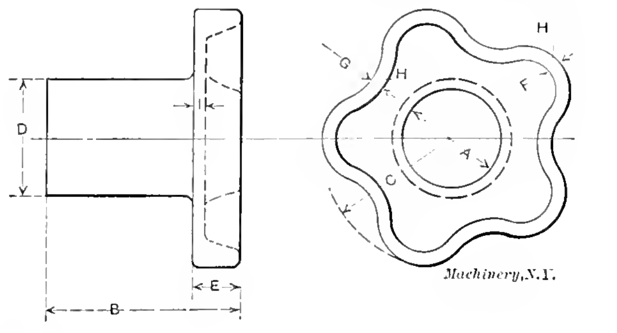
A number of armature shafts had to be finished in the lathe after being first roughed out in a screw machine, and micrometers were being used for measuring them; but there were not as many micrometers available as there were men on the job. Ring-gages were also used for the different sizes of shafts, but the men got along much better when using the micrometers, as they had to allow for finishing with emery cloth, and they could make this allowance much easier with micrometers than with the ring-gages. A lot of snap-gages were then made, which helped us a great deal. They were just like a regular snap-gage, except, instead of grinding the jaws straight all the way, they were ground straight and then re-ground 0.005 inch taper on one side, as indicated in the accompanying illustration, back within a short distance of the end. This left a short part of the gage jaw straight and the rest taper. The men using this style of gage soon became accustomed to it, and the allowances for filing and polishing were easily made. H. D. S.



Snap Gage with Tapered Jaw to allow for Finish

STAR HAND-WHEELS FOR JIGS

An excellent design of hand-wheel for use on jigs, etc., is shown in the accompanying illustration. The dimensions for five different sizes of these hand-wheels are given in the table beneath the engraving. After five years' experience, I have found that the particular style illustrated is well adapted to



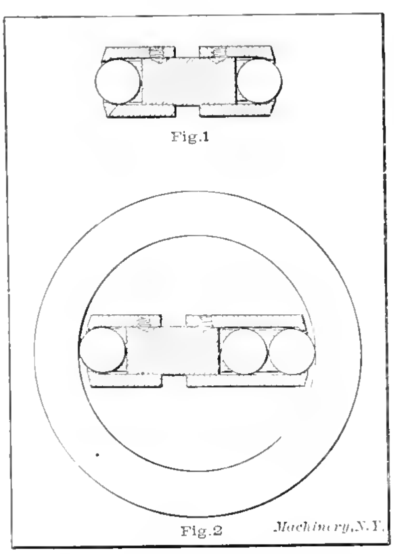
A	B	C	D	E	F	G	H	I
3/4	1 3/4	1	1	3/8	3/16	5/16	1/8	1/8
1	1 7/8	1 1/4	1 1/8	7/16	5/16	7/16	1/8	1/8
1 1/8	2	1 1/2	1 3/8	1/2	3/8	9/16	3/16	3/16
1 1/4	2 1/8	2	1 5/8	9/16	1/2	11/16	3/16	3/16
1 3/8	2 1/4	2 1/2	1 3/4	5/8	5/8	7/8	3/16	1/4

all-around jig use. By having the castings solid, they may be tapped out for any size thread and used in place of nuts, or a plain hole may be drilled and the castings pinned to round stock. The long stem gives a good length of thread for wear and brings the hand-hold far enough from the jig to prevent the fingers and knuckles from striking it. The star design gives a good grip for the fingers, and, as the top is hollowed out, the palm of the hand forms a suction, thus giving a stronger hold. This type of wheel is also easy on the operator's hands, and it is cheaper to produce in quantities, and more powerful than knurled nuts, pins, thumb-screws, etc. This wheel adds to the appearance of a jig and it can be operated very fast.

JIG AND TOOL DESIGNER.

AN INEXPENSIVE SET OF GAGES

As our manager could not be persuaded that a set of gages would be a profitable investment, I decided to make a set; but this did not appear, at first, like an easy job, as there was only a pair of one-inch micrometers to measure with. However, a highly satisfactory set of inside and outside gages, varying by 1/2 inch, was made. The inside gages have hardened ends, which may be replaced at any time at a cost of only a few cents.



Figs. 1 and 2. Inside Gages made by using Bicycle Balls at the Ends

Cast iron rings for the outside gages were first roughed out to within 1/32 inch of their finished size. To make a two-inch inside gage, a piece of half-inch round, cold rolled steel was first accurately finished to a length of exactly one inch. Two half-inch bushings, 3/4 inch long, were then turned on the screw machine and reamed part way through, a shoulder being left at one end to retain the half-inch balls which were placed in the bushings, as shown in Fig. 1.

Bicycle balls were used, and when tested they were found to be within 0.0001 inch of being accurate; therefore I was satisfied that the 2-inch gage was all right. In order to make sure that the balls came up tight against the end of the rod, set-screws were put in the bushings and the rods spotted so that the point of the screw would draw the bushing and with it the ball back against the rod. When this inside gage was finished the outside gage was bored to fit it. To make the 2 1/2-inch gage, one of the bushings from the 2-inch size was removed, and replaced with one a half inch longer, as shown in Fig. 2. In this longer bushing, two balls were placed, thus making it 2 1/2 inches in length. It was then used for turning the 2 1/2-inch outside gage. The one-ball bushing was then replaced and a drop of solder put on the set-screw to prevent its being tampered with. The 2 1/2-inch outside gage was next used as a master, and a rod was dressed down until with one ball at each end it fitted the 2 1/2-inch gage. This process was continued until a number of gages of different sizes had been made.

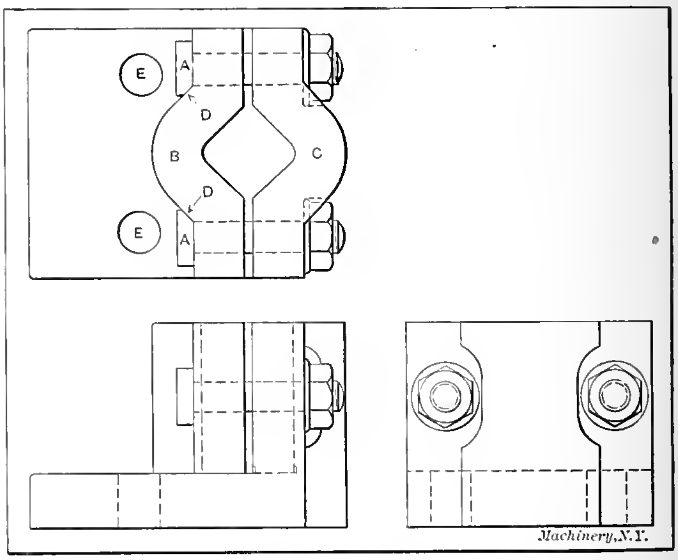
S. A. McDONALD.

Candiac, Canada.

[If gages produced by the foregoing method are to be accurate, it will, of course, be necessary to have a good fit between the ball retaining sleeves and the central plug, and also between the balls and the sleeves, so that the tightening of the set-screws will not cause the centers of the balls to be moved out of line.—EDITOR.]

FIXTURE FOR PUNCH-HOLDERS

A fixture designed for holding punch-holders on the face-plate, surface grinder, or miller, is illustrated herewith. In most shops the die-maker is compelled to use a substitute makeshift affair, which is merely a solid hub and flange with a hole bored and a set-screw in the side. The objectionable



Fixture for Holding Punch-holders of Various Sizes without marring them

features of this "job-spoiler" are legion, the worst one perhaps being the abominable set-screw (or rather the point of it) which, when tightened, not only throws the work over on an angle, but, when set up hard (as is necessary when taking heavy cuts on the miller), leaves unsightly marks in the soft shank.

The design submitted not only eliminates this annoyance, but it is preferable in every way. Obviously, it will take shanks a trifle over or under size as well as all standard sizes in use, the advantage of which should be apparent to any one caring to utilize the space that a half dozen or more of the other kind take up. As the illustration shows, the design of the fixture is very simple. The bolts *A* are a drive fit in casting *B* and a sliding fit in casting *C*. These bolts should have the under edge of the head cut away on one side, as shown at *D*, so they will lock against the side of the casting and not turn when the nuts are set up. The fixture is fastened down in the usual way by T-bolts, holes *E* being for that purpose. If the fixture is to be used for very large shanks, these holes should be placed far enough back so as to allow room for sliding jaw *B*. When so made, the fixture is excellent for grinding sub-press tools, the plunger being removed and held in the same manner as the punch shank. This fix-

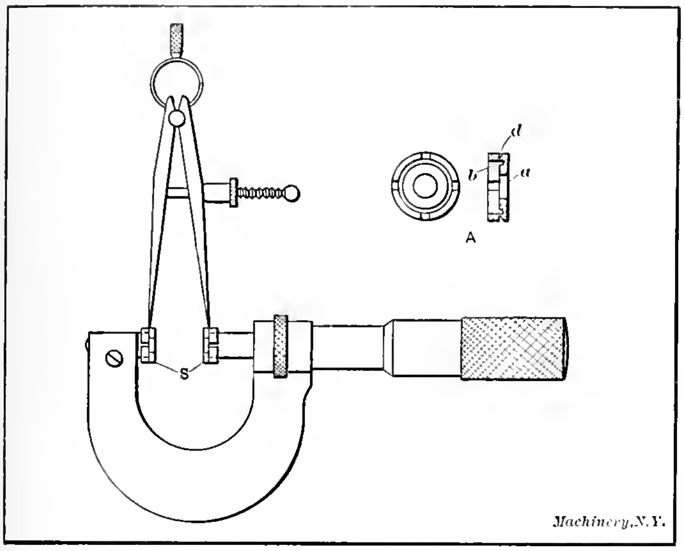
ture also makes an excellent inside angle-plate, it only being necessary to remove the sliding jaw.

The more common way, perhaps, of making tools of this class is to have the projecting base turn the other way; but the advantage in having the foot turn in under the work, as shown, is that when used on a faceplate, it does not overhang so much, thus doing away with much counterbalancing and allowing a smaller faceplate to be used.

Frankford, Pa. ROY PLAISTED.

MICROMETER ATTACHMENTS FOR SETTING DIVIDERS

One is sometimes confronted with the task of setting the dividers or trammels accurately when laying out work, such as jigs, dies, etc. If a vernier with facilities for setting the dividers is not available, the attachments shown applied to a micrometer in the accompanying engraving will be found very useful, as the dividers can be set with them quite as accurately as when the vernier is used. This is, of course, assuming that the attachments are made accurately.



The Way the Micrometer Attachments are used for Setting Dividers

As the illustration shows, these attachments consist of two sleeves *S*, one of which is fitted to the anvil of the micrometer and the other to the end of the spindle. An enlarged view of one of these sleeves is shown at *A*. A central hole *a* is drilled in the center of the sleeve so that it will be easy to see whether or not it is in contact with the anvil or spindle. Either four or six slots are sawed in the flange to insure a snug fit, and the corner is cut away, as at *b*, so that the inner surface will have a good bearing against the spindle or anvil. A groove *d* is cut in the outside, exactly in line with the inner surface, and into this groove the divider points are inserted when they are being set.

These sleeves are made in the following manner: A piece of tool steel about 1/16 inch larger in diameter than the anvil or spindle of the micrometer, is caught in the chuck and turned true on the outside, after which a central hole is drilled deep enough for the two sleeves. The end of the piece is then bored to a snug fit for the micrometer anvil or spindle, and a recess *b* is turned as shown in the sectional view at *A*. The first sleeve is then cut off, after which the second one is machined in the same way. The cutting of the V-groove *d* is the next and the most important operation. In order to cut this groove exactly in line with the inner surface of the sleeve, a piece is first turned to the same diameter as the anvil or spindle. After the end of this piece is faced square, the lathe carriage and turning tool are left undisturbed. The sleeve is then inserted over the end of the turned rod. By the use of a flat center in the tailstock, this sleeve is held firmly against the squared end of the rod while the V-groove is turned, with the tool set just as it was after the finishing cut was taken over the end of the rod. A depth of about 0.005 inch is sufficient for this groove. Slots are next cut in the sleeves in four or six places so that they may be sprung into place. The sleeves are then hardened and drawn to a blue color.

When turning the groove, and also when turning and facing the rod on which the sleeve is held, care should be taken to see that there is no lateral motion in the spindle of the lathe, as otherwise the tailstock center, when it is brought up against the work, will cause the groove to be out of alignment with the surface on the inside of the sleeve. L. E. KRAMER.

Newark, N. J.

SOLDERS FOR VARIOUS METALS

Soldering is divided into two classes, namely, hard and soft soldering. Ordinarily soldering with a heated copper bit employs "soft solders"—alloys of tin, lead, etc., which melt at comparatively low heats. The use of the blowpipe makes possible the employment of "hard solders" which are alloys of silver, copper, zinc, etc., and melt at a very much higher temperature than the soft solders. The hard soldering of copper, iron, etc., is generally known as brazing, and the solder as spelter. It must be borne in mind that both soft and hard solders deteriorate with age, if kept for a long time in a damp atmosphere. For electrical work, ingredients such as mixtures of vaseline, rosin, glycerine and chloride of zinc are used as non-corrosive fluxes. The accompanying table gives the composition of both soft and hard solders that are suitable for various metals. A. EYLES.

Manchester, Eng.

MACHINE CATALOGUE COVERS

A common fault with machine catalogues is that while they state just how many accessories are provided, and that this part and that are casehardened, and the other is bronze-bushed, etc., they omit to say how the machines operate and how much work of a given kind they will turn out per hour. Further, some of them do not bear on the cover the maker's name, or even that of the machine described.

How shall I index a catalogue "The Truth about Thingummies" or "The People's Verdict?" ROBERT GRIMSHAW.

Dresden, Germany.

Manufacturers interested in the International Exposition to be held at Turin, Italy, in 1911 can obtain further information relating to the exposition from the Italian Chamber of Commerce of New York, which has been appointed as the local committee for the United States.

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

TINNING STEEL PANS

G. S.—I have about 1,000 steel pans 12 inches long, 8 inches wide, 2 inches high, 1/64 inch thick, to tin. What is the easiest and cheapest method of obtaining a heavy tin coating? The pans are unpolished.

A.—The question is referred to our readers for answer. It is desired that the responses refer to methods of tinning that are practicable to follow in a plant not equipped with tin dipping facilities.

PROPORTIONS OF AUTOMOBILE PISTON RINGS

H. B.—What are the proper proportions of automobile cylinder piston rings? How do they compare with the proportions of gas-engine rings used by the leading gas-engine builders? How much smaller than the bore should a gas-engine piston be turned to secure the best results? We have found that the accepted proportions for steam engine cylinder rings make rings too stiff for gas-engine use.

A.—These questions are submitted to the readers for discussion.

FINISH ON IRON CASTINGS

E. S. S.—1. I have a few castings that I wish to paint and secure a glossy enamel finish. What is the best method to obtain this finish? Could it be done without baking on? I want a finish that will not crack and lose its gloss in a few weeks. 2. Why do gray or streaked spots work through the oxidized finish on malleable iron castings? Is there any way to prevent it? The spots do not show on steel. Is it the fault of poor oxidizing?

A.—These questions are referred to our readers for answer.

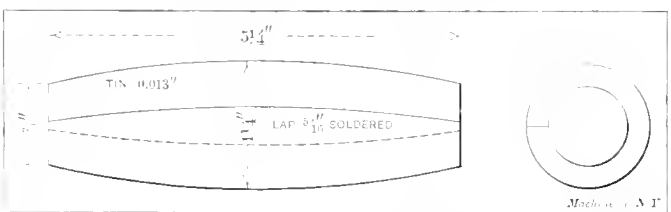
HOW TO BEND TAPERED BRASS TUBES

E. P. D.—I would like to know the best method of bending tapered tubes for automobile horns. The tubes are 9 inches long, 1¼ inch and ¾ inch diameter at the large and small ends, respectively. The tubes must be bent U-shape, the radius of the inside curve being 1½ inch. The metal is brass, 0.025 inch thick.

A.—Thin brass tubes may be bent without crushing or wrinkling by first filling them with melted rosin or melted sulphur. The bending should be done over a hardwood former shaped to the arc of the curve desired, but as a commercial process for bending tubes in large quantities this method is too slow. Descriptions of improved methods of bending tapered brass tubes are invited from our readers.

HOW ARE COFFIN HANDLES MADE?

R. S. B.—How is the coffin handle shown in the sketch made? It is of tin 0.013 inch thick, with seam lapped about



5/16, and soldered. The work shows very slight evidence of wrinkling, and if made in the press is a very good job.

A.—The question is submitted to the readers of MACHINERY for reply. A contribution describing the tools used for making this or similar pieces will be acceptable.

TO OBTAIN THE HEIGHT OF A SEGMENT WHEN THE AREA IS GIVEN

J. W. H.—How is the height of a segment found that contains one-third the area of a circle 4 inches diameter?

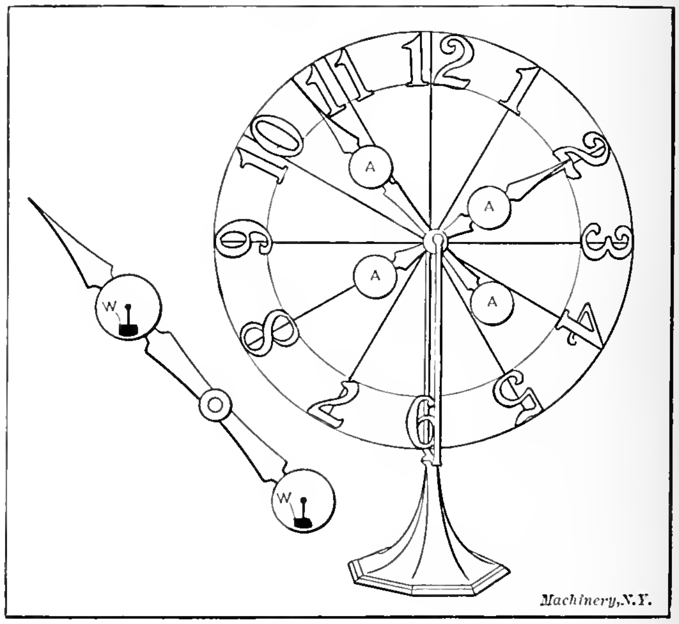
A.—Although the calculation of the area of a segment is comparatively simple, using the approximate formula

$$A = \frac{4h^2}{3}\sqrt{\frac{D}{h} - 0.608}$$

the converse proposition is more difficult, as there is no simple formula for finding the height or the chord of a segment when the area and diameter of the circle are given. Recourse must be made to tables of segment areas found in engineers' hand-books. The procedure in this case is as follows: First find the area of a segment that contains one-third the area of a circle having a diameter 1 inch. $1^2 \times 0.7854 = 0.7854$ square inch; $0.7854 \times 1/3 = 0.2618$ square inch, area of segment. Reference to a table of segments shows the height of the middle ordinate to be 0.3675 inch. The height of the corresponding segment of a circle 4 inches diameter is $0.3675 \times 44 = 1.5000$ inch, the required result. This is one of the several problems involving areas of segments, lengths of elliptic arcs, areas of zones, etc., that can be solved by ordinary mathematical processes only by reference to tables.

A CLOCK WITHOUT WORKS?

O. A. A.—What appears to be a most wonderful clock has recently come under my observation, and I would like to have the principle of its action explained. This clock is apparently without works, but it records the time accurately, and when the hands, which are easily moved in either direction, are



spun on their axes, they always come back to the correct position. The dial may also be whirled around, but even though the hands and the dial be set in motion simultaneously, they always come back to their correct relative positions.

A.—This clock is an interesting mechanism, but we believe that it is comparatively simple in its construction. The idea has been used for years in the construction of jewelers' clocks and other clocks where it is desired to attract attention. Usually the hands are made with large hubs in which the clock movements are located, and the hands are driven by the reaction of these movements against a counterweight within the hub. In the case of the clock referred to by our correspondent (see accompanying illustration), there are probably two movements for each hand, which are located in the cylindrical parts *A* and cause the rotation of the hand by reacting against counterweights. These counterweights *W* hang with their centers of gravity below the center of the clock mechanism, and as the hands are perfectly balanced, the action of the works is transmitted through the reaction of the counterweight to the hands, causing them to assume the hour and minute positions. Probably the action of the hands will be more easily understood if we assume that the weights *W* are being continually swung from their vertical position, to the right, thus shifting the hand's center of gravity and causing it to revolve. The two movements in each hand run in unison, the set for the hour hand being geared to revolve once in twelve hours while the minute hand revolves once in an hour. As this construction makes connection with the fixed support unnecessary, the hands, when spun around on their axes, will always come back to the correct position which is determined by the relative positions of the counterweights to the hands in which they are suspended. The dial is easily

made to finally stop in the correct position after it has been spun around, by adding a little additional weight to the bottom, thus throwing it out of balance.

MUTILATION OF U. S. COINS

W. H.—In the December, 1906, number of MACHINERY W. L. McL. described the making of a pretty stick-pin by filing out the profile of the head on a dime. I would like to know if the law regarding the mutilation of coins would apply to this case. If I make a pin in this way am I liable to prosecution?

A.—Technically the making of a stick-pin from a United States coin in the manner described is a violation of section 5459 of the revised statutes. Any defacement or mutilation of gold and silver coins short of complete destruction of the coin or change in shape which will make it impossible for it to circulate as money is, in the opinion of the chief law officer of the treasury department, illegal. It is not likely that an individual who merely makes an ornament for himself or a friend in the manner described would be prosecuted, especially if it were gold-plated afterwards, but anyone *manufacturing* ornaments from mutilated coins probably would get into serious trouble. The chief of the Secret Service informs us that jewelers who make a practice of transforming gold and silver coins into articles of jewelry usually fit a band of like metal around the coin and make any necessary attachments to that band rather than to the coin itself. In this way the coin is preserved in perfect condition, and there is not even a technical violation of the statute.

TO OBTAIN AN ANGLE BY COMBINING THE FEEDS OF A BORING MILL

H. N. K.—To what angle must I set a boring mill head to turn a taper at an angle of 45 degrees with the base when using both feeds in combination. The cross-feed screw is four threads per inch or ¼ inch feed for one turn of the handle, and the down feed is 3/16 inch for one turn of the handle. The pinions on the feed shafts have the same number of

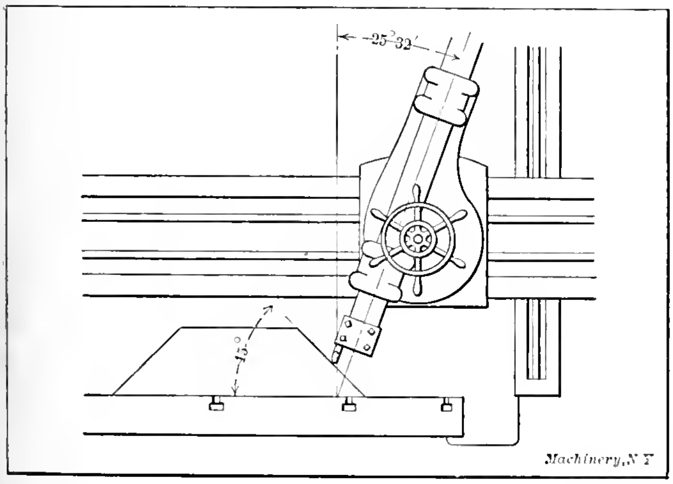


Fig. 1

teeth, and the ratio of feeds, therefore, is as 3/16 to 1/4. I would like to know if there is a method, table or formula for obtaining any desired angle with combined feeds.

A.—The angle can be found graphically in the following construction Fig. 2: Draw the horizontal line AB to represent the boring mill table and the line CD at an angle of 45 degrees, representing the angle to be produced. Now we require to strike two arcs with radii in the proportion of 3/16 to 1/4. To secure the desired accuracy, it is desirable to use longer radii, and we multiply 3/16 and 1/4 by, say, 32, giving as results 6 and 8 inches. With the dividers set at 8 inches, strike an arc from D as a center intersecting AB at E. With E as a center and with a radius of 6 inches, strike another arc intersecting CD at F. Then FEG, the angle made with the vertical EG, is the required angle to which the head should be set. The angle measured with a protractor is 25½ degrees. The method of solving when DEF is less than 90 degrees is:

$$\sin EFD = \frac{H_f \times \sin EDF}{V_f}$$

in which

H_f = horizontal feed,
V_f = vertical feed,
EDF = angle required on work,
FEG = angle to which the head must be set to produce angle EDF,

$$\sin EFD = \frac{1/4 \times 0.7071}{3/16} = 0.9428.$$

$$\text{Angle } FEG = (EFD + EDF) - 90$$

The angle whose sine is 0.9428 is found in a table of sines to be 70 degrees 32 minutes. Angle EDF = 45 degrees. Then

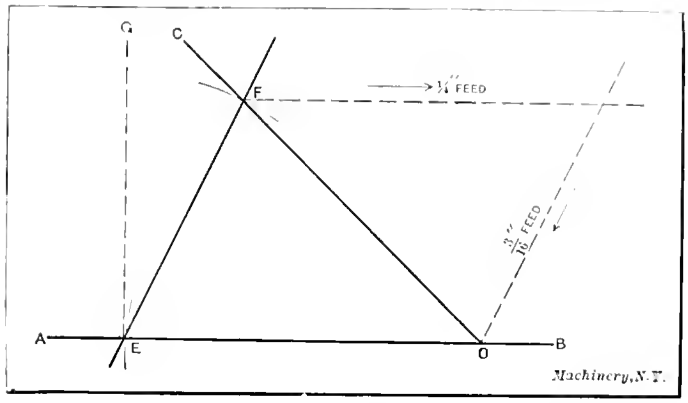

Fig. 2

angle GEF = (70 degrees 32 minutes + 45 degrees) — 90 degrees = 25 degrees 32 minutes. The same methods may be used for finding the angles produced by combined vertical and horizontal planer feeds.

* * *

FORMULAS FOR CALCULATING A FRICTION DISK BRAKE*

JOHN WILL†

In the following article will be given a set of formulas for calculations relating to the well-known mechanical brake used on electric hoists. A diagrammatical sketch of such a brake is shown in Fig. 1. An example illustrating the use of the formulas given will also be worked out.

The object of the brake shown is to permit the lowering of the load at a constant speed with the power reversed, and the holding of the load suspended when the current in the motor is shut off. When the load is lowered it rotates, by means of the drum and gearing, the flange D against the ratchet disk H; the flange E is mounted as a nut on the screw A; the flange C is keyed to the shaft as shown. The pawl engaging with the ratchet disk does not permit it to rotate when the load is lowered. As the ratchet disk thus is stationary, the work of the motor and of the lowered load must equal the work absorbed by the friction surfaces in the brake. When hoisting, the motor rotates the flange D against the nut E so that then there is no pressure on the friction disks; the motor is thus free to hoist the load without any frictional resistance.

The amount of opening between the friction disks should be as small as possible, and the number of teeth in the ratchet disk as great as possible, consistent with required strength. In this way excessive pressure on the ratchet teeth, due to the sudden dropping of the load when the current in the motor is shut off after hoisting, may be avoided. The drop of the load, of course, is proportional to the opening between the friction disks, and the amount the pawl allows the ratchet disk to rotate before engaging a tooth and stopping it positively.

The action of the load and the motor on the brake may be explained by a simple illustration. In Fig. 2 the bar A is shown resting on two wedges B between the walls C. The load P is a constant pressure acting downward on the bar A. This pressure, however, is not great enough to overcome the frictional resistance between the wedges B and the walls C. If an additional downward pressure P_1 is put on the wedges, so that the combined pressures P and P_1 equal or exceed the frictional resistance, then the bar and the wedges will slide

* Answer to an inquiry in the How and Why department, January, 1905.
† Address: 180 South 11th St., Newark, N. J.

downward as a whole. In the mechanical brake in Fig. 1 the load on the hook may be considered as the pressure P in Fig. 2. The pressure P_1 may be assumed to be the effort exerted by the motor in order to lower the load.

In the formulas following, the notation below will be used:

E = energy absorbed by friction disks in foot-pounds per minute,
E_1 = energy of the lowered load in foot-pounds,
E_2 = energy of the motor in foot-pounds,
e_1 = total efficiency of mechanism between load and flange D, Fig. 1,
e_2 = total efficiency of the mechanism between the motor and flange C, Fig. 1.
T = torque in inch-pounds on pinion F,
r = mean radius of screw in inches,
r_1 = inside radius of friction disks in inches,
r_2 = outside radius of friction disks in inches,
n = number of friction surfaces,
N = number of revolutions per minute of flanges C and D,
A = area of each friction disk in square inches,
W = total pressure in pounds on friction disk,
f = coefficient of friction between the flanges and the friction disks,
P = lead of the screw in inches,
ϕ = angle of repose of screw in degrees,
α = helix angle of the thread of screw in degrees,
y = number of thermal units of heat conducted away per square inch of bearing surface per minute; y may be considered to be from 4 to 7, when the mechanism is exposed to a current of cold air and in intermittent service, and as equal to 0.75 to 1 in tolerably cool places with intermittent service.

When a sufficient number of quantities are known, energy absorbed by friction, the pressure on the disks and the lead P of the screw in the brake may be found by the following formulas:

$$E = E_1 e_1 + E_2 e_2 \tag{1}$$

$$E = 0.349\, n\, f\, W N \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2} \tag{2}$$

$$W = \frac{T}{r \tan(\alpha + \phi)} \tag{3}$$

$$P = 2\pi r \tan \alpha \tag{4}$$

$$y = \frac{E}{778 \times 2A} \tag{5}$$

[Formula (2) is based on the theoretical assumption that the mean radius at the end of which the resultant of the frictional forces may be considered as applied, equals

$$\frac{2}{3} \times \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$$

thus taking the radius to the center of gravity of the small trapezoids into which the annular ring may be supposed to be divided. Although this is correct both theoretically and practically when the brake is new and the pressure distributed uniformly over the entire surface, the disk wears faster on the outside edges than on the inside, resulting ultimately in greater pressures at the inner edge, and it has been found that a formula considering the mean radius as the arithmetical mean between the outside and inside radii gives better results for working conditions.—EDITOR.]

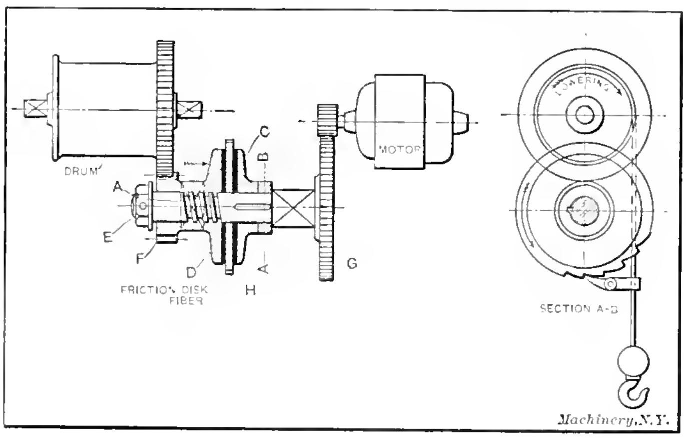

Fig. 1

Example:—Assume that we have the following data: At 230 volts and a speed of 1,000 revolutions per minute, 25 amperes are required for hoisting the load. At a speed of 1,500 revolutions per minute, 9 amperes are required for lowering the load. The motor efficiency is 80 per cent, the drum is 12 inches in diameter, the drum gear ratio is 1 to 7, and the motor gear ratio is 6 to 1. The efficiency of each set of gearing is 90 per cent. The outside radius of the friction disks is 7 inches, the inside radius 3 inches, and the mean radius of the screw, 1¼ inch. The number of friction disks is 2, as shown in Fig. 1, the number of revolutions of the friction disks is 1,500 ÷ 6 = 250, the coefficient of friction between the flanges and the friction disks is 0.07, and the angle of repose of the screw, 8 degrees 30 minutes. From this data we find that the maximum load of 2,200 pounds may be hoisted at a speed of 75 feet per minute and lowered at a speed of 112.5 feet per minute, as follows:

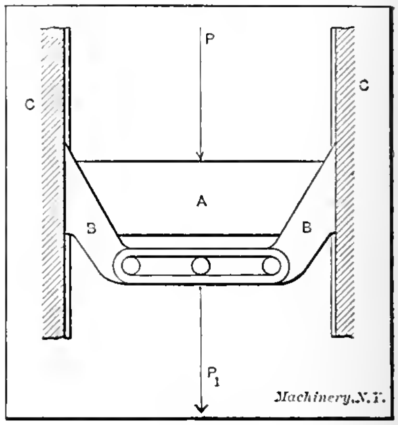

Fig. 2

$$\frac{1{,}000 \times 12 \times 3.14}{6 \times 7 \times 12} = 75 \text{ (hoisting speed)},$$

$$75 \times 1.5 = 112.5 \text{ (lowering speed)},$$

$$\frac{230 \times 25 \times 44.2 \times 80 \times 90 \times 90}{75 \times 100 \times 100 \times 100} = 2{,}200 \text{ pounds, nearly.}$$

We will now find the lead P of a screw which will give a lowering speed of 112.5 feet per minute with the given conditions.

$$E_1 e_1 = 2{,}200 \times 0.90 \times 112.5 = 222{,}750 \text{ foot-pounds.}$$

$$E_2 e_2 = 230 \times 9 \times 44.2 \times 0.90 \times 0.80 = 65{,}900 \text{ foot-pounds.}$$

From formula (1):

$$E = E_1 e_1 + E_2 e_2 = 222{,}750 + 65{,}900 = 288{,}650 \text{ foot-pounds.}$$

From formula (2):

$$W = \frac{E}{0.349\, n\, f N \dfrac{r_2^3 - r_1^3}{r_2^2 - r_1^2}} = \frac{288{,}650}{0.349 \times 2 \times 0.07 \times 250 \times 7.9} =$$

3,000, approximately.

From formula (3):

$$\tan(\alpha + \phi) = \frac{T}{Wr} = \frac{[(2{,}200 \times 6) \div 7] \times 0.90}{3{,}000 \times 1.25} = 0.453.$$

Hence, $\alpha + \phi = 24° \, 20'$, and $\alpha = 24° \, 20' - 8° \, 30' = 15° \, 50'$.

From formula (4):

$$P = 2 \times 3.14 \times 1.25 \times \tan 15° \, 50' = 2.23 \text{ inches.}$$

This gives a screw of practically 2¼-inch lead. If a double thread is used the pitch will be 1⅛ inch.

From formula (5):

$$y = \frac{288{,}650}{778 \times 2 \times 125.6} = 1.48,$$

which would be satisfactory when the brake is well exposed to the air.

The maximum allowable pressure per square inch on the friction disks should be limited to 200 pounds. In the example above we find that the pressure equals

$$\frac{W}{A} = \frac{3{,}000}{125.6} = 24 \text{ pounds per square inch, approximately.}$$

Don't start a piece of work until you have measured and examined the stock to see if it is correct for size and kind.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

MILWAUKEE PLAIN MILLING MACHINE

In the department of New Machinery and Tools in the August, 1908, issue of MACHINERY was described the No. 3B Milwaukee universal milling machine, made by the Kearney & Trecker Co., of Milwaukee, Wis. The same general lines of design followed in that machine have now been applied by the makers to their plain milling machine, which is here described and illustrated, with the changes permitted by the absence of the swivel carriage for the table. In connection with this plain design of machine, we are able to show a number of details of the very interesting driving and feed mechanism employed.

The main features of this line of machines are the geared feed and speed changes, the provision for continuous lubrication from an oil reservoir, and the permanent arrangements incorporated in the machine for supplying lard oil or other compound to the cutting edges of the mill. In connection with the first point, it will be remembered that the makers of this machine built it with geared drive only, their confidence in this construction being such that they have entirely abandoned the cone pulley, and do not employ it in any size or style of their products.

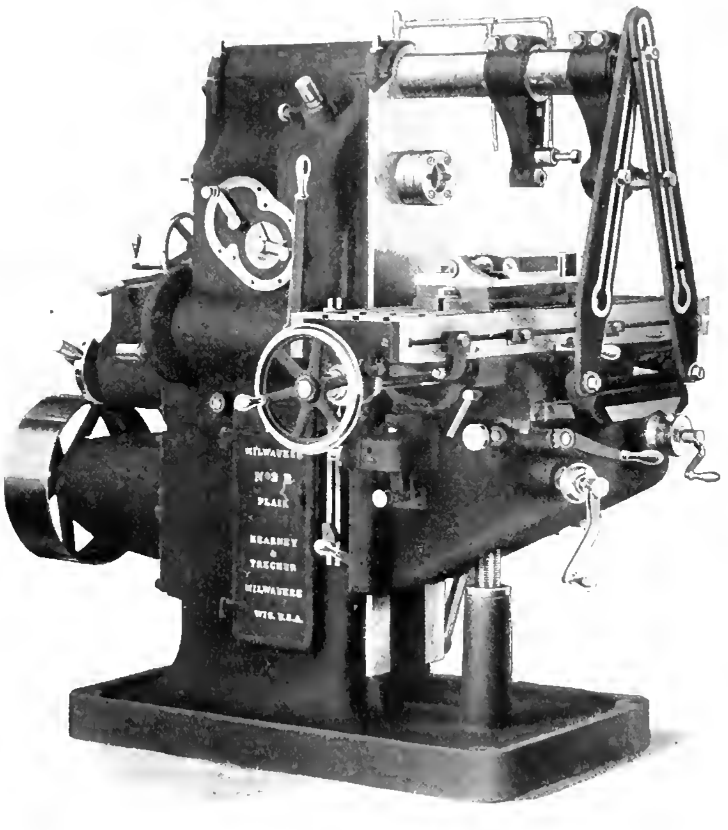

Fig. 1. Milwaukee No. 2B Plain Milling Machine, with Geared Drive and Feed

Structural Features

Rigidity in the framework is a fundamental requirement for an accurate and productive tool. In this machine the column is cast in one piece, with strong internal ribs. It has a box section, with as few and as small openings as possible, and it increases in depth as it extends downward toward the pan-shaped base. This latter is sufficiently high to leave room for heavy ribbing, which makes masonry and cement foundations unnecessary where the floor is strong enough to carry the load. The sliding surfaces for the knee extend clear to the top of the column around the spindle box, thus giving the needed additional metal at this point. The upward extension of the slide serves also as a convenient means of fastening the various attachments, which thus become practically an integral part of the machine, and capable of very severe service.

The knee is of the enclosed box form, with as few openings as possible, none being permitted in the upper surface. This is important as it obviates all danger of the closing together of the surfaces under the strain of clamping the saddle. It also obviates the necessity of a sliding cover to keep chips out of the knee mechanism. A long bearing is provided for the knee on the column, extending up above the saddle bearing.

The over-arm is a solid steel bar, located with great accuracy parallel to the spindle. The arbor supports are firmly clamped to this. The arm braces have been especially designed with regard to convenience in handling, there being no single piece too heavy for one man to adjust with ease. Throughout the structural design metal has been added with the single purpose of securing strength and ridigity; it has not been placed here and there in a haphazard way, merely for the purpose of getting a high total weight for selling purposes.

Spindle Driving Mechanism

The arrangement of the drive is best shown in the vertical section through the column, Fig. 2, in connection with the small details in Figs. 3 and 5. The driving pulley *A* runs at constant speed in one direction, there being no necessity for cone pulleys or a reverse clutch in the countershaft. The shaft on which it is mounted carries an integral pinion meshing with gear *B*, which is loose on the shaft above it. The hub of this gear carries a steel jaw clutch engaging a similar clutch on the face of gear *C*, which is keyed to the shaft. *B* is shifted longitudinally to engage or disengage the clutch connection by means of the vertical hand lever shown on the left side of the column in Fig. 1. Gear *C* meshes with *D*, which, in turn, may be connected with constant speed shaft *E*, either directly or through the medium of idler gears *F*. The shifting of pinion *G* by handle *H* governs this connection, and thus reverses the spindle.

In transmitting the motion from shaft *E* to *J*, six changes of speed are provided for by an interesting modification of the tumbler gear type of speed change mechanism. In this case a compound tumbler gear *K* having three steps, is used as shown. This meshes with the keyed sliding gear *L* on shaft *E*, and is carried by the swinging frame *M*. Either one of the three steps of gear *K* can be made to engage with either of gears *N* or *O* on shaft *J*, thus giving the six changes of speed.

The solid support given to the sliding gear *K* should be noted. It revolves on a hardened steel stud, firmly fastened in the steel frame. This latter is securely supported on both sides of the tumbler on one side by shaft *E* which is, for this purpose, made much larger than would otherwise be required; and on the other side by the teeth of the long pinion *P*. This latter is rocked by handle *Q* to raise or lower the tumblers into proper position to mesh with the gear *N* or *O*. The shifting of the tumbler lengthwise is effected by the lower swinging handle on the front of the frame in Fig. 1, operating through the segmental gear and rack shown at *R* in Fig. 4.

Three additional changes of speed are effected by sliding gear *S*, which may be shifted to the rear so that its small diameter engages with gear *O*, or it may be set in a central position where its larger diameter, as shown in Fig. 2, engages gear *N* on shaft *J*. Moving it still further to the right clutches it, by means of the driving pin shown, to the large gear *T*, which runs loosely on the spindle, driven by a pinion on shaft *J*. Eighteen changes of speed are thus provided for through a mechanism which is strong and direct.

The feed change mechanism is identical in principle with that provided for the spindle changes. Twelve rates of feed are provided for, controlled by convenient levers and indicated by an indexing plate. The feed is driven directly from the shaft on which gear *D* is mounted, so that it is driven at a

constant rate, giving definite feeds in inches per minute. This construction has become standard for efficient milling machine design, since it permits all the feed changes to be practically applicable to any speed, and thus allows a greater number of effective changes for the whole range of speeds, from that required for small mills on soft metals, down to the heaviest work the machine is capable of.

In any geared feed and speed mechanism the efficiency and durability of the gearing, bearings, etc., is largely dependent on the care with which they are lubricated. In this machine a reservoir of machine oil is provided from which a stream is kept constantly flowing whenever the driving pulley is in motion, over all the gears and into all the journals. These journals are provided with oil grooves open at the ends to permit a constant and rapid flow, thus keeping them constantly cool and flushed of foreign matter. This point in the design of these machines is so well known that it is not necessary to expatiate on it further.

For holding the spindle in inserting or removing cutters, etc., or for using fly cutters, a stop is provided which engages the teeth of large gear T. This engagement extends over several of the teeth, which it fits accurately. It thus holds the spindle without play and without danger of breakage. For turning the spindle through small fractions of a revolution, a handwheel is provided at the rear end of shaft J as shown. This makes possible more delicate adjustment than can be obtained even on the belt-driven machine. A knock-out for arbors and taper shank mills is permanently mounted in the machine. Large face mills are driven by a key and keyway set into the front face of the spindle. They are clamped in place by four screws passing through the mill into the spindle flange. This arrangement is preferable to the thread usually provided for the purpose, since this thread, if too fine, permits the cutters to jam in place under the strain of a heavy cut, and makes it difficult to remove them; while, if the lead be made steeper, there is a constant tendency to work loose.

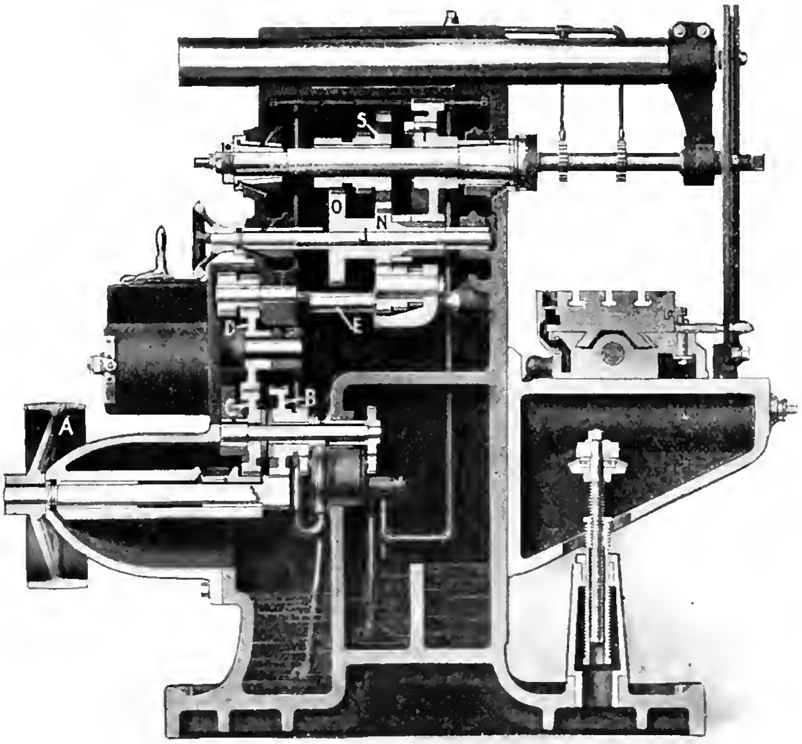

Fig 2. Section through Column, showing Spindle Drive

Details of the Feed Control

Another detail of the machine is seen in Fig. 4, which shows a vertical section through the knee, exposing the mechanism by which the table cross and vertical feeds are interlocked with each other so that no two can be engaged simultaneously. The telescopic shaft from the feed box leads to gear U, from which, through the intermediate gearing and clutch shown, the motion is transmitted to gear V. The clutch W serves to reverse the feed for movements in all directions.

Gear V gives movement to any one of three shafts, X, Y and Z. X is for the table feed, Y for the cross-feed and Z for the vertical movement. As shown in the engraving, with lever A_1 in the central position, clutch X is engaged, and consequently the table feed gearing is in motion. Whether the feed is in actual operation or not depends, of course, on whether the feed handle at the front of the table is thrown in. Now in order to have the plunger of lever A_1 enter the hole provided for it in the central position, it must pass through a hole in lever B_1 which must consequently also be in its central position. B_1 controls the clutches at Y and Z, respectively, which thus are always disengaged whenever the clutch at X is thrown in.

Lever B_1 and the clutches with which it is connected are operated by a lever at the front of the saddle, which thus serves to throw in or out the vertical and cross movements, respectively. Since these movements are locked, as explained, when the table feed is engaged, it is necessary before using either of them to disengage that feed. This is done by throwing lever A_1 to either one side or the other (depending on whether cross or vertical movement is desired) and locking it in this position. Lever B_1 and the clutches with which it is engaged are thus free to swing from the central or off position to one side or the other under the influence of the lever at the front of the saddle. It is thus possible to use this lever for throwing in or out either the vertical or the cross feed, depending on which side of the center lever A_1 is located.

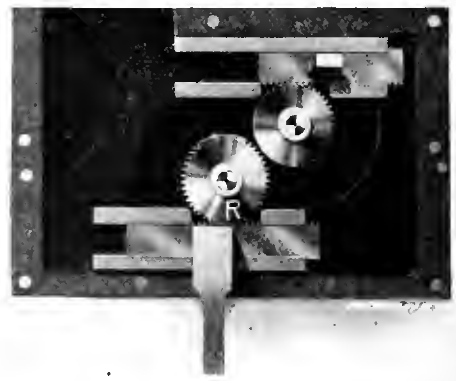

Fig. 3. Spindle Change Gear Controlling Mechanism

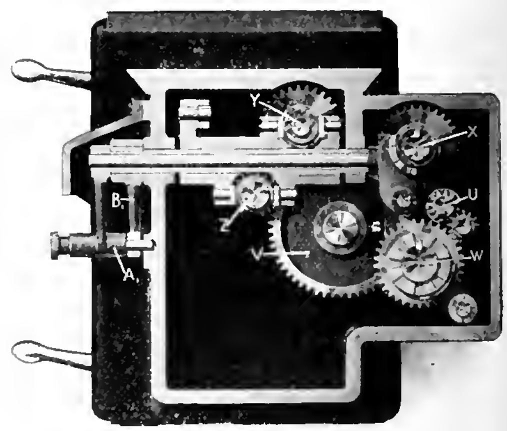

Fig. 4. Interlocking Feed Control in Knee

Fig. 2 shows the two sets of oil reservoirs and pumps supplied. The pump in the double front compartment forces a constant supply of cooling fluid over the cutters through piping regularly provided. Chip channels are formed in the table and a jointed pipe drain connection leads the lubricant back into the settling chamber again, so that a constant stream is provided to cool the cutters. This gives better finish, allows heavier cuts, and prolongs the life of the cutting edges of the tools. This useful provision is regularly furnished and does not have to be specially specified.

General Design

It will be seen that these machines are designed with the idea of providing for ample spindle power, for rigidity suffi-

cient to permit the highest output of any cutter that may be used, and for the accuracy required for interchangeable manufacturing. The convenience of the changes also adds highly to the productive capacity. Besides the universal type previously illustrated and the plain machine here described, the builders furnish this tool in a simplified form which they call their manufacturing machine. This retains the same features of feed and speed change and the same general construction throughout, but has a simpler feed mechanism in the knee and saddle, the power feed being applied only to the longitudinal table movement.

The bracket on which the constant speed driving pulley *A* in Fig. 2 is mounted is interchangeable with two other styles, so that any machine may be fitted up as required by the customer. One of these alternative forms gives a right angle constant speed pulley drive, for use where the line shaft and floor arrangements make this style preferable. The third style of bracket provides for the mounting of a constant-speed motor of any standard commercial type. It should preferably be of 5 horsepower, and capable of carrying 50 per cent overload for an hour without danger. The three systems of drive can be interchanged with each other at any time, without special preparation or changes in the machine.

The following dimensions refer to the No. 2B plain milling

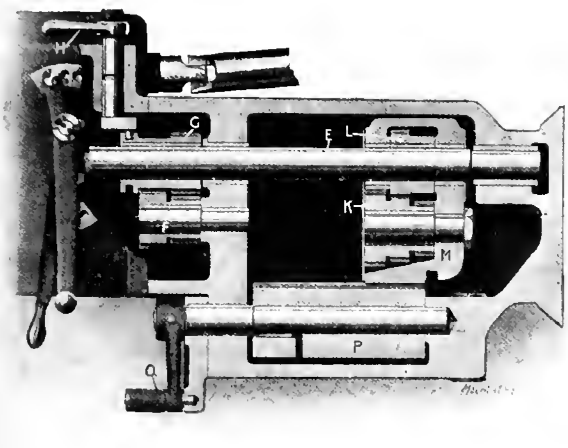

Fig. 5. Design of Tumbler Gearing for Spindle Drive

machine. The driving pulley is 16 inches in diameter for the 4½-inch table belt, and runs at 300 revolutions per minute. The spindle is of forged crucible steel, running in bronze bearings, adjustable for wear; it has a No. 11 Brown & Sharpe taper hole. Eighteen spindle speeds are provided in geometrical progression, ranging from 15 to 360 revolutions per minute with a maximum gearing ratio of 20 to 1. The twelve feeds range from ½ to 60 inches per minute. The table has a working surface of 47 by 12 inches with three T-slots. A plain vise and all necessary wrenches are furnished with the machine. The net weight is about 3,900 pounds.

FUNK MACHINE CO.'S POSITIVE PRESSURE BLOWER

An interesting type of rotary blower has just been brought out by the Funk Machine Co., 23-27 City Hall Place, New York. This firm, which manufactures printing and book-binding machinery, designed this blower for use in connection with a feeding machine. When the blower was tested, it proved so efficient that it was decided to place it on the market. An exterior view of the blower is shown in Fig. 1, while Fig. 2 shows the interior mechanism which consists of only a suction and discharge valve, and a piston with the two impeller blades. The valves which are closely fitted between the outer cylinder and the piston or central drum, are driven from the main shaft by gearing, as indicated in Fig. 1. This gearing is so proportioned that each valve makes two revolutions to one of the main shaft. The valves are crescent shaped in cross-section, and have solid disks on each end. Each valve is so set in relation to the impeller blades that the crescent-shaped part, which extends the width of the cylinder, rolls over the end of each blade as it passes. The impellers may be rotated in either direction, as a change in the direction of their movement simply causes a corresponding change in the position of the suction and discharge outlets.

If we assume that the piston, when viewed from the side shown in Fig. 2, is given a counter clockwise movement, the action of the blower would be as follows: As one blade passes the lower, and what in this case would be the suction opening, the air is drawn in back of it, the valve just above this opening being closed. As this blade moves around toward the top of

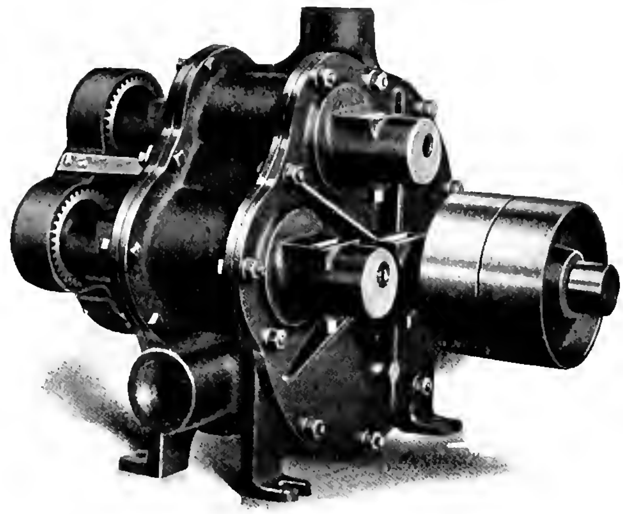

Fig. 1. Rotary Blower built by the Funk Machine Co.

the cylinder, this air is forced out through the discharge port by the following blade, as the space between the piston and cylinder is closed by the upper or discharge valve. When a blade is passing the discharge valve, the suction valve is closed, and remains so until the discharge valve has again moved around sufficiently to seal the space between the cylinder and the central drum or piston.

The impeller blades are of steel, and are firmly attached to the piston. Neither the blades nor the piston bear against the cylinder, but they are made with as little clearance as possible in order to reduce the friction to a minimum. An important point in the construction of this machine is that the friction remains practically constant as the discharge pressure increases. The valves are of bronze, as are also the pinions

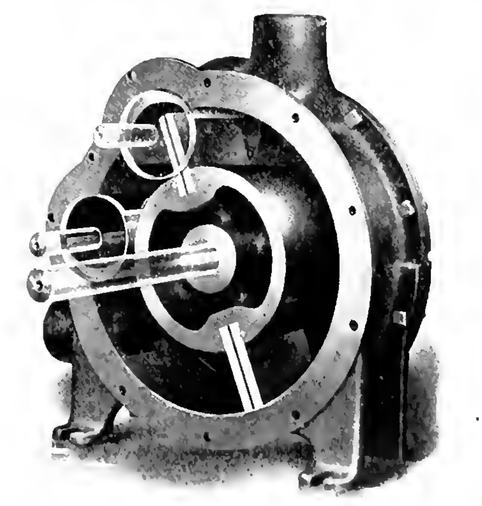

Fig. 2. Interior View of the Rotary Blower

by which they are driven. All bearings are self-oiling, and there are no parts that are likely to become deranged. These machines are built, at present, in three sizes, designated as Nos. 1, 2 and 3. The makers state that during a test run the smallest size delivered 45 cubic feet of air per minute, and maintained a pressure of 2 pounds against five openings ¼ inch in diameter, with a power consumption of 1-10 horsepower. The capacities of the two larger sizes are two and three times that of the smallest size, respectively. Obviously, this blower may be used either for exhausting or compressing air, or for both purposes simultaneously.

NEW LINE OF KELLY CRANK SHAPERS

A new line of crank shapers is now being manufactured by the R. A. Kelly Co., Xenia, O. In designing these shapers, one size of which we illustrate herewith, the company gave special attention to the proper distribution of the metal in order to have a machine with sufficient strength to resist the greatest working strains that are likely to be imposed on it by the use of high-speed steel. The question of strength in this connection, has not alone been considered, as the driving mechanism for each size is so proportioned as to give the greatest output within the limits of high-speed steel tools. This has been accomplished by using wide-faced, accurately-

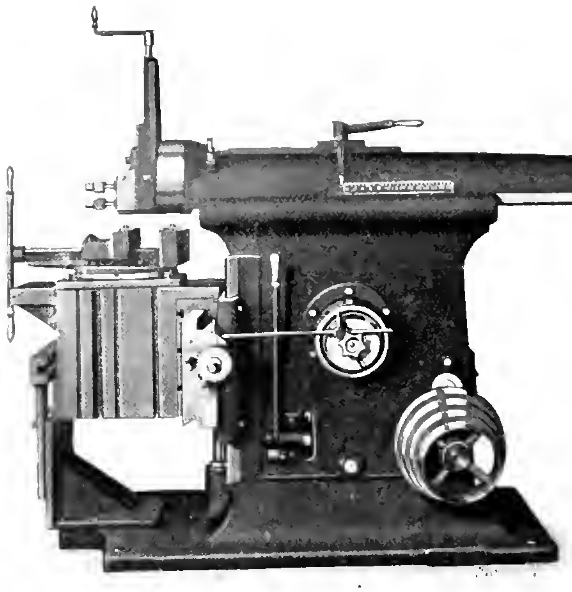

Fig. 1. New Design of Kelly Crank Shaper

cut gears, and employing high gear ratios, ranging from 24 to 1 to 33.2 to 1 in the 16- and 26-inch machines, respectively.

The arrangement of the driving mechanism is illustrated in Fig. 2. The drive is transmitted from a 4-step cone-pulley to the bull-wheel through either of two trains of gears, depending on the speed desired. By shifting the double-ended pinion *A*, which is free to slide on the driving shaft, to either of its extreme positions one of these trains is brought into action. The position of pinion *A* is changed by the vertical lever seen just back of the cross-rail in Fig. 1. It will be seen

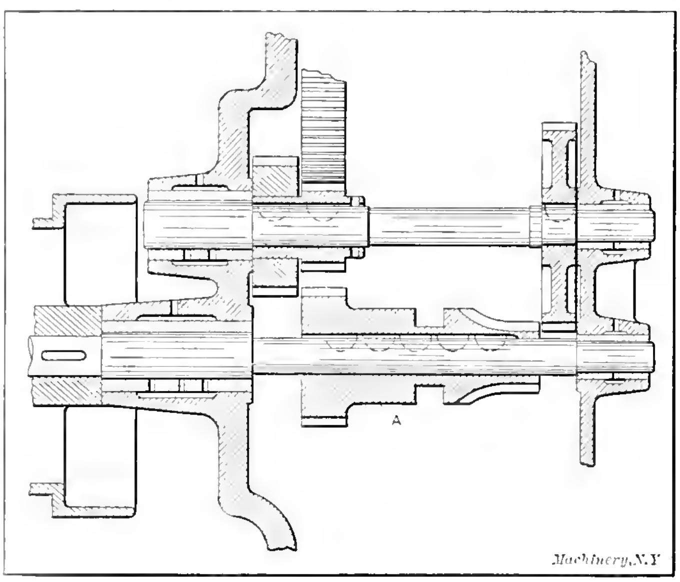

Fig. 2. Detail of the Driving Mechanism

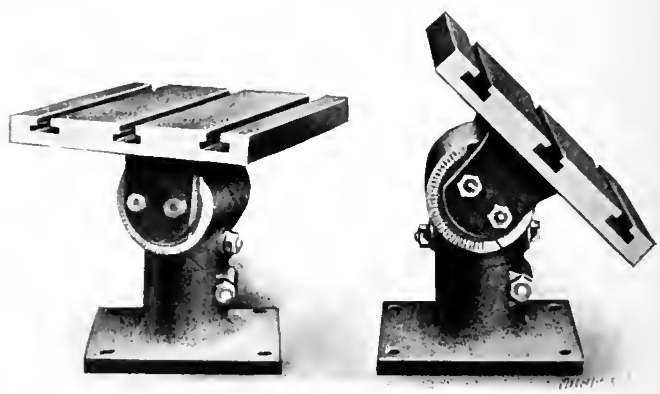
then that the four cutting speeds obtainable from the four steps of the cone-pulley, may be doubled by this arrangement of back gears, giving eight speeds in all. The machine may, of course, be stopped by shifting the driving pinion to its neutral position between the gears with which it meshes.

The bases of these machines are very heavy, and are provided with internal ribs giving them great rigidity. The table, which is of box form, is rigidly supported at its outer end as the engraving indicates. All the bearings in the column are cast integral with it, and those on the larger machines are bored and bushed with Lumen metal. These bearings are of ample length, and all are provided with oil pockets that will hold enough lubricant for one week's steady work. All of the machines have power elevating screws which are so arranged that they can be used as a power down feed on a great deal of work that is ordinarily done on a shaper. Each screw is of the telescoping type, thus making it unnecessary to bore clearance holes in the floor. The stroke of the ram can be changed while the machine is in motion or at rest, and a suitable scale indicates what the stroke is. A study of the machine illustrated, indicates that considerable thought has been given in the design, to the convenience of the operator. This is, of course, an important feature, as the efficiency of a tool of this kind, which is usually employed on a great variety of work, depends largely on the ease and convenience with which various changes, incident to the operation of the machine, can be made. Any of these machines will be arranged for electric drive if desired. The makers are also prepared to furnish any shaper attachments such as index centers, concave attachment, moldmakers' vise, etc., which may be wanted.

WILLIAMSON UNIVERSAL MACHINE TABLE

A new style of universal drill press table or angle-plate is now being made by the Williamson Vise Co., Bradford, Pa. Formerly the shank of this table was clamped to the table-arm of the drill press, the regular table being removed. The new design, which is illustrated herewith, is provided with an in-



Views illustrating the Movements of the Williamson Universal Table

dependent base which makes special changes, incident to its use, unnecessary. This table may be supported either on the regular platen, or on the machine base for large and heavy work. As the engraving indicates, the table may either be rotated in a horizontal plane or swung about its bearing to any desired position from the horizontal to the vertical. The angle for any position is indicated by suitable graduations. These tables are made in six different sizes: The platen of the smallest is six inches square, and its height, when in a horizontal position, is eight inches. The corresponding dimensions of the largest size are 30 and 41 inches, respectively. The usefulness of such a tool in a shop is so obvious that further comment is unnecessary.

SPRINGFIELD 36-INCH MOTOR-DRIVEN LATHE

Among the firms to recognize the superiority of the electric drive for machine tools, may be mentioned the Springfield Machine Tool Co., 631 Southern Ave., Springfield, O. This firm has given particular attention to the design and arrangement of the electrically-driven engine lathes which it manufactures. One of the heavy lathes built by this company, which has recently been equipped with a motor drive, is illustrated herewith. This machine has a swing of 37 inches over the bed and 24 inches over the carriage. The driving motor is of $7\frac{1}{2}$ horsepower and it has a speed range varying between

600 and 1200 revolutions per minute. Special attention has been given to the design of the headstock, which is completely enclosed and of symmetrical proportions. This enclosed type of headstock not only lessens the danger of accident, but greatly adds to the massiveness and strength of this part. The driving mechanism is provided with gears having wide faces, and is strongly constructed throughout. There are six mechanical changes of speed, which, together with the changes obtained from the motor, give all the necessary speeds required for a lathe of this size.

A sectional view of the headstock is shown in Fig. 2. The drive from the motor shaft is through a rawhide pinion that is shown directly back of the gear with which it meshes. This driven gear is keyed to a shaft which may properly be called the countershaft. On this countershaft there are three sliding gears which are tied together as one unit. These are brought into engagement with corresponding gears on the lathe spindle by means of the handle shown in the end elevation. By engaging first one and then the other of these gears three variations or mechanical changes of speed are obtained. These three changes are doubled by the use of back gears as in the ordinary lathe. The controller of the motor is mounted on the right side of the carriage, so that while it is convenient for the workman, it is not located so as to interfere with the operation of the lathe. As the illustration shows, this controller is connected through bevel gears to a splined rod extending the length of the bed, which transmits the movement to the starting box. This method of operating the motor from the carriage has proved so satisfactory that all the motor-driven lathes made by this company are so arranged. This lathe is adapted to cut threads ranging from 1/16 inch to 4 inches pitch. The lead-screw is prevented from sagging by a support which travels on the bed with the carriage and automatically stops off at certain points. This insures a longer life to the lead-screw and more accurate work from the machine. The lathe is equipped with power feeds for either longitudinal or cross movements, and, in addition, there is also power feed for angular positions of the compound rest. A dial in front of the headstock is so arranged as to give three changes of feed for screw cutting. There are also two intermediate positions in which the lead-screw remains stationary. This dial, together with a few change-gears, gives all the necessary changes ordinarily required for feeding or screw cutting on a lathe of this size.

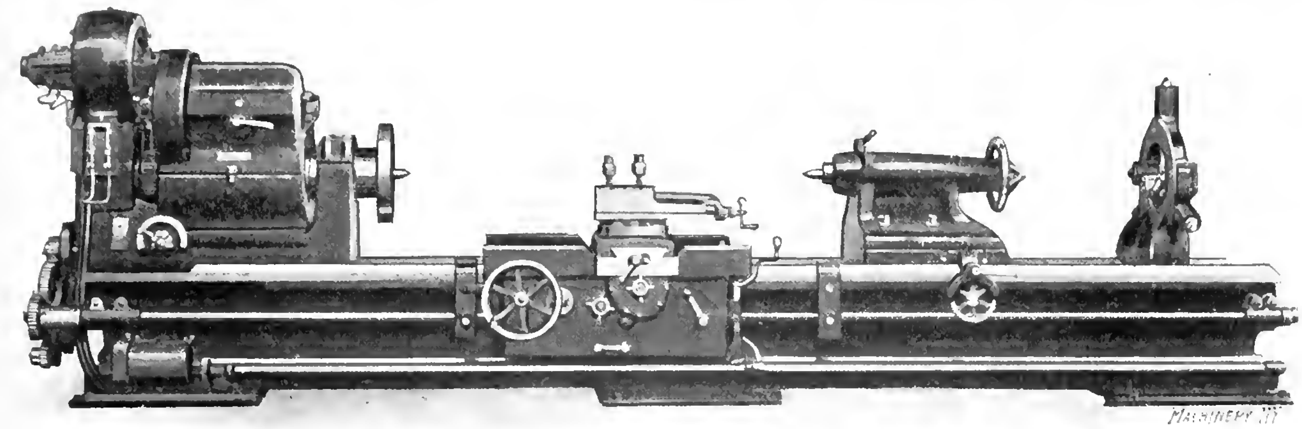


Fig. 1. Heavy Motor-driven Lathe built by the Springfield Machine Tool Co.

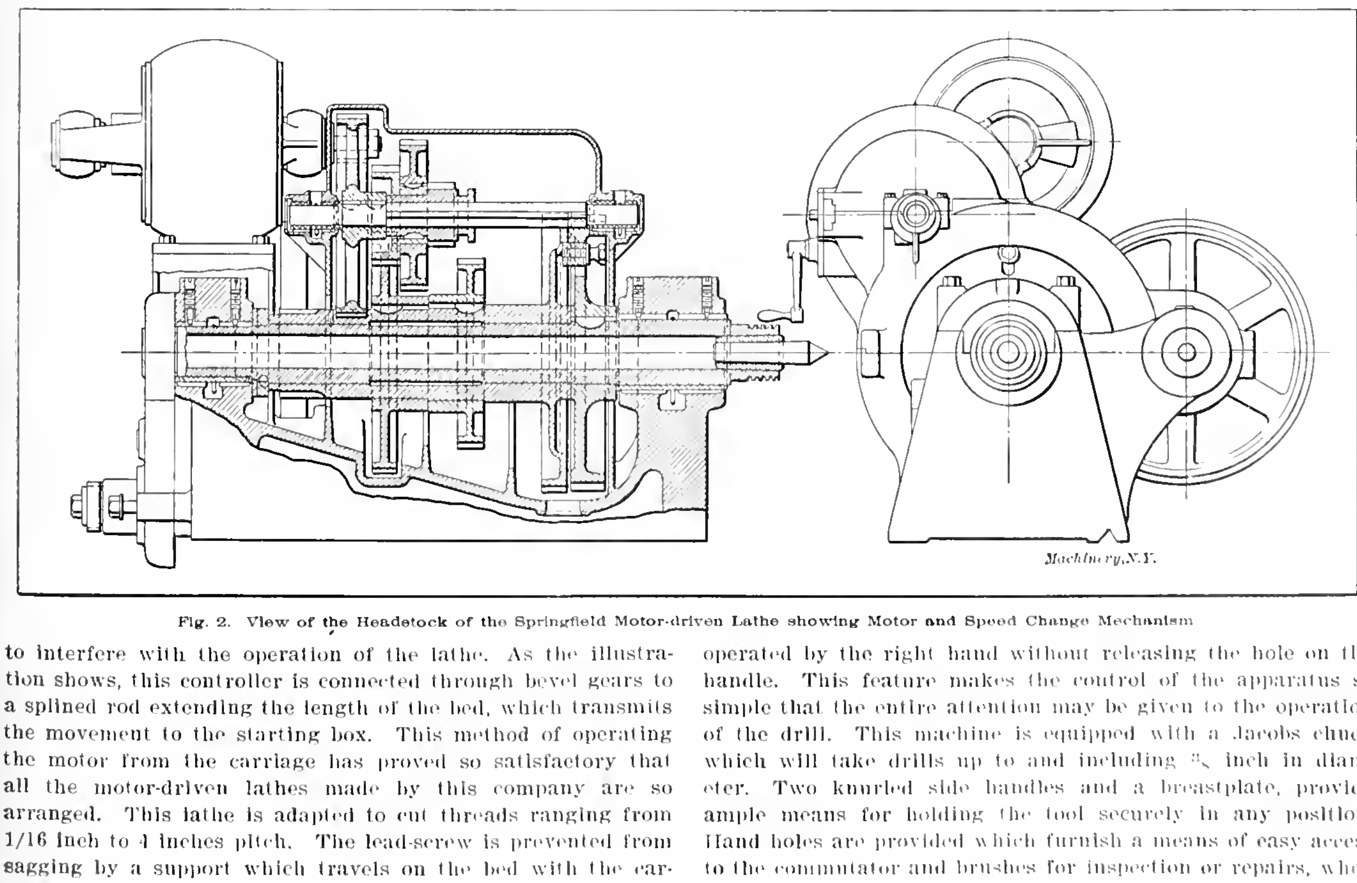

Fig. 2. View of the Headstock of the Springfield Motor-driven Lathe showing Motor and Speed Change Mechanism

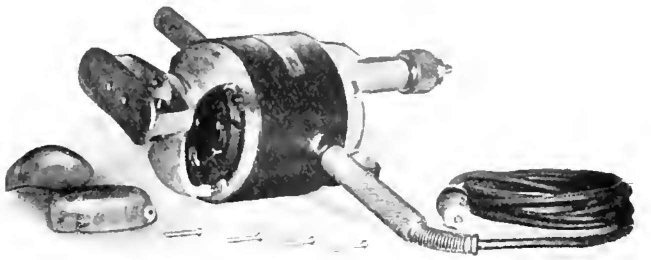
ALTERNATING-CURRENT PORTABLE DRILL

The direct-current type of breast drill which has been manufactured for some time by the General Electric Co., Schenectady, N. Y., has worked so satisfactorily that the company has now placed on the market a drill designed for an alternating current. This tool, which is illustrated herewith, while possessing the ruggedness of design required to withstand the hard usage incidental to its service, is constructed as lightly as possible, the weight being only 21 pounds. Lightness, of course, is a desirable feature in a tool of this kind. An indicating control switch for starting and stopping the motor, is located conveniently near the right handle so that it can be operated by the right hand without releasing the hole on the handle. This feature makes the control of the apparatus so simple that the entire attention may be given to the operation of the drill. This machine is equipped with a Jacobs chuck which will take drills up to and including 3/8 inch in diameter. Two knurled side handles and a breastplate, provide ample means for holding the tool securely in any position. Hand holes are provided which furnish a means of easy access to the commutator and brushes for inspection or repairs, when

necessary. The drill is shown in the accompanying illustration with these hand hole covers removed. An idea of the capacity and adaptability of this tool may be had from the following approximate data: A hole three-eighths-inch in diameter and one inch deep may be drilled in cast iron in 27 seconds, or in machine steel in 95 seconds. The machine will

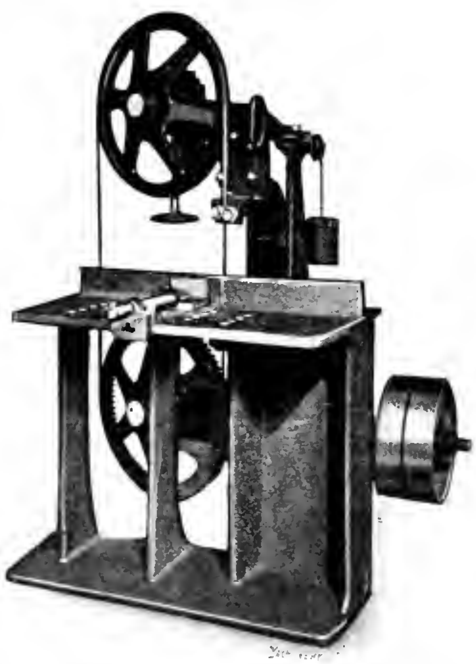


General Electric Co.'s New Drill for Alternating Current

also satisfactorily operate a $\frac{3}{4}$-inch wood bit. From these figures it is evident that much time can often be saved by the employment of this tool, as it will render unnecessary the moving of heavy castings to the stationary drill for many of the minor drilling operations. This machine is designed for operating on either a 110- or 220-volt, 60-cycle circuit, to which it may be quickly connected by simply screwing an attached plug into a standard lamp socket.

BAND-SAW MACHINE FOR CUTTING METAL

A band-saw that is intended for doing practically the same line of work in the machine shop as that which is ordinarily done by the power-driven hack-saw, is now being built by E. R. Klemm, 103 West Monroe St., Chicago, Ill. This machine, as the engraving shows, resembles somewhat in its design the



Metal-working Band-saw with Gravity Feed

band-saw of the wood-working shop. There are, however, a number of radical changes in its construction which were necessary to adapt it to the work for which it is intended.

The frame of this saw, on which are mounted the band-saw wheels, is free to swing about a bearing at its lower end, and it is by this movement that the saw is fed into the work. The feed is by gravity acting on the weight seen suspended by a chain at the rear. This chain, after passing over the pulleys shown, is attached to the swinging frame which is thus pulled forward. It will be noticed that the band-saw wheels lie in a vertical plane that is inclined considerably to the back or locating strip on the table against which the work is clamped. These wheels are located in this way in order that long stock will not come into contact with the idle side of the saw blade. Means are provided for changing the center-to-center distance of the band-saw wheels, to accommodate saws of different lengths and for varying the tension. The machine is strongly built, and it is provided with a large table equipped with a suitable vise for holding the stock. Practically any shape whether round, square or flat can be held securely and cut to any desired angle. The drive is through a shaft at the rear which has on its end a bevel pinion meshing with teeth cut on the lower band-saw wheel. Two disks, which are located a short distance above the table and on either side of the saw blade, deflect the latter so that it is square with the work.

The maker states that this saw cuts as squarely as any on the market, and also that it severs the stock with considerable speed and with a low power consumption.

BAIRD WIRE FORMING AND FERRULING MACHINE

In Fig. 1 is shown an interesting machine made by the Baird Machine Co., of Oakville, Conn., for the automatic production of pieces such as shown in Fig. 2. These pieces, which are bent in various shapes, have a ferrule around them,

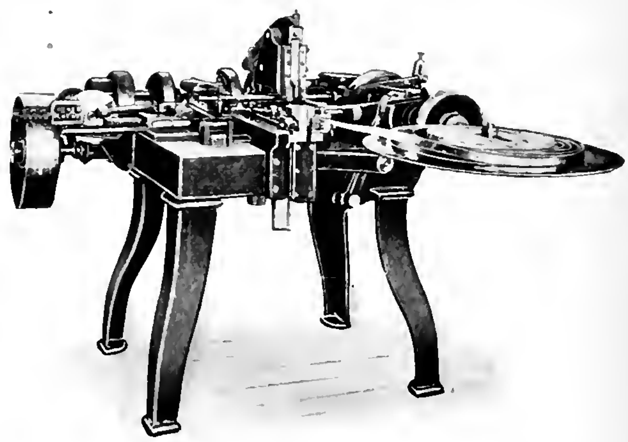


Fig. 1. Automatic Machine for Wire Bending and Ferruling

usually over the closed joint, made from strip metal. Such parts are used extensively for suspender loops, buckles, easel stands for photograph frames, etc.

The machine is a combination of two mechanisms, one of which performs the bending operations, while the other forms the ferrule. The action is entirely automatic. The wire is received from the coil, is straightened, threaded, cut off and formed; and at the same time a strip of sheet metal is received from a reel, is cut off, formed and pressed in place around the work as shown in Fig. 2. The capacity for completely ferruled work is from 60 to 80 per minute, according

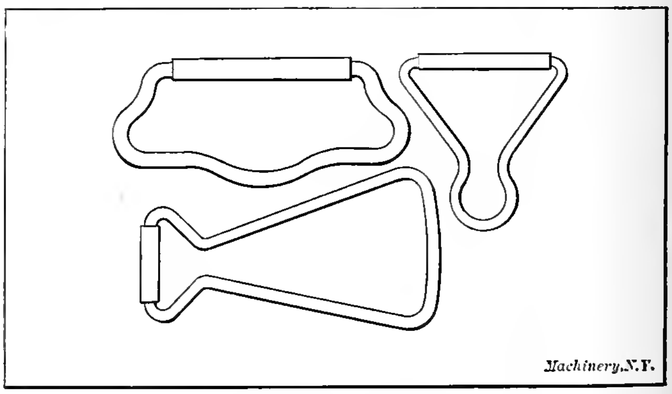

Fig. 2. Character of Work produced

to the size and shape. No further attention is required than that of keeping the machine supplied with strip metal and wire, and removing the finished product.

This machine is built in various sizes and for various styles of work. A high-grade of workmanship and construction is employed throughout, liberal use being made of hardened and ground tool steel for lining, tools, etc. All sliding surfaces are carefully scraped.

SPECIAL LE BLOND MILLING MACHINE FOR JIG BORING

The milling machine is now generally used in the tool room for the purpose of drilling bushing holes in jigs and fixtures, as well as for the machining of the various flat surfaces required in that work. The use of the miller is due to the convenient provisiou it offers for adjusting the work in two directions at right angles to the spindle, in the provision of a feed in line with the spindle, and in the rugged design and accurate construction, which permit much finer results to be obtained than would be possible on the ordinary drill press, even though supplied with the required adjustments.

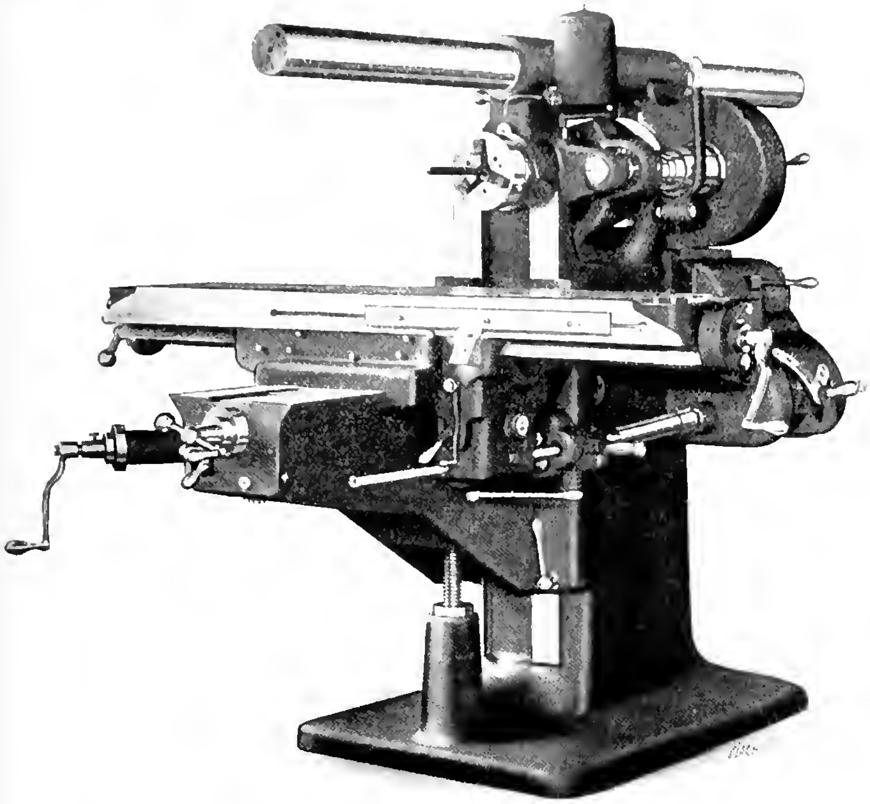

Fig. 1. Miller provided with Vernier Gages and other Conveniences for Jig Boring

The usual method of locating the holes for boring in the milling machine is by the use of ground bushings or "buttons," located by accurate measurements in the positions where it is desired to bore the holes. The buttons thus located are, in turn, lined up with the spindle of the machine by means of indicating devices, and the holes are then bored to the required size.

This button method is exceedingly accurate, but is correspondingly tedious. Another method which has sometimes been adopted consists in fitting accurate scales with vernier attachments to the miller, so as to read the various movements directly without requiring the setting of jig bushings or buttons with special instruments. This greatly increases the rapidity with which such work may be done, but, in general, it has not given as good results as have been obtained by the button method.

The R. K. Le Blond Machine Tool Co., 4609 Eastern Ave., Cincinnati, O., has, however, a special milling machine equipped with vernier scales, in which such care has been taken, both in design and construction as to insure close work. As a result the accuracy in jig and fixture work produced is high enough to meet all except what might be called extreme laboratory requirements, and this accuracy can evidently be obtained with a great saving of time and work for the toolmaker.

The salient features shown by an inspection of Figs. 1 and 2 are the heavy column and wide range of movement provided for the cross and table feeds, the special design of the automatic feed mechanism on the saddle, the increased stiffness of all the structural members and the modified arrangement of the handles, to permit the workman to use them while in a convenient position in relation to the work.

The spindle is unusually heavy. The front taper bearing is hardened and ground and runs in a close-grained cast iron box of special mixture. This insures a permanent bearing that will run indefinitely, showing no wear and requiring little attention. The rear journal is straight and runs in a bronze box fitted to a taper hole in the housing. This box is split and can be drawn into the taper to take up the wear on the rear journal. The end thrust of the spindle is taken by a hardened steel and a babbitt collar. An oil slot is milled in both boxes connecting with reservoirs in the column. These slots are filled with felt, through which the oil filters to the bearings. The arbor is driven by a clutch milled in the end of the spindle nose. An arbor bolt is provided which extends through the hollow spindle, and provides a convenient means of inserting and removing the arbors.

The cone is three-stepped, the largest step being 13 inches in diameter for a 3½-inch belt. The back gears are of the maker's double friction type, which, in addition to all the advantages of double back gears, provides a means for quickly stopping and starting the machine, a feature of equal value to the friction head on a chucking lathe.

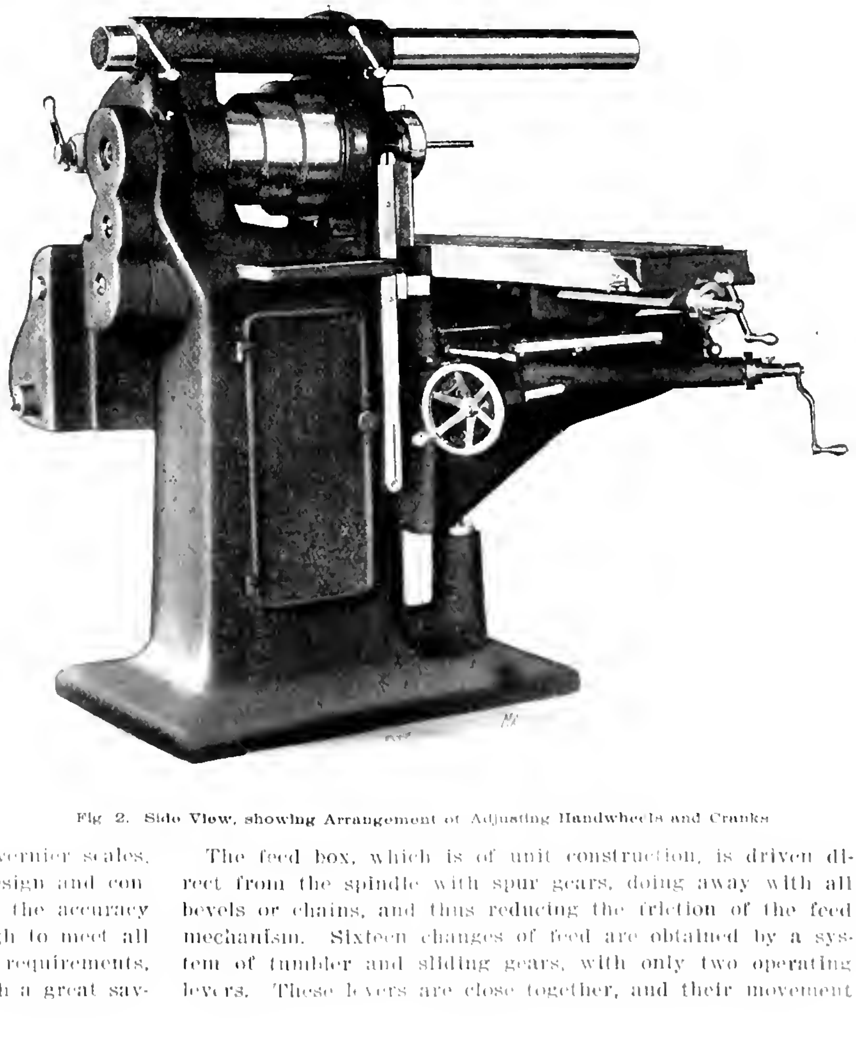

Fig. 2. Side View, showing Arrangement of Adjusting Handwheels and Cranks

The feed box, which is of unit construction, is driven direct from the spindle with spur gears, doing away with all bevels or chains, and thus reducing the friction of the feed mechanism. Sixteen changes of feed are obtained by a system of tumbler and sliding gears, with only two operating levers. These levers are close together, and their movement

is such that a direct reading index plate enables the operator to tell at a glance the correct position for a given feed. The table feed is driven with a direct spur drive on the end of the saddle, instead of the usual construction of coming through the center of the knee and saddle, which further reduces the frictional losses in the feed mechanism. The reverse and trip for the table feed are operated by one lever, the mechanism being carried in a box on the end of the saddle. When the feed is tripped there are no gears or clutches running idle on the screw or in the saddle.

The table is unusually heavy, with arched ribbing to counteract the strains of bolting work on its surface. The bearing is taken on the outside of the dovetail and extends the full width of the table. Large oil pockets extend entirely around the table, and the oil is drained to each end, where it may be removed through cocks provided for that purpose. The table feed-screw is $1\frac{3}{4}$ inch in diameter, of coarse pitch, and geared 2 to 1 on the quick return. The thrust is taken on ball bearings at the ends of the table, and the screw is therefore always maintained under tension, regardless of the direction of movement.

The knee is made in box section, ribbed and braced transversely and laterally. The column bearing is extended up almost to the top of the table, which adds greatly to its rigidity. The saddle bearing is wider than the column bearing, giving support to the ends of the saddle. The cross feed screw is set in the center of the knee, overcoming all side strains and giving an easy movement. The saddle is of unusual length, and is braced its entire length with arched ribs through which the table screw passes. The taper gib for the table bearing is made with a tongue to avoid any tendency to lift. The lower gib as well as the gib on the column bearing are made with two angles, adjustment being effected with fine thread screws. Locking screws with fixed handles are provided on both gibs, which draws them in like wedges, and these provide metal to metal contacts the entire length of the gibs.

The machine has a longitudinal feed of 34 inches, a vertical feed of 20 inches and a cross feed of 18 inches. The unusual length of the cross movement is one of the chief advantages over an ordinary plain miller for boring jigs, as it permits the use of long boring bars for box jig work and for deep holes. In order to use the machine to the best advantage in boring, the cross feed is arranged in such a manner (see Fig. 2) that its movement can be controlled from the rear of the table—a position most convenient to the operator. This is accomplished by the introduction of the diagonal shaft through the knee which is connected to the cross feed screw at the front by means of bevel gears.

The longitudinal and vertical movements are fitted with vernier scales 24 inches in length, thus enabling the operator to lay off centers with extreme accuracy without the use of auxiliary measuring instruments. An interesting feature in connection with the completion of this machine was the testing of the accuracy of the screws. The vernier scales provided an ideal condition for such a test, which showed the screws so accurate that the error was invisible to the naked eye in a length of twenty inches.

MASSACHUSETTS FAN CO.'S "SQUIRREL CAGE" FAN

The increased use of mechanical ventilation and the extent to which motors and steam turbines are now employed, has resulted in what is called the high-speed or multi-blade fan. This type, because of its high rotary speed, is, of course, for the same capacity, smaller than the older types, for, naturally, the higher speeds make possible a reduction in the wheel diameter; in fact, this diminution in diameter was necessary to keep the rim velocity within practical limits. One of the greatest losses of power in the operation of a fan, is in the creation of an inlet velocity that is entirely destroyed before the air is delivered. In order to decrease this velocity, the area of the inlet is increased to as great an extent as the depth of blade will permit. It is well known that there is a very exact proportion existing between the volume of air delivered and the blade area of the wheel, and in order that the proper blade area may be maintained, a reduction in the depth of the blade must be accompanied by an increase in the number.

By increasing the size of the inlet, using many shallow blades in place of a few deep ones, and increasing the rotary speed, a marked increase in the air delivered and a greater capacity in a given space has resulted. In fans of the older designs, commonly known as the "paddle-wheel" type, the blades were wide apart at the periphery and nearer together at the inner ends. With the blades arranged in this way, the greater density of air at the outer ends caused the formation

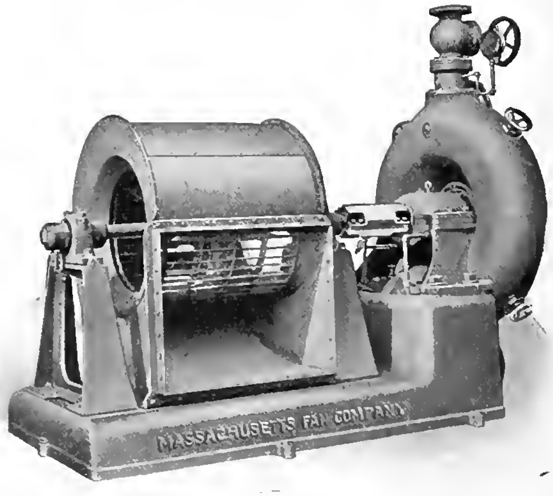

Fig. 1. Turbine-driven "Squirrel Cage" Fan built by the Massachusetts Fan Co.

of eddies and pulsations which reduced the efficiency and caused noisy operation at high speed. In order to reduce the effect of eddies, multi-blade fans were designed so that the air would be subjected to blade action during the shortest period possible. To accomplish this, blades were made very shallow.

The Massachusetts Fan Co., of Watertown, Mass., employs in addition to the blades around the periphery of the blast-wheel or cage, a few long and tapering blades, which extend toward the center of the wheel. These blades may be seen in Fig. 2, which shows a view of the blast-wheel for a double inlet blower. The theory is that these extra blades work with a scooping action which gives the entering column of air a slow whirling motion and a rapid radial motion toward the shal-

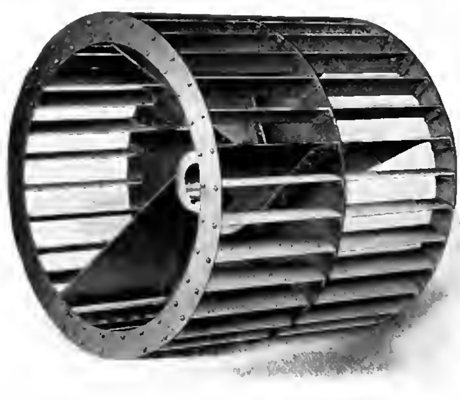

Fig. 2. Blast-wheel or Fan Runner of the Double Inlet Type

low peripheral blades, thus increasing the efficiency of the fan. Inasmuch as the centrifugal force acting on the entering column of air varies with the speed, the angle of these inner blades should be changed for different peripheral speeds. In order that fans working under different conditions will have a maximum of efficiency, the company referred to has developed three standard designs of the "squirrel-cage" type; these are as follows: Type A for the low peripheral speeds which have been found to be best adapted for building work, and for certain conditions for high pressures when the fans may be driven by a direct-connected steam engine; type B for higher peripheral speeds such as those of high-speed motors,

especially of the alternating current type; type C for very high speeds, as when driven by steam turbines.

One of these squirrel-cage fans of the double-inlet type is shown in Fig. 1 directly attached to a steam turbine.

SPECIAL WALTHAM BENCH LATHES

The Waltham Machine Works, Newton & Cutter Sts., Waltham, Mass., has for many years manufactured a line of bench lathes which are used for general manufacturing and special work, where parts to be made are small or require great precision in workmanship. These lathes are regularly provided with tailcenter, slide-rest, etc., and used in the same way as the largest size engine lathes in the machine shop.

A number of special appliances are provided for them, however, by means of which they may be converted into special machines. Some of these arrangements, of recent design, are herewith illustrated and described.

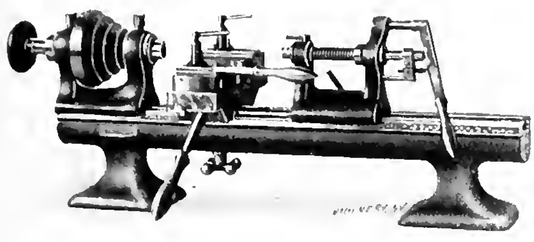

Fig. 1. Precision Drilling, Turning and Cutting-off Lathe

In Fig. 1 is shown a drilling, turning and cutting-off lathe, consisting of a plain head with a spring chuck, a double slide-rest and lever tailstock, mounted on a two pedestal bed. The movements of the various slides are controlled by lever, so that the action is very rapid. Stops are provided in all directions. The front toolpost on the cross-slide is mounted on a compound block which may be set to any desired angle, so that either cylindrical or taper surfaces may be turned and bored by the manipulation of the upper handle.

Fig. 2 shows a shortened one-pedestal lathe bed on which is mounted a headstock and a grinding wheel slide. This machine is intended for grinding small short work, one end of which is held in a spring chuck, while the other is supported by a center in a bracket attached to the back side of the headstock. A grinding wheel is mounted on a traverse spindle in a swivel support which may be set to any angle desired.

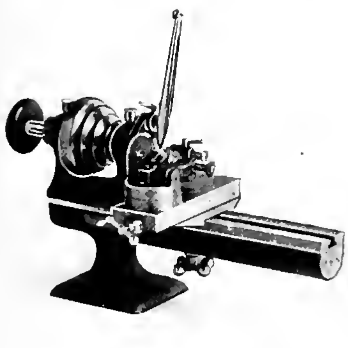

Fig. 2. Special Grinding Lathe with Self-contained Measuring Indicator

An indicator is shown, which is provided with a sapphire point bearing against the work. This records the diameter, so that it is not necessary to stop the spindle and take measurements for every piece, this being done only occasionally.

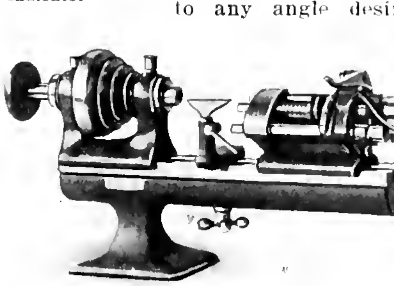

Fig. 3. Precision Lathe with Three-spindle Tumble Tailstock

The machine shown in Fig. 3 is a combination of a plain chuck headstock, a hand-rest and a three spindle "tumble" tailstock, mounted on a single pedestal bed. The center spindle of the tailstock can be driven by a belt, thus making it an excellent tool for spotting, drilling and reaming small holes.

The machine illustrated in Fig. 4 is provided with a headstock of special construction. The cross-slide is similar to that shown in Fig. 1. The lathe tailstock is of the "half bearing" variety, which may be provided with a multiplicity of spindles, each containing one tool of a number which it may be desired to use. Each spindle has its own stop, so that each may be set independently. To change from one to the other it is only necessary to pick out one tool and lay in the next in order. The headstock is of the slide spindle type, with a lever-operated chuck and wire feed. A two-step cone pulley

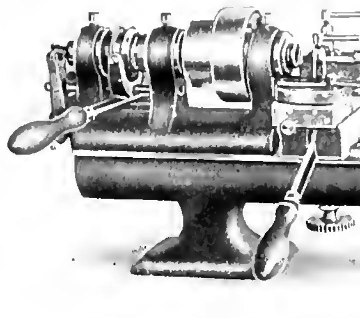

Fig 4. Lathe with Double Lever Cross-slide and Half-bearing Tailstock adapted to Screw Machine Work

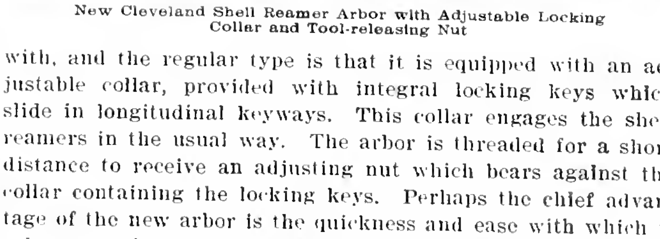
is provided. This equipment is used in much the same way and for the same kind of parts that in larger work would be placed on a hand or automatic screw machine.

The various lathes here illustrated have, for the most part, a swing of 3¼ inches and a chuck capacity of 5/16 inch. Three other sizes are made, however, swinging 6¾, 7 and 8 inches, with 3/8, 1/2 and 5/8 inch chuck capacity, respectively. These lathes, with special equipment, are usually made only to order, though the makers occasionally have some of the parts in stock. As all the equipment of one size is interchangeable, any style of headstock can be used with any style of tailstock and slide rest, giving several other combinations in addition to those shown.

CLEVELAND TWIST DRILL COMPANY'S SHELL REAMER ARBOR

The Cleveland Twist Drill Co., Cleveland, O., is about to place on the market a new patented arbor for shell tools. The principal difference between this arbor, which we illustrate here-



New Cleveland Shell Reamer Arbor with Adjustable Locking Collar and Tool-releasing Nut

with, and the regular type is that it is equipped with an adjustable collar, provided with integral locking keys which slide in longitudinal keyways. This collar engages the shell reamers in the usual way. The arbor is threaded for a short distance to receive an adjusting nut which bears against the collar containing the locking keys. Perhaps the chief advantage of the new arbor is the quickness and ease with which it releases a shell tool, no matter how tightly it may have become jammed on the arbor. This is accomplished by a turn or two of the adjusting nut, and without the necessity of removing the arbor or resorting to the vise and hammer methods which often cause considerable damage. Another decided advantage is that the collar can always be set so as to allow the shell tool to fit snugly on the arbor, and yet fully engage the collar keys.

CINCINNATI-BICKFORD 2½-, 3- AND 3½-FOOT RADIAL DRILLS

The radial drilling machines made by the Cincinnati-Bickford Tool Co., Cincinnati, O., (formerly made by the Bickford Drill & Tool Co.), are well known in their general characteristics. The smallest sizes of this line (2½-, 3-, and 3½-foot) have recently been redesigned by the makers. The main characteristics have been retained and there is, in fact, com-

paratively little change in their appearance. Improvements have been made, however, throughout the whole structure and mechanism of the machines, radically affecting the strength, durability, convenience, accuracy and productive capacity.

The design has a column extending to the top of the sleeve, ribbed internally so as to furnish a high degree of stiffness. It is mounted on a base which has been considerably strengthened at the point where the flange is bolted down. The ring which supports the elevating screw and takes the weight of the arm itself, is now supported on ball bearings, greatly reducing the force required to swing the arm. The pipe section of the arm has been retained, giving a high degree of strength and stiffness. In fact, in the matter of the general structure of the machine, all that was good in the old design has been kept, with the addition of improvements that increase its efficiency.

The power of the drive has been augmented by putting on a larger driving pulley, giving, consequently, a greater belt capacity. The well-known form of gear box provided, allows changes to be made while the machine is running at a high speed, by the simple tossing of the lever from one notch to the other. This can be done without taking special precaution to prevent breakages. The settings for the different diameters of drills are given below the notches in which the change gear lever rests. Gears subjected to hard service are of hardened steel. The bevel gears transmitting the power to the column have been increased in size, so as to make them proportionate to the greater power transmitted.

The back-gears are located in the head. They are of simple construction, consisting of three gears and a clutch, and may be engaged or disengaged while running. The clutch is made of high-grade carbon steel and has hardened teeth. The gear-box and back-gears give twelve changes of speed, ranging from 38 to 356 revolutions per minute, making them correct for a cutting speed of 35 feet per minute for drills from 3/4 inch to 3½ inches in diameter. This increased speed range is a new feature in this design.

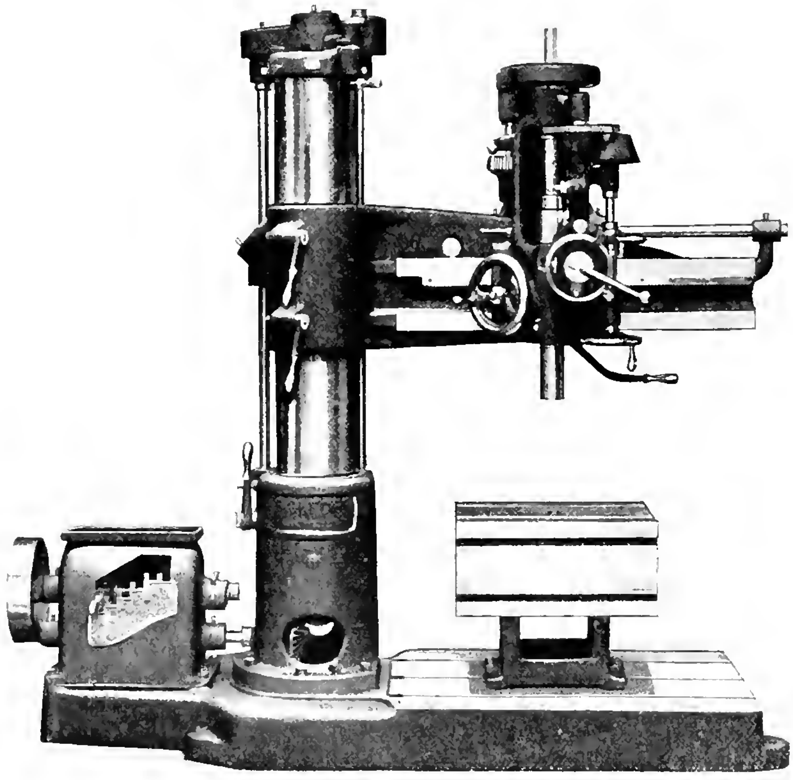


Fig 1. Improved Design of Cincinnati-Bickford Radial Drill

The reversing clutch, the lever for which may be seen extending below the head in Fig. 1, is now expanded by a plunger and toggle-joint arrangement, whereby its capacity is increased many times over that of the wedge type of clutch formerly used. Adjusting screws permit the friction rings to be set to any tension desired. The reversing lever is employed for starting and stopping the machine as well, being within convenient reach from the operator's position.

The feed change device operates by means of a ball handle controlling a driving key mechanism. This gives four changes ranging from 0.008 to 0.020 inch advance per revolution of the spindle. Any one of these feeds is instantly available. The feed clutch is made of hardened steel. The thrust of the feed worm is taken on a ball bearing instead of on a fiber washer, reducing the power consumed by this member of the machine. The spindle sleeve also exerts its pressure on the spindle through a ball thrust bearing, reducing the power to run the machine nearly 22 per cent. This, with the increased diameter of the driving pulley, makes the machine capable of doing much heavier work than formerly.

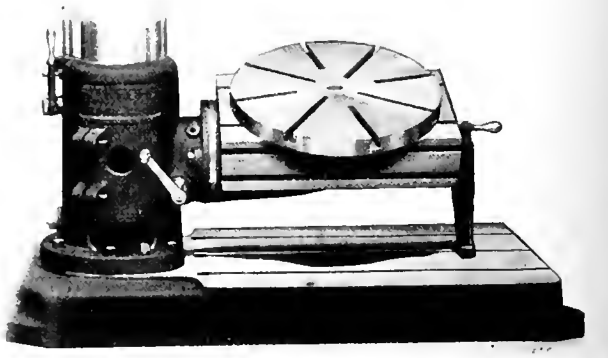

Fig. 2. Universal Swinging, Tilting and Rotating Work Table

The quick return handle on the feed pinion shaft is now provided with a toggle-joint type of adjustable clutch. This requires but a slight force to engage it, thereby avoiding the possibility of throwing the handle out of position by a sudden violent effort. Instead of graduating the spindle sleeve as formerly, depths are now read from a dial permanently located on the quick return head on the feed pinion shaft. The automatic stop is also made a part of the depth gage, and it may be set in position instantly without requiring trial cuts or measurements.

The guide on the top of the arm for the adjustment of the head is made flat instead of angular as usual, thereby allowing the head to move more easily, and minimizing the tendency for it to rock on the arm while the machine is in operation. The head clamping device has the important feature of tightening the gib in the head instead of lifting it away from it. This gib is now made taper instead of flat and is fitted with an improved adjusting device which eliminates the undesirable feature of having the weight of the head rest on the point of two screws. It also prevents the possibility of any end play.

Three forms of table are provided. Fig. 1 shows the box table clamped on the base of the machine, and provided with working surfaces on both sides as well as on the top. Fig. 2 shows a swiveling table provided with a wormwheel adjustment for setting it to any angle about a horizontal axis, the angle being indicated by a graduated ring of large diameter; a dowel is provided for locating it in the horizontal position. This design is also furnished, if desired, as a plain swinging table, without the swiveling attachment. The round work-table shown is a supplementary device which may be placed on the box, swinging or swiveling tables.

Special attention should be called, in Fig. 1, to the very complete set of gear guards provided. This is in line with the modern tendency of safe-guarding the workman. It has other advantages as well, however. It protects the gears from accidents, such as are particularly likely to occur in shops having traveling cranes. It prevents the throwing of oil over

the clothes of the operator. Besides all this, it adds so much to the appearance of the machine that it would seem to be a commercially profitable policy to provide complete gear guards on that score alone.

These machines are made in 2½, 3- and 3½-foot sizes, which dimensions give the radius of the circle to the center of which it is possible to drill on the base of the machine. The vertical adjustment of the arm is about 53 inches for each of the three sizes. The maximum height of the end of the spindle above the base is about 4 feet 3 inches. The vertical range of the spindle is 11 inches. It is bored for a No. 4, Morse taper. The weights of the 2½-, 3-, and 3½-foot machines with swinging table, are, respectively, 4,100, 4,250 and 4,400 pounds.

SIBLEY HIGH-SPEED GEARED DRILL

The Sibley Machine Tool Co., South Bend, Ind., makes a high-speed drill, which was illustrated in the department of New Machinery and Tools in the November, 1909, number of MACHINERY. This machine has recently been equipped with an all-geared power feed, which is illustrated in the accompanying engravings together with details of the speed change mechanism.

The gear-box for the feeds is mounted at the side of the lower spindle head, being connected in the casing at the top of the column with the horizontal spindle driving shaft. Four sets of gear ratios are provided, the change from one to the other being made by the sliding key mechanism operated by the knob plainly shown in the hub of the handwheel, which, it will be seen, places it within convenient reach of the operator.

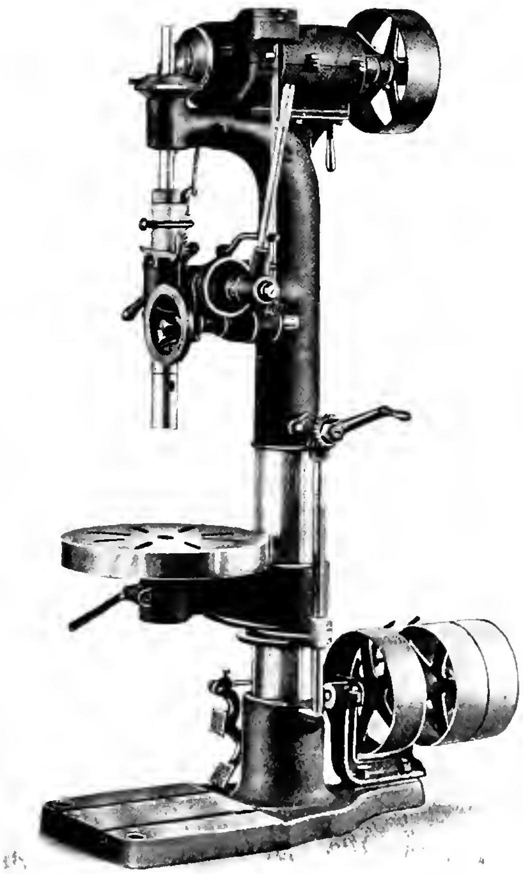

Fig. 1. Sibley Drill Press with Geared Quick-change Speeds and Feed

The usual drop worm mechanism is provided in connection with an automatic stop, actuated by an adjustable clamp dog on the spindle sleeve. A lever is provided for quick handling of the spindle for light drilling operations, while the handle at the left-hand end of the pinion shaft serves for the quick return movement.

The control of the spindle speeds will be understood by reference to Figs. 2 and 3. The constant speed driving pulley may be connected by either of two sets of gearing with the horizontal shaft at the left of the casing. The change from one set of gearing to the other is made by the lever shown in Fig. 2, just in front of the driving pulley at the top of the machine. This second shaft also carries a set of four gears meshing with a corresponding set of four gears on the spindle driving shaft, to which the driving bevel gear is connected. By the manipulation of the lever at the front, any of the four ratios provided may be obtained. The combination gives eight changes in all. The elimination of the cone pulleys permits the use of a wide belt running constantly at a high speed, giving greater power, besides having the obvious advantage of simpler and more rapid manipulation.

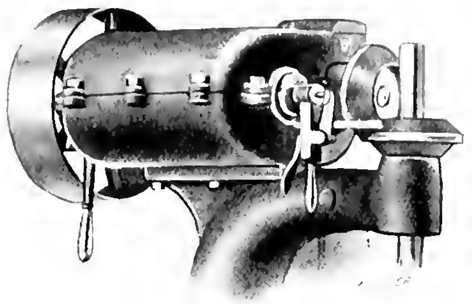

Fig. 2. Speed Change Box and Handles for Operating

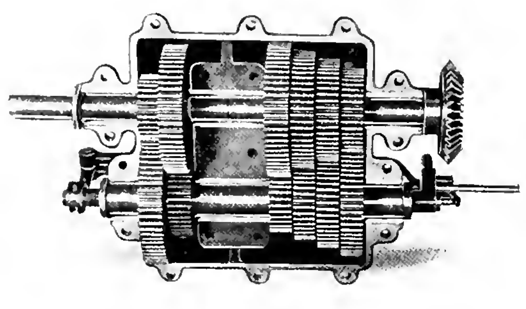

Fig. 3. Arrangement of Gearing in Speed Box

The bearings in the speed box are of bronze, the gears run in oil, and the whole construction is rugged and strong. All the changes of spindle speeds and feeds can be controlled without leaving the operator's position at the front of the table. The speed change is of the selective type—that is, the required speed may be obtained without running through the intermediate speeds and without stopping the machine. All the bearings are long, and the spindle and shafts are ground. The stiffness of the column is apparent in the illustration.

This style of machine is built at present only in the 22½-inch swing size. The total height of the machine is 6 feet, 5½ inches. The maximum distance from the spindle to the base is 39¾ inches, and from the spindle to the table, 19½ inches. The table is 19 inches in diameter. A No. 4 Morse taper hole is provided in the spindle. The eight speeds range from 99 to 600 revolutions per minute, while the feeds range from 0.0052 to 0.0169 inch per revolution. The spindle has a feed of 7 inches. The weight of this machine is about 850 pounds.

ROCKFORD ADJUSTABLE COLUMN GANG DRILLING MACHINE

In Figs. 1 and 2 is illustrated a novel design of gang drill, made by the Rockford Drilling Machine Co., of Rockford, Ill. As will be seen, the new feature is the provision made for adjusting the columns to different spaces along the planed top surface of the base. This allows the machine to be used, of course, for ordinary gang drilling operations, in which its merit over the use of four separate machines is principally that of compactness; but it makes it available as well for a large range of work which comes under the head of multiple spindle drilling—that is to say, it is adapted to the drilling of four holes in a line simultaneously on a given piece of work, or two holes in two pieces of work; and the spindles may be spaced to drill these holes at the different dimensions required.

The base has a planed top surface, provided with two T-slots in which each column is clamped by four stout bolts. A tongue in the rear T-slot serves to guide the columns and keep them in line. Each pair of columns is connected with

a screw by means of which they are adjusted along the top of the bed to the desired position. In this adjustment one column is clamped, while the other one is free to move under the influence of the screw. When this column has been moved to the desired position, it is clamped, in turn, and the other one is loosened and adjusted by the operation of the same screw. The minimum adjustment is 13 inches, center to center, for each of the pairs, and the maximum 30½ inches, center to center, between the adjacent spindles.

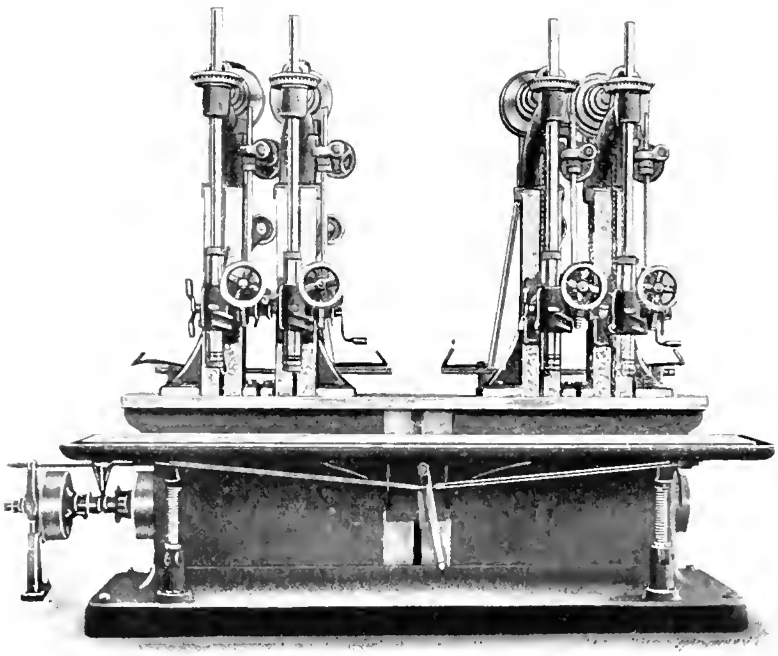

Fig. 1. A Four-spindle Gang Drill with Adjustable Columns

This adjustable column arrangement introduces a problem in the provision of a suitable belt drive, and bracing for supporting the belt pull. These problems have been solved in a way best shown in the rear view of the machine, Fig. 2. In place of the usual solid brace, running from the lower drive cone frame to the arm at the top of the machine, a strut has been provided which is pivoted at both top and bottom. At the lower end this is fitted into a socket where it is held by screws. Before the adjustment on the columns of the bed is changed, these screws are loosened, permitting the strut to slide freely in and out. When the adjustment has been made and the column is clamped in place, the screws are again tightened, to provide the compression strains due to the belt tension with a resisting member at this point. The tension under the varying adjustments is maintained by means of the idler pulleys shown, which work on the slack side of the belt, and may be adjusted to the belt's position.

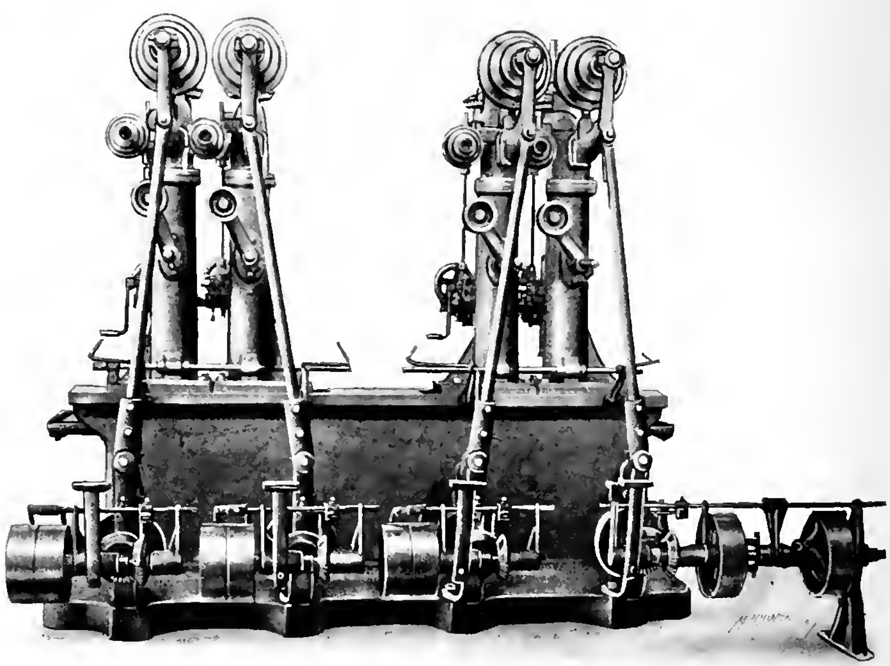

Fig. 2. Rear View of Gang Drill, showing Adjustable Back Braces and Belt Idlers

Each head is provided with a separate set of cone pulleys and a separate countershaft with its own tight and loose pulley and shifting lever, which is brought around to the front of the machine between the columns, where it can be readily handled by the operator. Power feed with automatic stop is provided for each of the spindles, thus making them independent.

The tool illustrated has the same dimensions and capacities for the individual spindles as the makers' regular 28-inch gang drill. Eight speeds are provided by the use of the internal back-gears, and there are four changes of power-driven feed. The table is mounted on two raising screws, geared together for changing the height adjustment. It is tongued and gibbed to the column, and may be rigidly clamped in place.

ALMOND GEARED DRILL CHUCK

T. R. Almond Mfg. Co., of Ashburnham, Mass., has made further improvements in the chuck with which its name has been connected for many years. The new design has the same internal construction as the original standard chuck, the improvements consisting in the application of a tightening device operated by a bevel pinion cut on the end of the tightening wrench. This construction is shown in the engraving.

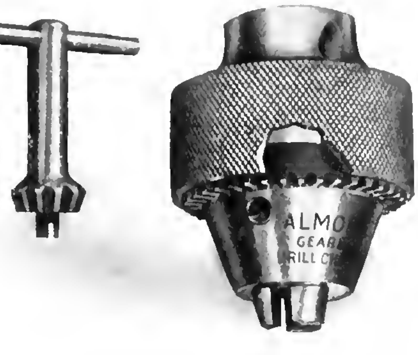
The main point of advantage in the new design relates to the gear teeth. Instead of being cut on the knurled sleeve as usual, they have been formed on the edge of the split nut or ring which operates the jaws. This nut is made of hardened and tempered tool steel, giving a great increase in durability and strength as compared with former designs in which the teeth are cut on ordinary mild, case-hardened metal in the sleeve. There is also an advantage in applying the tightening power directly to the nut, since it has been noticed that the frequent pressing of the sleeve on or off of the nut for cleaning purposes in the old design, tended to loosen the fit, so that the sleeve would slip when a firm tightening pressure was applied. The knurled sleeve is still, of course, available for quick adjustment by hand, the same as with the original construction.

Another improvement consists in bushing with hardened steel the holes in the body of the chuck, which receive the pilot of the pinion wrench, when the jaws are being tightened. These holes are subject in ordinary workshop practice to very severe usage, and by bushing them in this manner the fit of the gear teeth and the consequent satisfactory action of the chuck is prolonged indefinitely. This new design employs the same size pinion for both sizes of chuck, so that they are interchangeable. The wrench may, in fact, be chained to the drill press the same as the drift key, and be used for whichever size of chuck the workman happens to employ.

Improvements in general construction have resulted from the cutting of the teeth on the nut instead of on the edge of the sleeve. One result is the increase in the diameter of the nut and the consequent enlarging of the thrust area. The surfaces are thus better adapted to withstanding the pressure and

wear imposed on them when the jaws are forced out to receive the tool. The lubricant is also retained in these surfaces for a much longer period. This means that a greater tightening force may be safely employed, giving a higher gripping power.

The Almond chuck is made in three sizes. No. 1 takes up



Geared Drill Chuck of Improved Construction

to 3/16 inch, No. 2 up to 5/16 inch, and No. 3 up to 1/2 inch diameter. The two larger sizes only are furnished in the geared style, as No. 1 size will hold securely by hand tightening anything up to its capacity. The geared and standard designs in the larger chucks are furnished at the same price. The pinion wrenches are made of high grade tool steel, tempered, and have a high durability, so that replacements are

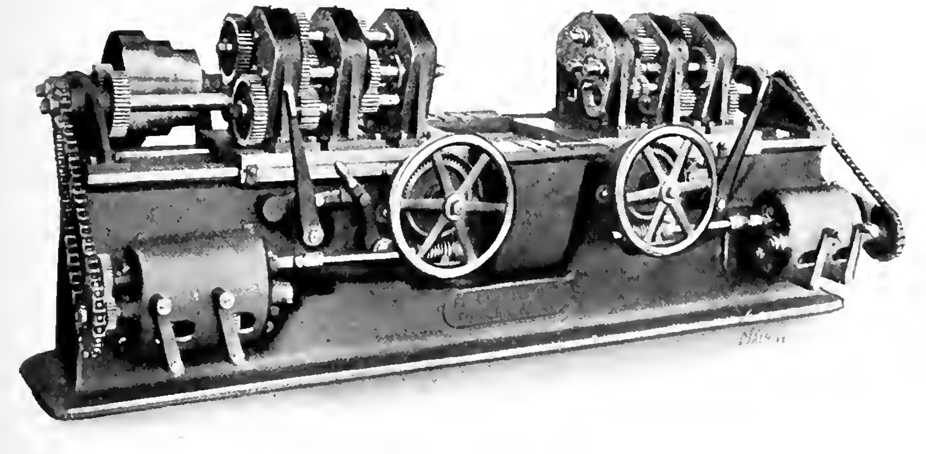


Fig. 1. A Transmission Case Boring Machine which provides for a Variety of Lay-outs

unnecessary. As in previous designs, long life and continued accuracy in the chuck itself have been secured by the high quality of materials employed, and a high grade of workmanship.

BEAMAN & SMITH TEN-SPINDLE TRANSMISSION CASE BORING MACHINE

The accompanying illustrations show a ten-spindle boring machine made by the Beaman & Smith Co., of Providence, R. I. It is intended for the special work of boring the shaft and intermediate stud holes in automobile transmission gear cases. These holes are bored from both ends of the case simultaneously, and provision is made in the arrangement of the spindles for different lay-outs for the positions of the shafts in the work. In the example shown the spindles are arranged for cases of four different designs, as indicated in Fig. 2; three of these are of the vertical type (Nos. 1, 2 and 4), while the other (No. 3) is of the horizontal type. The distances between the main shafts in Cases 1 and 3 are the same, and in Cases 2 and 4, but the lay-outs for the intermediate stud may be different for each, by having two of the spindles for these in one head and two in the other.

The general arrangement of the tool will be easily understood from Fig. 1. The machine consists of a long base provided with ways on its top surface on which slide the two spindle heads. These latter are each driven by separate cone pulleys and each is provided with its own feed mechanism, so that the two may be operated entirely independently of each other, both as to feeds and speeds. The work fixture is clamped to the top surface of the slide brackets which may be seen extending out front and back of the machine between the heads. Suitable T-slots and grooves are provided for

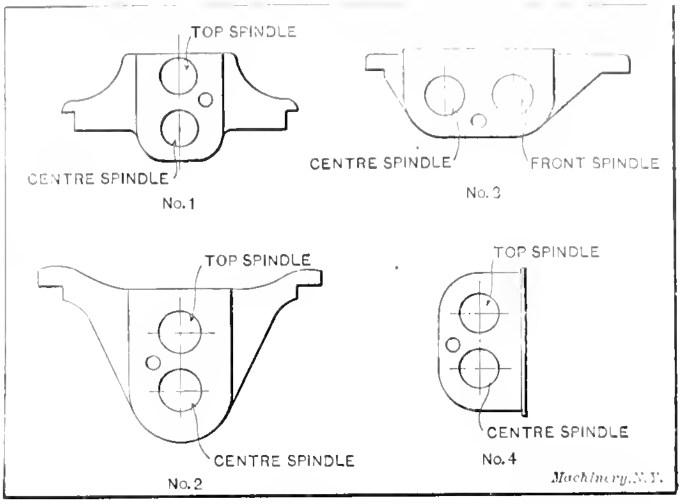

Fig. 2. Four Designs of Case for which Machine is adapted

locating it and bolting it down. The spindle head slide will be seen to extend forward of the heads, passing underneath the fixture when fed up to the work. The various boring tools are thus firmly supported, having a thrust directly downward onto the bed of the machine without any real overhang.

Three threaded spindles and two smaller slotted ones are provided on each head. The former bore the holes for the main and secondary bushings, while the latter drill the holes for the intermediate studs. Not more than three spindles in a head are in use at one time. The ordinary arrangement would be to have three employed in one head and two in the other, since the intermediate stud hole is found at one end of the work only. For boring the vertical type of gear-box, the top and center spindles, as shown in Fig. 1, would be used, with the upper of the two slotted spindles. For the horizontal type, the center and front spindles would be used, with the lower of the slotted spindles for the intermediate stud. The arrangement of the intermediate stud holes may be somewhat different in the left-hand head, making provision for different lay-outs, as has been explained.

The method of driving the various spindles and of chang-

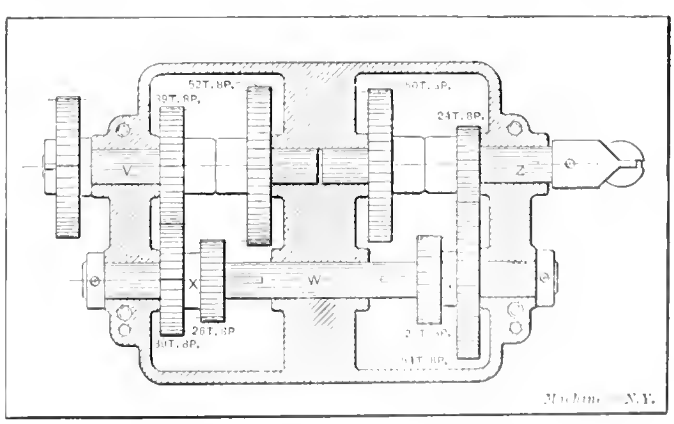

Fig. 3. Arrangement of Gearing in Feed Box

ing the connections for either the horizontal or vertical types is most plainly shown in Fig. 1. Gears *E* and *F* are driven from the pinion on the driving shaft geared to the cone pulley (see Fig. 1), and revolve continuously. Gear *E* drives shaft *A*, which has mounted on it a slip gear *D*, which may be changed to take the position *D'* if desired. In the position *D*,

this slip gear engages gear G on the center spindle H. (It should be understood that this diagram is a development and not a plan.) In the position D' it drives gear J, which is connected to the top spindle K. This spindle, in turn, carries a gear L which, through intermediate gear M, drives pinion

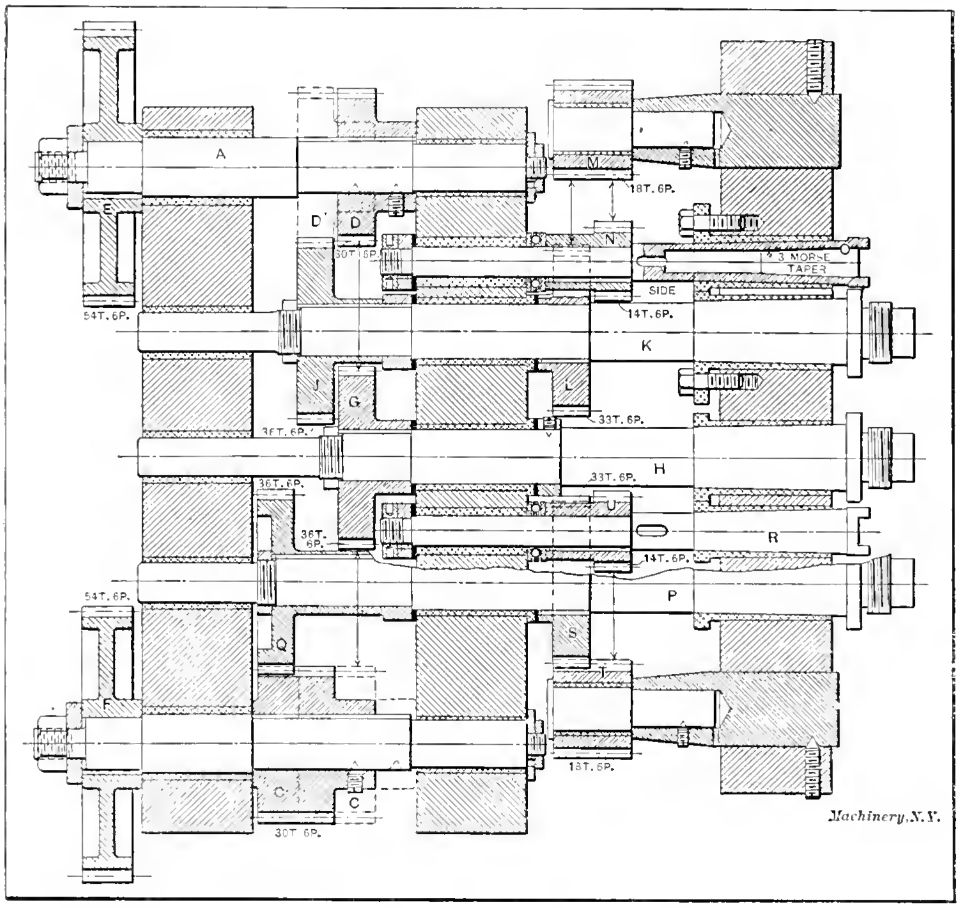

Fig. 4. Arrangement of Head Gearing, by means of which Spindle Movements are controlled

N on slotted spindle O. Thus in position D, center spindle H is driven, while in position D', top spindle K and slotted spindle O are driven.

In a similar manner, gear C has two positions. In the position shown, it drives front spindle P through gear Q and also slotted spindle R, which is connected with P through gears S, T and U. In position C', center spindle H only is driven through gear G.

It will be seen that in the position shown, with the slip gears at C and D, spindle H, slotted spindle R and front spindle P are being driven. This is the combination used for the horizontal transmission case. For the vertical case, the slip gears are changed to position C' and D', driving top spindle K, slotted spindle O and center spindle H. The three-step cone pulleys provide three changes of speed for each head.

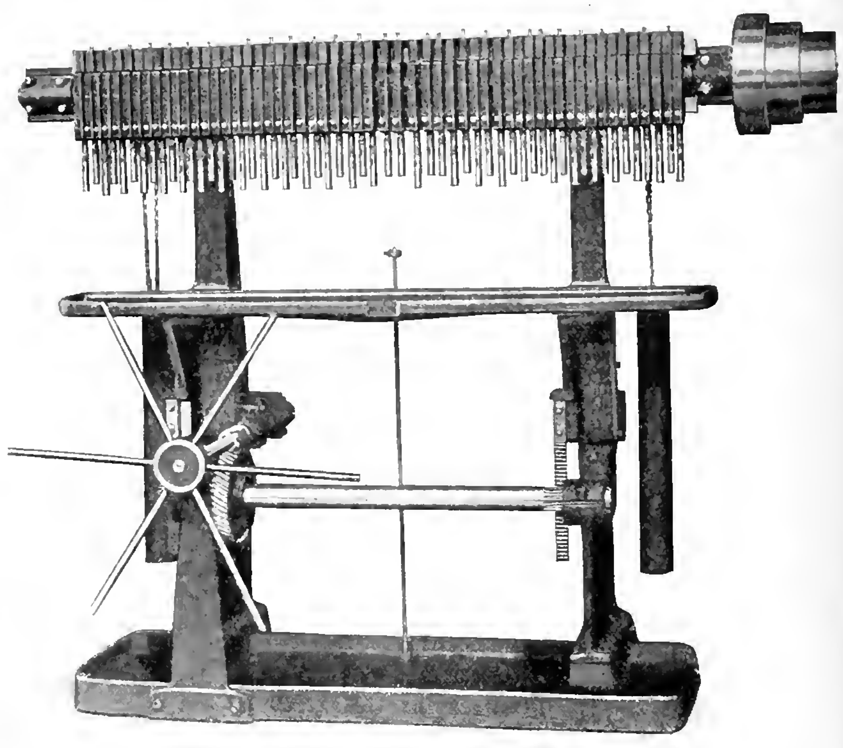
The gear-box gives four changes of feed; the construction is shown in Fig. 3. Motion is received by shaft V, which is provided inside the casing with two gears, one of 39 and the other of 52 teeth, as shown. On the intermediate shaft W is mounted the double gear X, either end of which may be engaged with the corresponding gear on shaft V by manipulating one of the handles shown at the front of the casing. At the other end shaft W carries a similar double gear Y, either side of which may be thrown into engagement with the mating gears on shaft Z by the operation of the second lever on the front of the casing. Four speeds may thus be given to shaft Z for each speed of shaft V, by the manipulation of the two levers of each gear-box. The feed is through a rack and pinion motion, driven by worm-gearing. An automatic stop is provided to arrest the feed, when the proper depth of boring has been reached. The length of feed is about two feet, and quick power movement is provided in each direction. The control handles are all in convenient reach of the operator. All feeds and speeds are positive. The machine is shown in Fig. 1 with all the gearing exposed. This is done simply to show the arrangement of the drive in actual use. Guards are provided which completely protect the gears from accident, either to themselves or to the operator.

This machine will, of course, be furnished with heads to suit any lay-out of transmission case. It weighs about 9,500 pounds.

MOLINE MULTIPLE SPINDLE DRILL

The multiple spindle drill made by the Moline Tool Co., of Moline, Ill., is unique in a number of particulars, especially in the closeness of spindle spacing permitted by the construction, the wide range of horizontal adjustment provided, and the ingenious arrangement of the drive. These characteristics are well illustrated in the special drill of recent design shown herewith.

The cross-rail at the top of the machine is provided with ways along which the narrow spindle heads are adjusted. Journal bearings are placed at each end for supporting a spiral gear which extends the full length of the ways. This spiral gear has further support besides that given by the journals, having a continuous bearing on its outside diameter in a seat formed



A Fifty-eight Spindle Drill, permitting Unusually Close Spacing

in the cross-rail. The heads are of steel to give them the required strength and stiffness in the very narrow width allowed them. The spindles are of tool steel, ground to size,

and run in bronze bushings. They are provided with ball thrust bearings. The lower bushing is threaded to give a vertical adjustment accommodating different lengths of drills. These heads are but ⅞ inch thick and may be brought close up into contact with each other, so that the minimum spacing possible is ⅞ inch.

The table is mounted on brackets gibbed to ways on the face of the housings at each end of the machine. The feed is by a rack and pinion movement. The pinion teeth are cut directly in the heavy feed shaft shown. In the particular case here illustrated, hand feed only is provided, being applied by a pilot wheel connected to the shaft by worm-gearing. Power feed will be furnished when desired. The table is counterweighted, and a stop is provided for its vertical movement, thus limiting the depth of holes drilled.

In the machine here illustrated, fifty-eight spindles are provided, but, of course, only as many of these will be furnished as are required by the purchaser. The adjustment range gives a minimum of ⅞ inch and a maximum of 5 feet. The machine is intended for light drilling particularly, but where comparatively few spindles are used drills as large as 5/16 inch may be employed.

IMPROVEMENTS IN KINKEAD SHAFT LEVELING APPARATUS

In the June, 1909, issue of MACHINERY, we illustrated a line of shaft leveling apparatus made by the Kinkead Mfg. Co., 7 Water St., Boston, Mass. This apparatus consists essentially of a special architect's level, a portable target hung from the shafting to be lined up, and a fixed target attached to a wall or other convenient permanent support. A line is established between the level at one end and the fixed target at the other. The portable target is moved along the shafting, to successive locations near each of the hangers, in turn. Error in alignment is noted through the telescope of the level by direct reading on notched graduations provided in the target. The method of doing this is given in detail in the article referred to, and will not be enlarged on here.

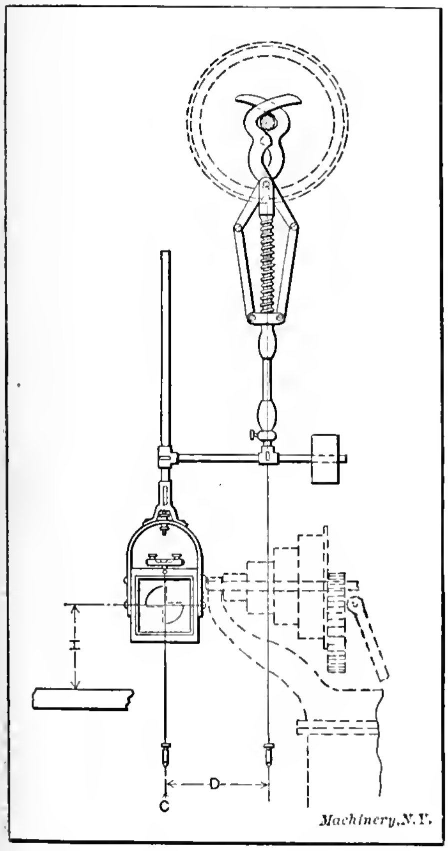


Fig. 1. Running a Line around Obstructions

The makers of this device have recently provided attachments and improvements which enlarge its range and increase its convenience, particularly in the aligning of shafting located in other positions than the usual one of suspension from the ceiling. The various attachments and methods of using them are illustrated in Figs. 1 to 4, inclusive.

Fig. 1 shows a difficulty occasionally met with. In this case, owing to the location of machines or other obstructions, it is impossible to run a straight line directly beneath the shafting, so offsetting the line has to be resorted to. In this case a special offset fixture is provided, as shown, with an adjustable counterweight which is used to bring the device into plumb in the vertical position. The vertical plumb bob is used as in the regular apparatus to determine when this vertical position has been obtained.

Occasional cases are found in which shafting is laid in pits or beneath the floor. Provision for lining up shafting thus located is shown in Fig. 2. Here the portable target is reversed, being supported in this upright position by an adjustable leg at the side, as shown. The plumb-bob also has to be reversed, of course, being hung from the target itself.

For shafting located in pillow blocks on piers, the arrangement shown in Fig. 3 is employed. This is preferable to the vertical arrangement shown in Fig. 2 since this shafting is usually very heavy and the pulleys on it large, and the horizontal position enables the operator to work from the floor.

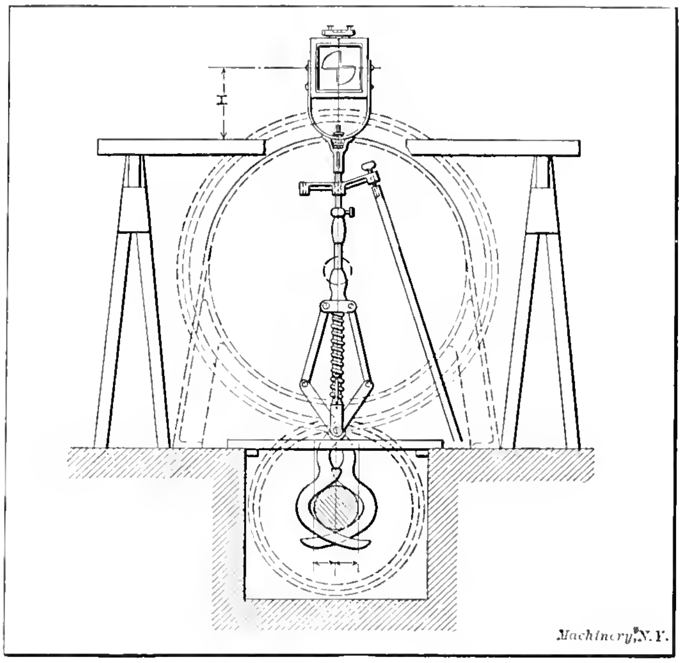

Fig. 2. Lining up Shafting carried in a Pit

The spirit level is attached to the face of the target by means of a special casting designed for the purpose. The target is supported by means of the rod shown, on which the adjustable thumb-screw rests.

It is common in a great many industries to arrange machines on benches, and drive them from a lineshaft beneath. For such work the arrangement shown in Fig. 4 may be employed. The portable target is mounted in fixtures which bring it at right angles with the clamping mechanism and bring it in a suitable place for working the architect's level and the fixed target.

All the various arrangements described provide for the accurate locating of both the level and the fixed target in positions convenient to the operator, and by means which permit

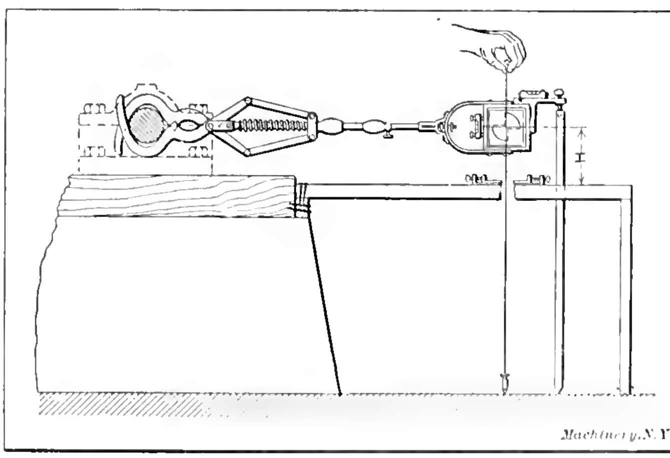

Fig 3. Application to Shafting carried on Pillow Blocks

of the accurate alignment of the shafting. It will be remembered in connection with the former description that the jaws for gripping the shafting are so designed that they will clasp varying diameters without making any difference in the distance from the center line to the center of the target, as they automatically compensate for changes of diameter.

This equipment will be found useful in other ways. It may be employed for running lines of shafting through walls, or for setting up counter- or jack-shafts. It is also applicable to such jobs as the grading of steam and water pipes, the setting up of machinery, and the common problems in surveying

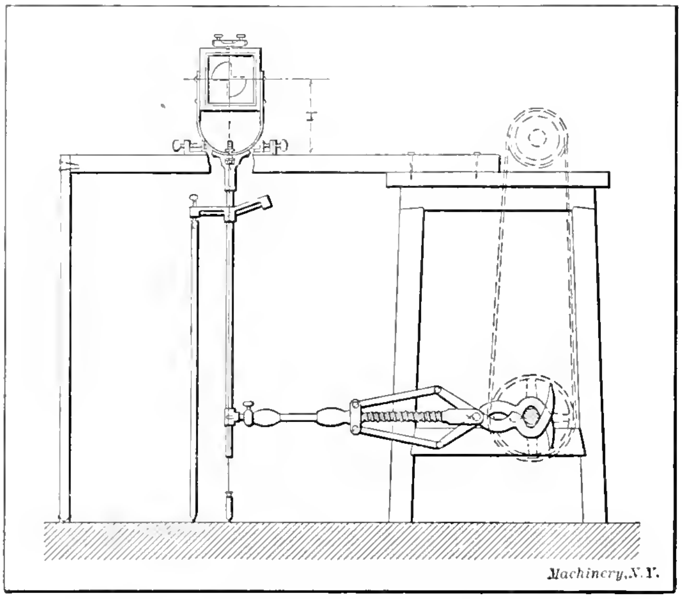

Fig 4. Special Attachments for Lining up Shafting Mounted under the Bench

met with around manufacturing plants. This apparatus is now in use in many large and important mills and manufacturing establishments. It has been found that the accurate testing and maintenance of alignment in line shafting results in a surprisingly large saving of power, and the consequent avoidance of much trouble and expense.

PRENTICE 12-INCH GEARED HEAD REVERSING LATHE

The Prentice Bros. Co., of Worcester, Mass., has built for a number of years a geared head high-speed lathe, which has come into extensive use. The headstock provided with this lathe gives eight spindle speeds, any of which may be obtained while the lathe is in motion, since the changes are made by means of friction clutches of special design, operating without shock or danger to the gears. The arrangement is

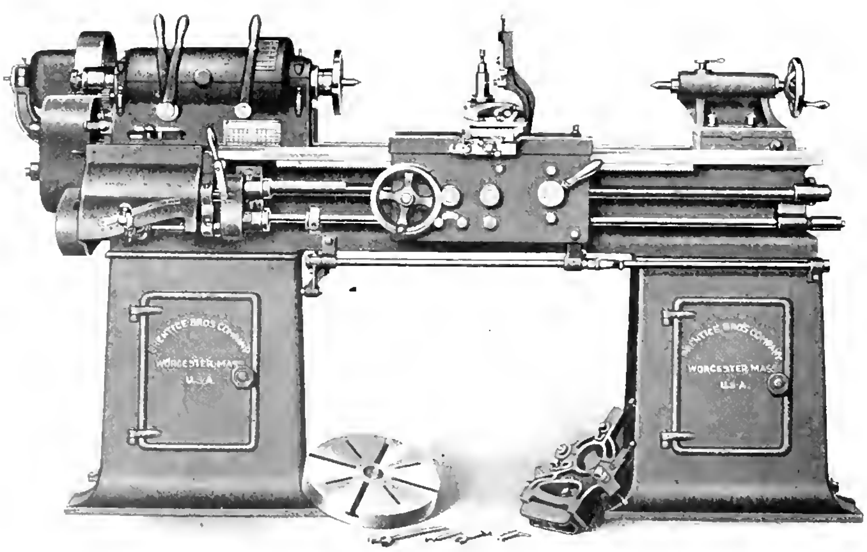

Fig 1. Geared-head Prentice Lathe with Reversing Mechanism incorporated

such that it is impossible to engage two conflicting gear ratios at the same time. The advantages of a constant speed pulley drive of this kind are now well understood, in the matter of giving a constant belt horsepower at any speed throughout the whole range. On this 12-inch swing machine, the belt has a capacity for about 10 horsepower when the countershaft is speeded at the proper rate of 400 revolutions per minute.

An improvement recently incorporated in the design of this machine is shown applied to the lathe in Fig. 1; it is illustrated in detail in Fig. 2. The improvement consists in doing away with the countershaft, by making the reversing mechanism a part of the headstock drive. This is located on the driving shaft and consists, as shown in Fig. 2, of three bevel gears and two friction clutches, together with a lever for operating them.

One bevel gear, *A*, is mounted on the hub of the driving pulley *B*, and when this is engaged to the driving shaft by clutch *C*, a forward movement is given to the spindle through driving shaft *D*. For reversing the spindle, clutch *C* is disengaged and *E* is engaged, so that the spindle movement in the opposite direction is transmitted through gears *A*, *F* and *G*. These bevel gears transmit power, it will be seen, only when the shaft is reversed for threading or similar work. The lever for operating this reversing mechanism is located on and travels with the apron, so that no matter how long the lathe bed may be, the operator always has immediate control of the starting, stopping and reversing of the lathe spindle.

With this reversing mechanism, the countershaft becomes unnecessary, thus saving the two pulleys, shaft, clutches and hangers usually required when using a double friction countershaft. Whenever it is convenient, the lathe may be located underneath line-shafting and belted directly to it.

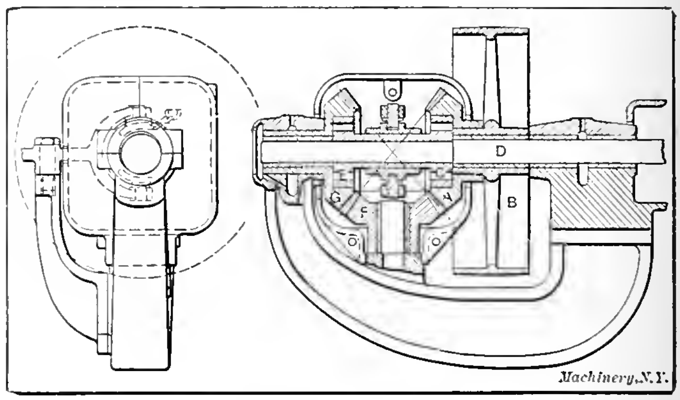

Fig. 2. Arrangement of Gearing and Clutches for Reversing

This construction also has advantages in the application of motor-drive to the lathe; the only additional mechanism that has to be furnished in this case is the motor itself. This is mounted on a bracket which is bolted to the rear side of the head-end cabinet leg. The motor is bolted directly to the driving pulley of the lathe. Provision is made for adjusting the height of the bracket and the tightness of the belt. One of the greatest objections to motor-driven lathes in the past has been the delay in obtaining the motors. This construction will do away with practically all trouble from this source, as any standard type may be used.

As mentioned, the lathe is practically of the same mechanical design as those previously built. It has, however, been redesigned throughout with the idea of making it heavier and capable of more severe service. The carriage is rigid, with an unusually stiff bridge, has a long bearing on the V's and is gibbed to the bed. The end thrust of the spindle is taken by a step bolted to the end of the headstock and entirely independent of the spindle bearing. A gear mechanism is furnished which permits the instantaneous change from one feed to another. There are 44 ratios available for screw cutting, ranging from 4 to 60 threads per inch. The index plate provided makes these changes so simple that an inexperienced hand can operate the mechanism without danger of mistake. An automatic stop to the feed is provided, which disengages a clutch on the feed rod at any desired length of cut.

Large and small faceplates, center-rest and follow-rest, and

the required wrenches, are supplied with each lathe. When specified, the makers will supply at extra cost, taper attachment, countershaft (either of the tight or loose pulley styles) and electric motor attachment of any style or make of motor. The net weight of the machine with a 6-foot bed is 2,065 pounds.

CELFOR TAPER SHANK TWIST DRILL

The Celfor Tool Co., of Buchanan, Mich., has for some time past been supplying a drill made from a flat bar of high-speed steel. These drills are twisted while hot in especially designed machines. The resulting form has an increase of torsional strength of nearly 50 per cent over that of the flat bar from which it is made.

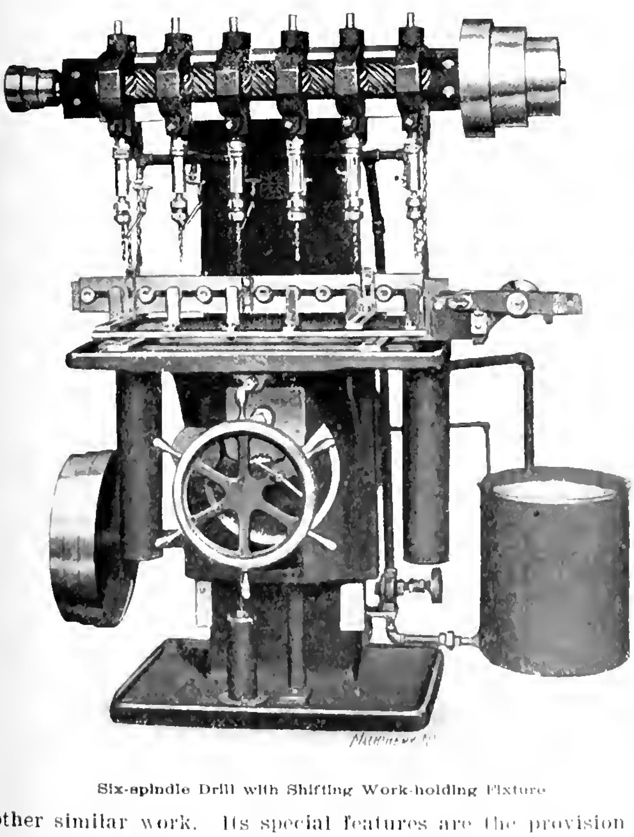
This drill has previously been left with the flat tang, and so has required a special form of drill chuck. The manufacturers are now, however, furnishing it with standard Morse

Celfor Drill, Twisted from Flat Stock, and set in Taper Shank

tapers, so that they can be used in the drill press spindle directly. The drills themselves, which are unchanged, are set into these taper shanks. The taper is one size larger than the standard employed for twist drills, so that ample driving power is assured, avoiding the difficulties met with in the failure of the tang on high duty work. As compared with the standard twist drill, the Celfor type is nearly twice as thick through the center, and has nearly 60 per cent more clearance space for the escape of chips. This results in requiring less operating power, owing to the relief from the clogging of the chips in a deep hole. The drills are accurately finished, being milled and ground in accordance with the best practice for such work.

MOLINE CONTINUOUS SIX-SPINDLE PIN DRILL

The machine shown herewith is made by the Moline Tool Co., Moline, Ill. It is designed especially for the rapid and economical drilling of cotter holes in brake pins, or for any



Six-spindle Drill with Shifting Work-holding Fixture

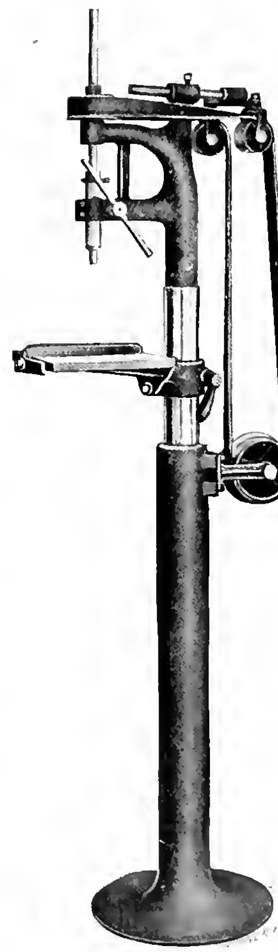
other similar work. Its special features are the provision of an adjustable jig for holding pins of different diameters and different lengths with precision, and also the arrangement for inserting and removing one set of parts while the others are being drilled. The machining operation is thus practically continuous.

The jig has twelve stations, while the machine has but six spindles. The operator places the pins to be drilled in every alternate station of the jig, which he then slides endwise to bring beneath the drill spindles, after which he starts the feed. While these are being drilled, the operator removes the work from the other stations and fills them again, ready to be shifted in their turn under the spindles as soon as the first lot is completed. The feed mechanism, as will be seen, is effected by a cam movement, so that the work-table drops instantly when the holes are drilled through. This movement is continuous, although it can be thrown out and the table lowered by hand if desired. There is an adjustable stop under the table so that it drops only far enough for the jig bushings to clear the drills. This can be dropped out of position and the table lowered clear down.

The spindle drive and the spindle head construction is along the lines of the regular multiple spindle drills made by this firm, and illustrated in connection with the fifty eight spindle drill described elsewhere in this number. The spindles have ball thrust bearings and vertical adjustment for different lengths of drills. The machine is furnished with or without pump tank, piping, jigs and chucks. It may be used as a regular six-spindle adjustable drill when the special jig is removed.

TEN-INCH FLOOR DRILL

The bench sensitive drill press made by the Rockford Lathe & Drill Co., of Rockford, Ill., and described in the department of New Machinery and Tools of our number of November, 1909, is now furnished by the makers as a floor machine. The accompanying illustration shows it so arranged. It will be furnished with or without countershaft. It is provided with a belt-tightener and endless belt as shown. A tool-pan is mounted on the column, which does not appear in the engraving.



Ten-inch Sensitive Floor Drill

The spindle is 17 inches long and 3/4 inch diameter. It is provided with a lever feed of 3 inches. The table has a surface of 8 by 8 inches and a vertical adjustment of 9 inches. The greatest distance from the spindle to the table is 12 inches. The driving pulley on the countershaft is 5 inches in diameter, 1 5/8-inch face, and should run 550 revolutions per minute.

The advantages of the swiveling and tilting table and adjustable gage, furnished with this machine, have been described in connection with previous designs.

FRITZ "IDEAL" DRAFTING TABLE

The Fritz Mfg. Co., of 60 Alabama St., Grand Rapids, Mich., builds a line of drafting tables designated as the "Ideal," which is intended to meet the demand of draftsmen, students, etc., who need a good piece of furniture at a reasonable price. The construction is designed to be strong, durable and unusually rigid.

The standards are slotted and the cross bar is tenoned into the slot. The cross bar is bored its full length for a rod, carrying a hand nut at one end, by means of which the legs are clamped in place. By loosening this adjustment the table

may be raised or lowered. When the nut is turned up, the table is held firm and rigid and does not allow the slightest vibration. The table can be tilted from a vertical to a horizontal position. This is effected by metal slides and braces. After the adjustment, it is clamped at both sides by a single thumb-nut at the right-hand side.

A Rigid and Inexpensive Drafting Table

When desired, a carefully finished tool cabinet will be furnished. This cabinet is provided with two drawers, the upper one of which may be drawn out to be used as a tray. These drawers are 6 by 20 inches; the upper one is two inches deep, and the lower three inches deep, inside measurement.

The frame of the table is of hard wood. The top is ordinarily made of soft wood, but for the smallest size (22 by 30 inches) it will be furnished in hard wood if desired. Four sizes are made, ranging up to 37 by 48 inches.

KEMPSMITH NEW UNIVERSAL DIVIDING HEAD

One of the most important accessories used with a milling machine is the universal dividing head, and many considerations must be taken into account in its construction. The dividing head is used frequently and on greatly varying classes of work, and the work done must, as a rule, be accurate. It is, therefore, necessary that the dividing head be carefully designed and accurately made; at the same time it must be of such construction that the requisite strength is provided. The accuracy must be preserved, facilities for proper adjustments must be included, and when in use it must be convenient to handle and operate, as well as universal in its scope.

An improved universal dividing head as illustrated in the accompanying half-tone, Fig. 1, has recently been brought out by the Kempsmith Mfg. Co., Milwaukee, Wis. In the design of this dividing head the various considerations referred to above have been given due attention. The dividing head is substantial and compact in its construction, and there is a notable absence of complicated mechanism.

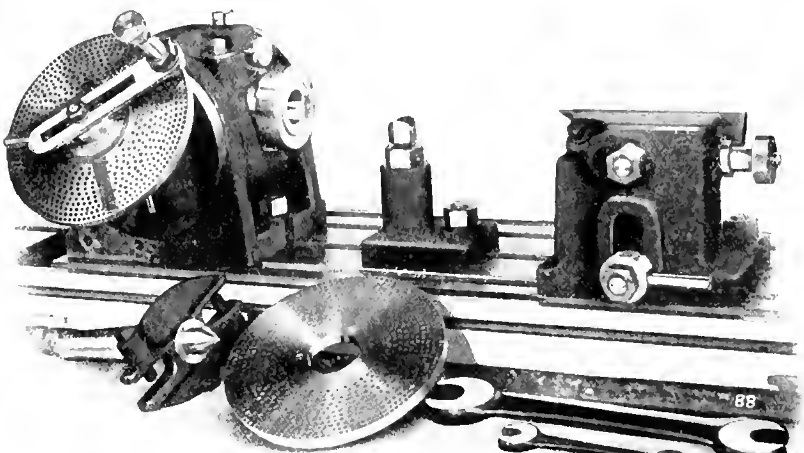


Fig. 1. New Type of Universal Dividing Head, brought out by the Kempsmith Manufacturing Co., Milwaukee, Wis.

Dividing Mechanism

It is evident that the most important feature of any dividing head is the dividing mechanism, and a large diameter of the worm-wheel is essential for accuracy. The usual method employed for making the worm-wheel of large diameter is to mount it at the extreme end of the spindle, practically outside of the main frame. This method, however, is objectionable because it brings the working strain on one end of the spindle, and the worm-wheel casing is in the way when work is to be done close to the head. On the dividing head shown in the illustrations, the worm-wheel is mounted centrally inside of the head, between the front and rear spindle bearings. It is pressed on the spindle and keyed, thus insuring a positive movement of the spindle when the wheel is engaged by the worm. The angular position has been adopted for the worm-shaft. It is at an angle of 36 degrees with the horizontal, which brings the point of contact of worm and worm-wheel correspondingly around at an angle with the vertical. This arrangement makes it possible to increase the diameter of the worm-wheel because the angular position of the worm-shaft and index plates avoids interference of the latter with the table. In the head of 10½ inches swing, the diameter of the worm-wheel is 5¼ inches, and in the head of 13¼ inches swing, the diameter is 6½ inches. Fig. 2 shows the rotating arm or block with the spindle and worm-wheel in place, and Fig. 3 the spindle and worm-wheel assembled. In Fig. 4 is shown a horizontal and vertical section of the dividing head, giving a general idea of its design.

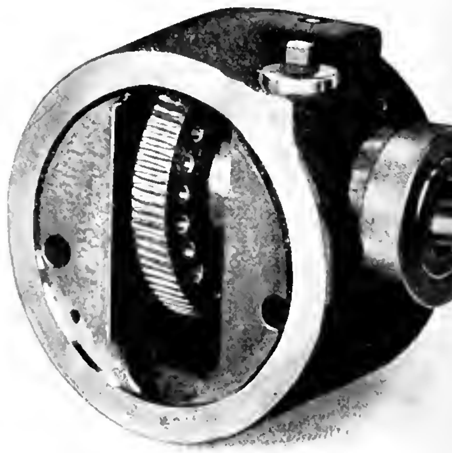

Fig. 2. Rotating Block of Kempsmith Dividing Head

As will be seen, the worm is in one piece with the worm-shaft, which is mounted in a long bearing extending up to the shoulder formed by the worm itself. This arrangement provides for a strong bearing support close to the point of contact between the worm and the worm-wheel. The worm runs in oil, the oil pocket being shown in Fig. 3 and in the vertical section of Fig. 4. An outside adjusting screw is provided by means of which the wear between the worm and worm-wheel is taken up. This adjustment is in a straight line, perpendicular to the axis of the worm-wheel, and thus preserves the alignment and accuracy, even after repeated adjustments. When direct rapid indexing is required, the worm can be

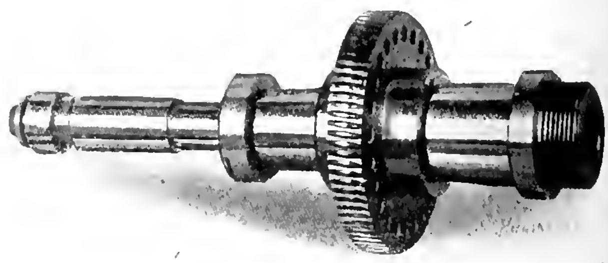

Fig. 3. Dividing Head Spindle and Worm-wheel Aseembled

easily disengaged from the worm-wheel. The arrangement for disengagement is entirely independent of the adjustment, so that this latter is not disturbed. Another advantage of the disengagement is that when tightening the nut on arbors put into the spindle, the worm-wheel teeth do not take the stress.

Range of Index Plates

Two index plates are regularly furnished, providing divisions for all numbers up to 60, and for all even numbers and all multiples of 5 up to 120, and a very liberal number of divisions between 120 and 400. Three specially high number index plates can also be furnished, providing 122 additional divisions between 61 and 400. These plates include all divisions up to 200, which are not obtained by the standard index plates. The arrangement of mounting the index plate at an angle permits of still larger plates being used, if for any extremely special case this should be required, without it being necessary to increase the swing of the dividing head to provide room for the larger plate.

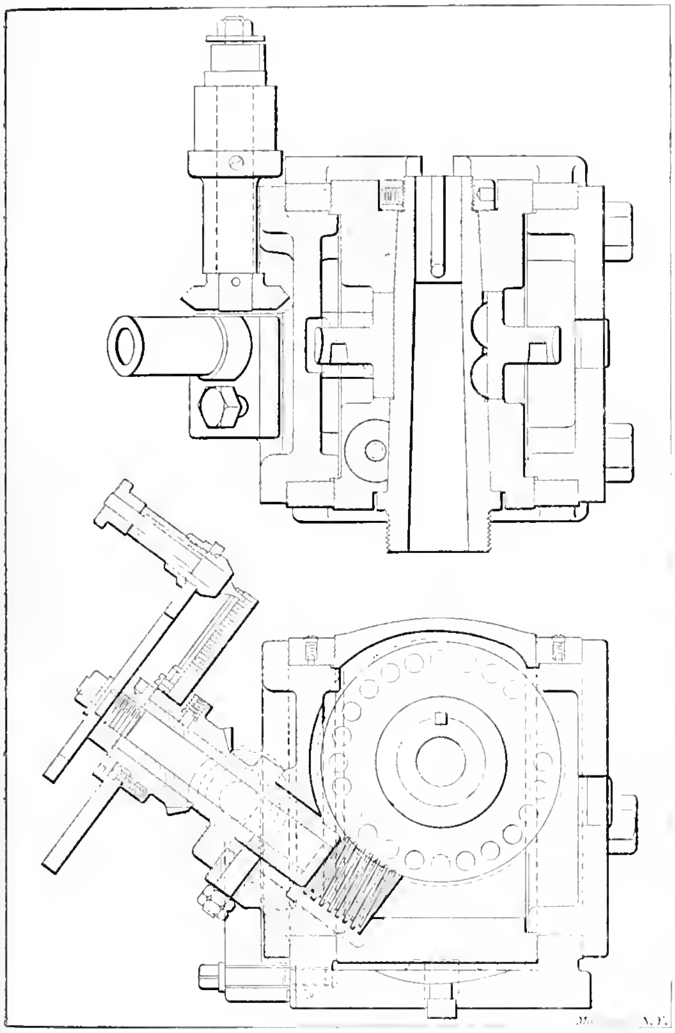

Fig. 4. Horizontal and Vertical Sections of Dividing Head

The index handle is mounted directly on the worm-shaft as shown in Fig. 5, so that its movements are directly transferred to the worm-wheel, leaving no chance for error or inaccuracy through a train of gears. The angular location of the index plate makes it much easier for the operator to see it clearly when indexing, because it is directly in his line of vision as he stands in his natural operating position. It is not required that he stoop down, as in the case when the index plate is vertical.

Direct indexing is easily accomplished with the worm and worm-wheel disengaged. A plunger engages a circle of holes in the front of the worm wheel, as shown in the vertical section of Fig. 4. The spindle is graduated correspondingly on the front of the shoulder, so that the movements can be easily determined. This quick indexing is valuable for small numbers of divisions—for example, when milling hexagons, or the flutes in taps or reamers.

Spindle and Rotating Block

The spindle is of liberal diameter and is mounted in taper bearings provided with a simple but efficient locking device, as indicated by the clamping bushing in the horizontal section in Fig. 4. The taper hole and the threaded nose on the index head spindle are the same as on the main spindle of the milling machine with which the dividing head is regularly furnished. Thus all tools are interchangeable between the main spindle and the dividing head. A large hole runs clear through the spindle. The rear end is arranged to receive an extension stud which is used when the spindle is geared directly to the feed-screw. This arrangement is used when cutting spirals of very short leads as will be mentioned later. This stud is shown in place in Fig. 3. The rotating block which carries the spindle is capable of swinging through an arc of 150 degrees, from 10 degrees below the horizontal to 50 degrees beyond the perpendicular. It is firmly clamped in whatever position set by means of two large bolts with hexagon heads placed in the rear of the head.

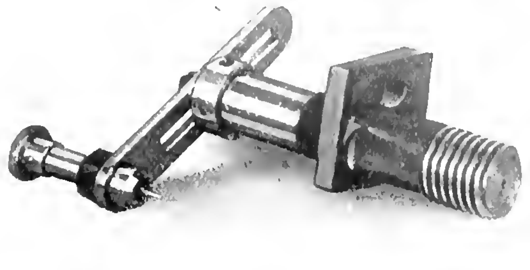

Fig. 5. Worm and Worm-shaft with Index Handle

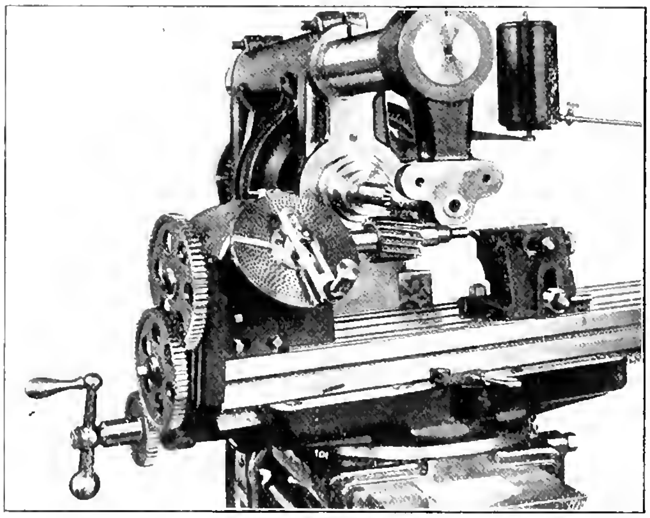

Fig. 6. Dividing Head arranged for Spiral Milling

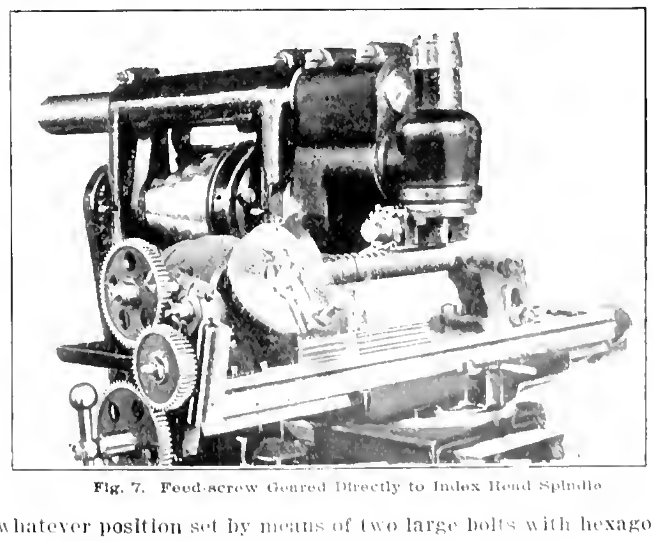

Fig. 7. Feed-screw Geared Directly to Index Head Spindle

Change Gears for Spiral Milling

Twelve change gears are furnished with the dividing head for spiral milling. The change gear bracket is quickly attached or removed. The drive from the change gearing to the

worm-wheel is through two miter gears, one being on the same stud as the last gear in the change gear train, and the other being attached directly to the index plate. In Fig. 6 is shown the dividing head arranged with a train of change gears in the usual manner for cutting a spiral, the work in this case being a spiral milling cutter three inches in diameter, 18 teeth, with 48-inch lead of spiral. When the lead is less than 1½ inch, the gear ratios become so high that too much

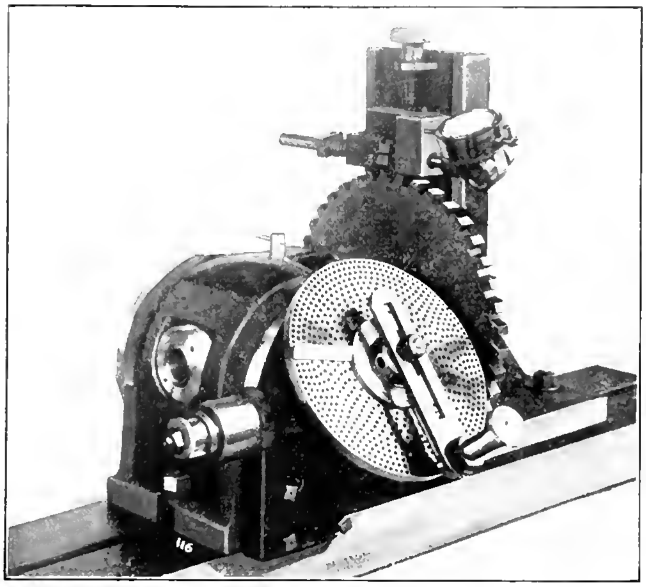

Fig 8. Testing the Worm-wheel

power is consumed in transmission and these leads, therefore, cannot be cut in the usual manner. A very interesting method is, therefore, used for short leads, in that the gear train is led directly from the feed-screw to the dividing head spindle, as already mentioned, the extension stud being provided on the spindle for this purpose. A gearing arrangement of this kind is shown in Fig. 7, which also shows the use of the universal milling attachment when the angle between the cutter and the work is greater than that which can be obtained through the swiveling table. In the charts which accompany the dividing head, the gears required for leads from 0.120 to 1.500 inch are given for direct gearing, and for leads from 1.550 to 100 inches for gearing in the ordinary manner.

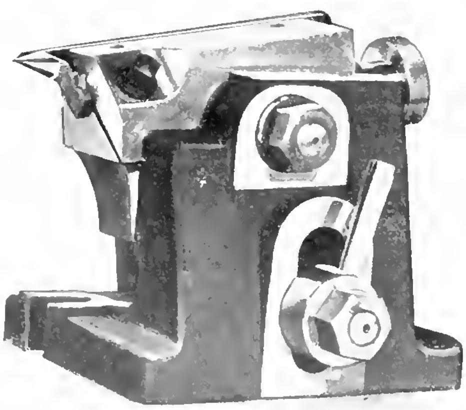

Fig. 9. Tailstock of Kempsmith Dividing Head

Testing the Worm-wheel

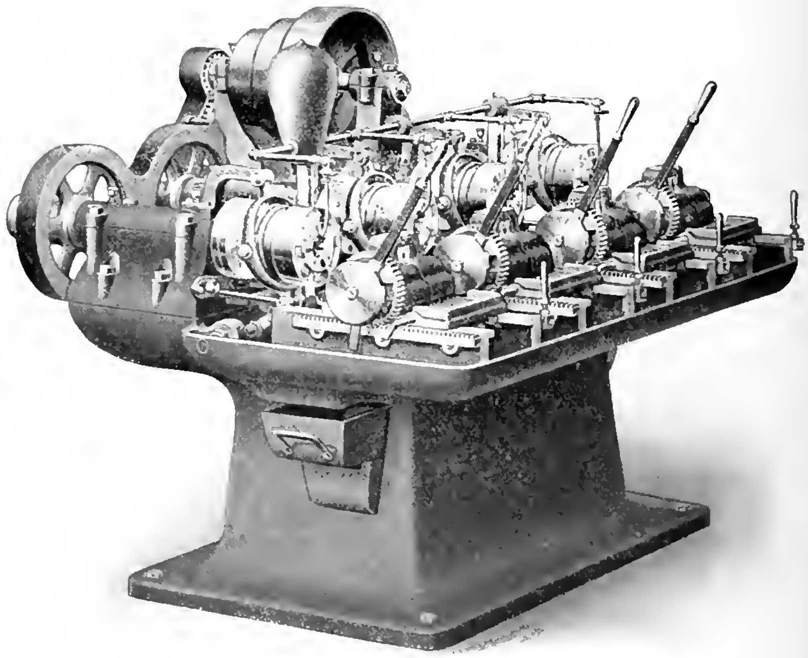
The method employed in testing the accuracy of every tooth in the worm-wheel may be of interest, and is shown in Fig. 8. The master plate is mounted in the spindle. This plate has 40 perfect divisions, and, therefore, makes it possible to test the relative and cumulative error for the individual teeth. The maximum relative error allowed on the master plate itself is 0.0005 inch, and the maximum cumulative error at any point on the master plate is 0.002 inch. The average is less than one-half of this. The master plate is 11 inches in diameter and the worm-wheel for the 10½-inch swing head, 5¼ inches, as already mentioned; hence errors on the master plate are correspondingly reduced on the worm-wheel proper.

The Tail-stock

The tail-stock is of the side center type and is shown in Fig. 9. The center is set into the tail-stock at an angle so that the actual center is within ⅛ inch of the inner side of the tail-stock and within ⅛ inch of the top. This arrangement is of great importance as it provides for clearance for cutters and makes it possible to use much larger cutters on many classes of work than would otherwise be possible. This, again, often effectually increases the output of the machine in such instances. The center, by a special arrangement, as indicated in Fig. 9, is firmly fixed in the tail-stock, and a rapid and easy adjustment is provided. A rack and pinion furnish means by which it can be elevated for milling tapers, after which it can be tilted and clamped in alignment with the work.

NATIONAL QUADRUPLE-SPINDLE BOLT CUTTER

The National Machinery Co., of Tiffin, Ohio, is building the four-spindle bolt cutter illustrated herewith. This is provided with the makers' standard opening die and is built in several different sizes. The convenient design of this machine makes it possible for a workman, where the thread is of reasonable length, to feed all four spindles with as little loss of time as when handling the ordinary single or double spindle bolt cutters. A patented single lever vise and carriage movement is used, which enables him to control the carriage and the gripping of the work with a single lever. This is operated with the left hand, leaving the right hand free for placing and removing the work in the vise. The machine is thus particularly adapted to large lots with comparatively long lengths of thread.



National Quadruple-spindle Bolt Cutter

A combined automatic and hand opening and closing device for each head will be furnished, and these heads can be run independently or in unison. The drive is furnished by a three-step cone pulley, placed on top of the machine. This reduces the floor space, enables the shaft to be supported at both ends, and keeps the belt free from grease and chips. The die heads provided on the machine are self-contained, and do not depend on outside mechanism to control the locked position. This makes the head practically a solid die when closed, insuring accuracy in the product. The makers' interchange-

able case dies are used. The machine has a forced-feed lubricating pump, with adjustable stroke for regulating the flow.

WALKER "SINGLE STROKE" SURFACE GRINDER

The accompanying engravings illustrate a very attractive design of rotary surface grinder of the cup wheel type, made by the Walker Grinder Co., Worcester, Mass. This machine differs from other cup wheel surface grinders in that no reciprocating movement is provided for, the work being mounted on a rotary magnetic chuck, while the wheel is fed straight down against it until it has been finished to the proper thickness. It thus has a large field in the accurate surfacing and sizing of such parts as piston rings, thrust collars, small dies, milling saws and other work of a like nature.

General Design

The general design of the machine comprises a stiff colnmn of vertical form, provided with two vertical slides, the lower of which carries the rotating wheel-spindle, which is adjustable for height to give the desired thickness of work; the upper or wheel-slide carries the wheel-spindle, and is fed down against a positive stop to obtain the proper thickness in the parts being ground. A single pulley drive is employed which provides power for all the movements of the machine, and makes it easily adaptable to motor driving. Two work-spindle speeds are furnished. The single lever which controls

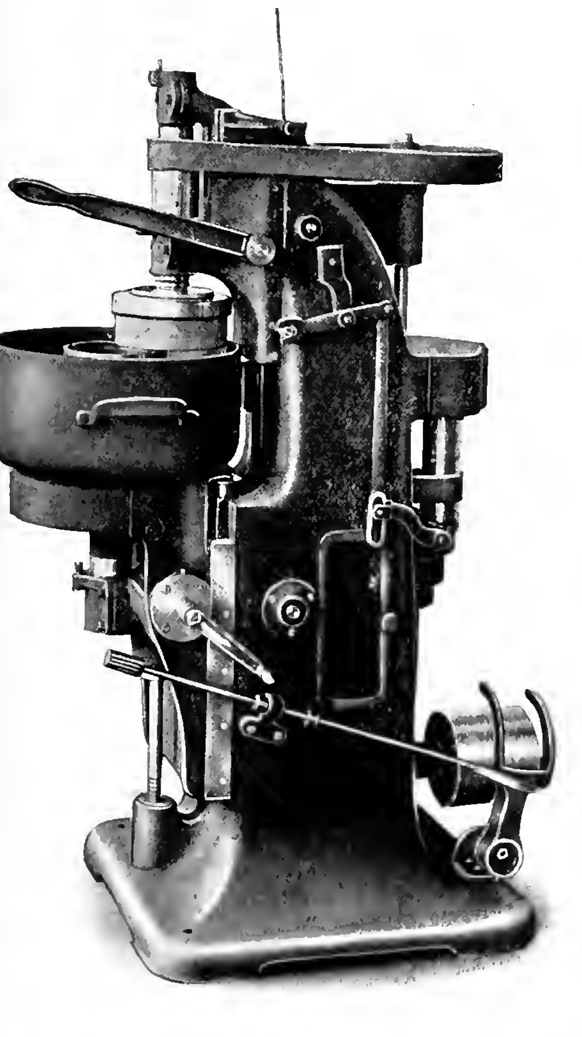


Fig. 1. A Rotary Surface Grinder, provided with Magnetic Chuck

the feeding movement of the wheel-spindle slide also operates to control the starting and stopping of the work-spindle, the switching on or off of the magnetizing current for the chuck, and the control of a demagnetizing current for eliminating the residual magnetism, to permit the work to be removed easily and without scratching. These last features are recent inventions of Mr. Walker, which will be described further on. Their use, in combination with the other improvements furnished, has made possible the rapid manipulation of the machine, and, consequently, gives it a very high output.

The Driving Mechanism

The details of the construction are best shown in Fig. 3, which should be studied in connection with the elevations in Figs. 1 and 2. The tight and loose driving pulleys are shown at *A*. A belt shifter is provided whose handle extends forward to the operator's working position. The pulley *B*, inside

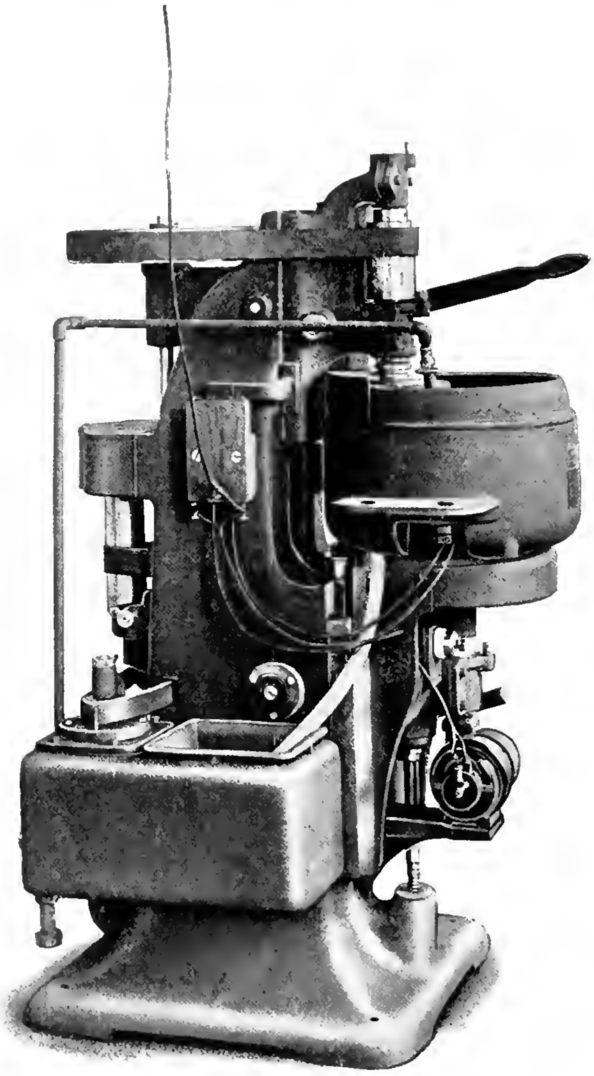

Fig. 2. Machine as arranged for Wet Grinding

the column, is connected by a quarter turn belt with pulley *C* on a vertical driving shaft, the upper end of which carries a large pulley *D*, belted to the driving pulley *E* on the wheel-spindle. The latter has a long enough face to permit the free vertical movement of the wheel-slide *F* by the operation of handle *G*. The wheel-spindle is provided with ball thrust collars on both sides of its lower bearing. Vertical shaft *H* is also connected by gearing at *K*, with drum *J*. This gearing gives a change of speed for the work-spindle. Pulley *L* on the latter is belted to this drum *J* over an idler. *J*, it will be seen, is long enough to permit the vertical adjustment of work-slide *M* throughout its whole range.

The Automatic Control of Work-spindle Drive, Magnetizing Current, etc.

The grinding wheel *N* is brought down to the work and is fed against it by the operation of hand lever *G* and the rack and pinion movement connected therewith. The positive stop which limits this downward movement is shown at *O*. This wheel-slide is counterbalanced by a weight inside the column, as shown, so that when the handle is released it returns to its upper position, leaving plenty of room under the wheel for the easy placing and removal of the work. The link and lever connections shown at *P* connect the wheel-slide *F* with a jaw clutch inside of drum *J*, disconnecting the latter from the shaft on which it is mounted when slide *F* is in the upper

position. By this means the work-spindle is automatically stopped whenever the wheel is raised from the work.

The automatic control of the magnetizing current is effected by a switch mechanism enclosed in the casing shown at the side of the frame in Fig. 1. The wheel-slide carries an arm provided with electrical contacts, which slide over corresponding contacts in the switch box. In the lowermost position, when the wheel is pressed against the work, the direct current is flowing through the chuck. As the wheel is withdrawn, this contact is broken and a new one is made, sending a demagnetizing current through the coils of the chuck. In the final upper position of the slide, the chuck is entirely disconnected from the current, leaving it free for the removal of the work.

The Work-spindle and its Slide

As explained, the wheel-spindle slide is brought down each time to a positive stop. The adjustment for thickness of the work is therefore obtained by raising or lowering the work-spindle slide *M*, by means of the crank shown at the side of this slide in Fig. 1 and connected with elevating screw *R* in Fig. 3. When this adjustment is once made, it holds for successive operations, except as it is affected by the wear of the wheel. For this, compensation is made by the gradual raising of the work-spindle slide. The slide is very long in proportion to its overhang, so that there is little elasticity or lost motion.

Special Provisions for Wet Grinding

Fig. 2 shows the machine as arranged for wet grinding, and Fig. 1 for dry grinding. It will be noted that besides the provision of the standard type of centrifugal pump, reservoir and piping, a blower at the lower end of the work-spindle has been furnished. The purpose and construction of this is most plainly shown in Fig. 3, where it is shown at *Q*. It is driven, as shown, by a direct connected motor, and exhausts into the hollow work-spindle, where the current of air is forced through its whole length up into the interior of the chuck, through the magnet coils, and out under the guards into the water space. This current of air effectively prevents moisture from getting into the coils, and thus obviates any difficulty arising from cross-circuits or other electrical troubles, which are otherwise difficult to avoid where a flood of water is employed. Guard *U*, fixed to the lower slide, and *V*, attached to the upper one, keep the water from flying over the machine and operator.

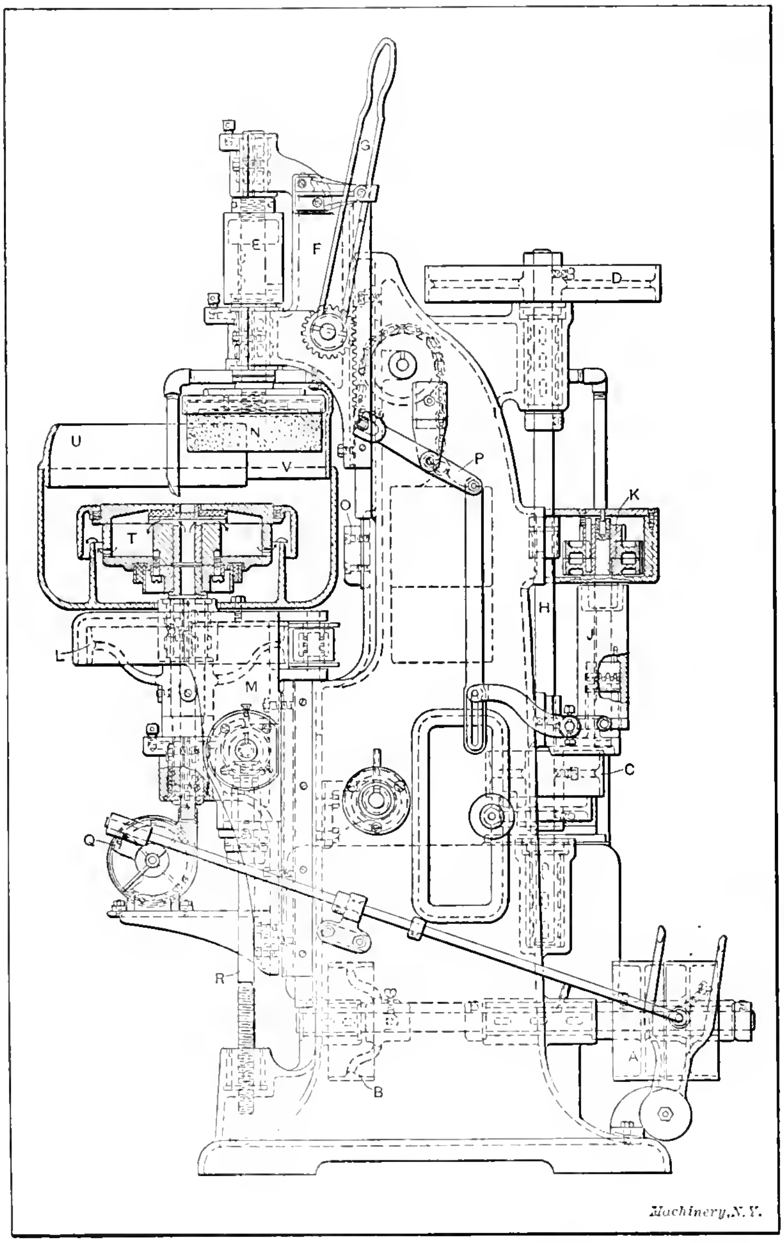

Fig. 3. Details of the Driving and Feeding Mechanism

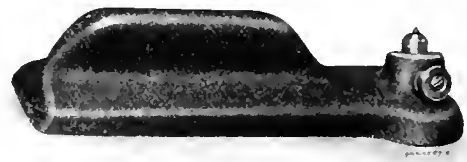

Fig. 4. Tool for Truing, which permits Adjustment of Carbon to present Fresh Cutting Edges

Truing Device for the Wheel

One of the difficulties met with on this style of grinder is the use of the diamond in truing the wheel. The surface of the wheel must obviously be kept true and parallel with the chuck face. To secure this it is necessary that the diamond be mounted in a holder which slides on the chuck face or platen, underneath the wheel. It will be seen that with this arrangement, the wear must necessarily come in one place on the carbon, resulting in a gradual flattening of the cutting edge, and the consequent glazing of the wheel.

Fig. 4 shows an improved carbon truer designed to overcome these objections. In this device the stone is set in a shouldered stem, fitted in the top of a flat holder. This stem is set at a considerable angle from the vertical. With this arrangement, when a flat spot has been worn on the carbon, the stem can be swiveled slightly and fastened in a new position, thus providing a means of obtaining new cutting points on the carbon and a keen cutting surface on the grinding wheel. Means are also provided for disconnecting the automatic switch so that both the magnetizing and the demagnetizing currents are cut off, allowing the free manipulation of the carbon holder when truing the wheel.

An Inexpensive Outfit for Wire Belt Lacing

The diameter of the wheel is 8 inches, and that of the chuck is 10 inches. By reason of the provision of the magnetic chuck, a large number of small pieces may be held at once, making the machine especially suitable for rapid and accurate manufacturing.

MUMFORD WIRE HINGE BELT LACING DEVICE

In the department of New Machinery and Tools of the July, 1909, number of MACHINERY, we illustrated a belt-lacing device made by the Mumford Mfg. and Supply Co., 258 West 22nd St., New York City. This device makes a lacing of the type in which a coil of wire is threaded through each end of the belt. When these coils are interlocked a raw-hide pin is drawn between them, forming the hinged wire belt lacing which has become so largely used on account of its efficiency and durability.

The improvements in the device consist in making provision for both single and double belts and in avoiding the necessity for turning the templet over for lacing the opposite ends of the belt. The way in which these improvements are made will appear from the description. The templet is fastened to the bench in any convenient way. As shown, it is done by staples which project through slots in the plate, and it is locked by a wire rod passing through the staples. The end of the belt is inserted in the turned-up front of the templet, where it is held by lightly driving in one or two wire nails as shown. The slots serve to guide the workman in making the holes with the awl, and in threading the wire through them with a pair of pliers. The wire lacing is threaded over a mandrel placed in the templet in front of the belt as shown.

It will be noted that the slots run right-hand on one side of the center and left-hand on the other. For narrow belts, such as that shown in the engraving, the belt may be doubled back so that both ends are laced at once, one of them right-hand and the other left, allowing the laced ends to interlock properly. Wide belts should be placed in the templet evenly spaced on each side of the center line, so that half of the lacing is right-hand and the other left-hand. When the other end is placed in the similarly laced templet the other side up the two ends will interlock. The original construction provided right-hand slots at one end of the templet and left-hand ones at the other end, necessitating a reversal for each operation. In this improved construction the templet at one end provides for single thickness belts and for double thickness at the other. The slots for the latter are alternately long and short, allowing for staggered lacing.

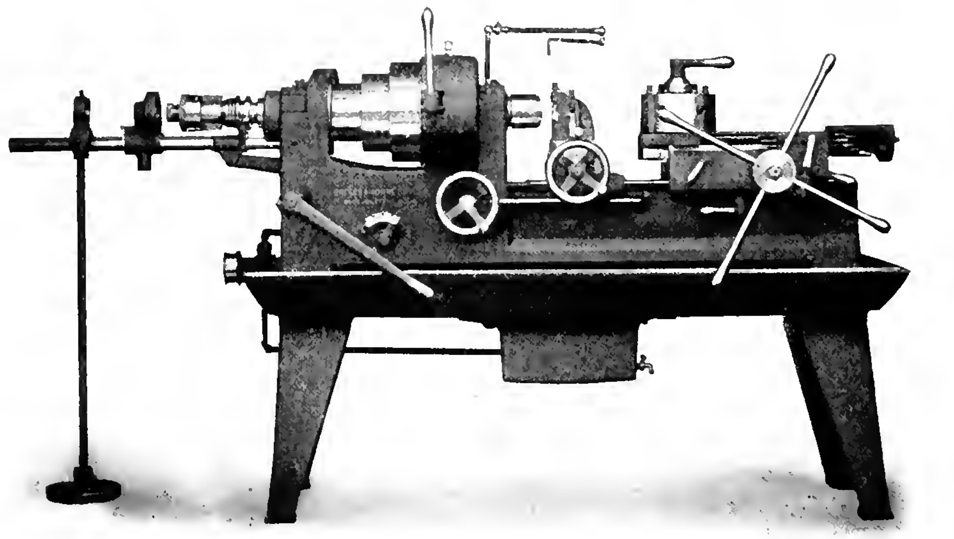
While the device has a width of only 6 inches, it may be used on any width of belt by shifting from one position to another. It is the only tool of its kind which can be used for a belt wider than itself. As previously described, the equipment comprises the templet, the necessary mandrels, an awl, pliers, and a supply of wire and raw-hide pins.

DRESES POWER FEED SCREW MACHINE

The illustration shows a very complete screw machine made by the Dreses Machine Tool Co., Cincinnati, O. This machine is provided with an automatic chuck and wire feed, friction back-gears, positive quick-change feed gearing, power feed for turret slide, separately adjusted automatic stop for each hole in the turret, and fine longitudinal adjustment for cross-slide. The facilities thus provided, in combination with the general excellence of design and workmanship, produce a machine which should be well adapted to a wide range of manufacturing work.

The headstock and bed are cast in one piece, and the design of the headstock provides within itself for the adequate protection of the feed and back-gearing. The spindle is driven by a three-step cone. The frictions for the back gears are of the toggle-joint type, and are so designed that the entire operating mechanism can be put in place or removed without taking out the spindle. These clutches are powerful, easily adjusted and noiseless in operation. The spindle bearings are of the highest grade of babbitt metal, upset into their seats. The nose of the spindle is of an improved construction which provides two blank cylindrical portions each side of the thread, fitting the thimble or faceplate of the chuck. There is no bearing on the thread itself, which merely serves to hold the chuck on and does not in any way affect the alignment. The nose is made very short to bring the work close to the spindle bearing. The thrust is taken up against the inner rear housing of the head, allowing play in the front bearing for the elongation of the spindle from temperature changes. This also reduces the overhang and the length of the front bearing, compared with what would be necessary if the thrust were taken up at that point.

The standard design of chuck and stock-feeding device is used, but special attention has been given to simplifying the operating mechanism, and arranging it for convenient handling. The operating lever, as will be seen, is placed in a position where the workman can exercise the greatest force with the least exertion. The split hub and clamp nut provide for changing the position of this lever to agree with the build or strength of the operator. It will be noted that the thimble for spreading the chuck fingers at the rear end of the spindle is provided with steps, which permit of a considerable variation in the diameter of the stock used without requiring the machine to be stopped for readjustment.



Dreses Screw Machine with Improved Friction Head, Geared Feed and Multiple Stops

The turret has an index ring of as nearly the full diameter as is practicable. A long square gibbed locking bolt holds it firmly into position. By the construction employed, the wearing surface of the turret and slide is not interrupted by the locking bolt, and no particle of metal from the wear of this member in its seat can abrade the surface. Provision is made for taking up the wear of the turret on its stem.

The turret slide is provided with a series of six stops, one for each hole in the turret, mounted on a bracket in the turret slide base. An abutment on the turret slide is provided, which is shifted from one of these stops to the other by a cam placed on the bottom of the turret. This abutment or stop dog makes about one-quarter revolution between the extremes of its movement. By means of an automatic locking plug, it may be instantly put out of action so as to clear all six stops. The bracket in which the stop screws are placed slides in a dove-tail on the turret slide bed. When the stop dog strikes one of the screws, it moves this bracket forward, knocking off the power feed. A slight additional movement can be given it by the pilot wheel for taking a finishing cut on a shoulder, and for cleaning out the chip left by the tool. A geared power feed of four changes is placed in the rear of the bed, and the changes are controlled by the small crank-handle shown beneath the headstock.

The cutting-off rest has a fine longitudinal adjustment on the bed by means of the handwheel, bevel gears and adjust-

ing screw shown. The cross-feed screw is provided with a graduated dial on the handwheel hub. The toolposts are of an improved design. They are open at the left-hand side, permitting them to be adjusted close to the face of the chuck. The wedges under the tools have a single dove-tail to keep them back in position, and knurled thumb-screws are provided for shifting them to adjust the tools to height.

Provision for a large supply of cutting oil or compound is provided by the very deep pan, mounted under the bed of the machine. The oil reservoir is hinged to the pan so that it can be readily cleaned. The inside is provided with two chambers, in the first of which the grit and dirt is separated and deposited before passing into the second or supply chamber, where the pump suction is placed. The leg at the small end of the table is provided with a hinge-joint, so that the machine rests, in effect, on a three-point bearing support, and the alignment is not disturbed by irregularities in the pull.

The tool weighs about 2,600 pounds. It is built in three sizes to take 1, $1\frac{1}{2}$ and $2\frac{1}{4}$ inches through the wire feed. The illustration shows the $1\frac{1}{2}$-inch machine.

ONEIDA STEEL-REINFORCED INDEPENDENT CHUCK

The line of four-jaw independent chucks made by the Oneida National Chuck Co., of Oneida, N. Y., has recently been greatly improved by an ingenious and inexpensive improvement, the nature of which will be readily understood from an examination of Figs. 1 and 2. This improvement consists in furnishing a steel reinforcement for the cast-iron body of the chuck, so located as to receive the tensile stress imposed by the tightening of the jaws on the work, and at the same time furnish a durable steel seat for the thrust bearing of the screws.

Fig. 1. Independent Chuck, Reinforced for Tensile Strains with a Steel Ring

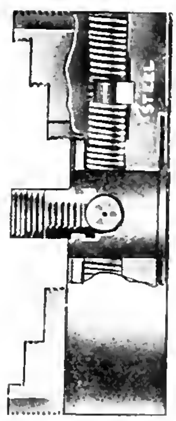


Fig. 2. Showing Steel Ring Cast into Iron Body

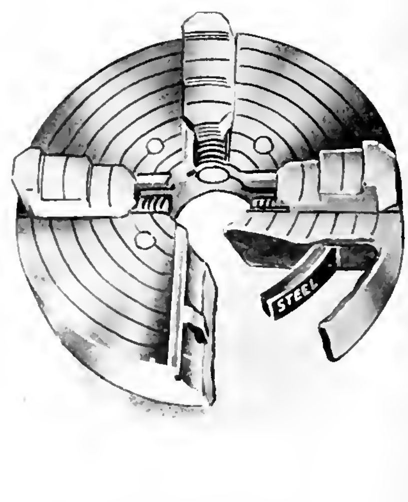

Fig. 3. Showing Location of Reinforcement at Screw Thrust Bearing

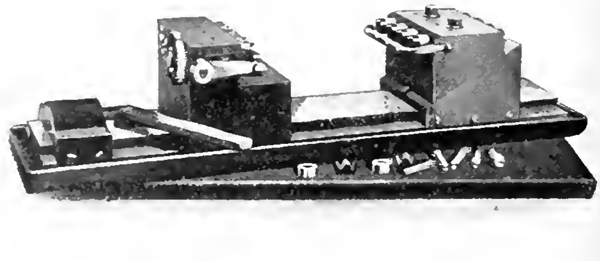
The interesting point in this construction is the way in which the steel is located in place in casting. The steel reinforcement is made in the form of an electrically welded ring of bar stock, which is centered in the mold when the chuck body is cast. When the iron is poured it surrounds this steel ring and incorporates it in the casting. Thus no fitting or machining or extra trouble has to be taken at all in the construction. The various machining operations are gone through with as before, and the added expense of the reinforcement is, consequently, negligible. When the chuck is completed, however, the steel bearing surfaces and the steel ring will be found in their proper places to take care of the tensile forces and to furnish the step bearing for the screw.

Fig. 2 best shows the effect of the ring chuck. It ties the body together, as will be seen. All disruptive strain, due to the tightening down of the jaws, is received by the steel in tension, thus relieving and reinforcing the iron, which is notoriously weak for a stress of this kind. Fig. 3 shows most plainly the way in which the thrust bearing is reinforced by the ring, which gives added durability at this point.

The chuck itself is of high-grade construction, with steel operating screws and jaws properly tempered and hardened. The screws, having a center bearing for the end thrust, are threaded to the extreme outer and inner end, giving the jaws the greatest possible capacity for large diameters. Owing to the reinforcement, it is possible to provide a deep seat for the jaws in the body, giving them unusual resisting power to strains tending to overturn them. The enlarged bearing area thus provided also adds very materially to the length of the useful life of the tool.



Four Spindle Index Head Designed for Rapid Manipulation and Convenient Adjustment

Three sizes of this chuck are now in stock, the 10-, 12- and 14-inch, and it is expected to have all sizes ready shortly after February 1. Inasmuch as this improvement is so inexpensive as not to add to the cost of the chuck, its advantages to the purchaser are obvious.

BICKFORD & WASHBURN FOUR-SPINDLE INDEX CENTERS

The tap and reamer fluting device herewith illustrated is made by Bickford & Washburn, 12 Chapman Street, Greenfield, Mass. It is an apparatus of simple construction for a common operation, and is one of a large number of similar devices which have been in use for many years. In spite of the fact that the purpose of the tool is not new, however, we think it will be agreed, after examination, that the designers have succeeded in incorporating a number of new and valuable features in its construction.

The tool comprises a base provided with a dove-tail slide, on which are mounted a tailstock adjustable for height, a headstock carrying the indexing mechanism, and a clamping block and lever for locking the work in place. This base, with the parts mounted thereon, is clamped bodily in place on the table of the milling machine, so that the device is handled as a single unit.

The headstock contains four spindles, connected together by spur gearing so that they are indexed in unison. The front spindle has mounted on it a bevel gear, meshing with a bevel pinion, which latter is provided with a crank and mounted in a bracket attached to the front of the headstock. One revolution of this crank or handle indexes the work between each cut. By changes in the gearing, 3, 4, 5, 6, 7 or 8 cuts may be taken, and a corresponding number of flutes given to the tap

or reamer. The changes in indexing are made by using different bevel pinions to engage with the large bevel gear on the first spindle. One of these pinions is shown in place in the machine and five more are lying on the bench in front of it. The large bevel gear has seventy teeth cut on one side and seventy-two on the other, further extending the range of indexing mentioned. The fact that the index crank is turned exactly one revolution, whatever the number of flutes being cut, is one of the good points of the design, as it makes mistakes in indexing impossible.

The work is held between drivers on the headstock spindles and center points on tailstock spindles. Two forms of these drivers, one for square and the other for round shanks, are shown on the bench in front. The squared ends are driven by the socket shown with square tapered holes, while round work is held and driven by the prong type of driver.

The headstock is a close sliding fit on the dove-tailed base, and it is moved in for clamping, or withdrawn for releasing by the operation of a toggle joint connected with the handle shown. The thrust is taken against the fixed block clamped to the left-hand end of the slide. The tailstock centers are each backed by heavy coiled spring, the strength of whose compression is adjustable by means of the screws and lock nuts shown at the rear of the block. As the headstock is pressed forward by the clamping lever, the blanks are brought up against the spring-supported tail centers to a greater or less degree, depending on the over-all length of the pieces of work. This spring pressure has the advantage over a positive abutment of taking up the looseness which results from the pressing together of the drivers and work at the headstock end under the thrust of the cut. The center points on the tail-stock are easily renewed in case of wear or accident.

Attention should be called to the means provided for facilitating the removal and insertion of the work. When the headstock is drawn back, the work, while still confined by the drivers at the left-hand end, drops off the tail centers into the notches on the support shown, whence they may be lifted out all together with one hand. In putting the work in the machine this support serves the same purpose, as the blanks are placed in the drivers at one end and dropped into the notches on the support at the other, which brings the center holes at the right height for the tool centers. A single movement of the toggle handle then serves to clamp all four blanks in place.

Another improvement, which will be seen from an examination of the engraving, is the provision of an adjustment for varying the height of the tool centers for cutting taper flutes. This obviates the necessity for blocking up the tail stock on operations of this kind. The tail centers are mounted in a wedge-shaped block which is adjustable on the inclined base provided for it, as shown, thus raising or lowering the tail center points. This gives a vertical adjustment of one inch.

The special advantages of this multiple spindle indexing device may be summed up as follows: First, it provides for great rapidity of action, owing to the use of the support for holding and locating the work before clamping, and the provision of a single movement of the lever for locking four pieces of work in place; second, and perhaps most important, the work when pressed back by the cutter into the driving dogs, is followed up and held fast by extra heavy springs, without the loosening which would result with screw tightened or other positively operated centers; third, taper work is provided for without blocking up. The size shown has a capacity for taps or reamers from ½ to 3 inch.

* * *

The annual reunion of the sales organization of Hill-Clarke & Co., Chicago, Ill., at which were present a large number of the manufacturers whom they represent, was held in the banquet hall of De Jonge's restaurant in Chicago on January 11, and the following evening they attended the theater as guests of the firm.

NEW MACHINERY AND TOOLS NOTES

Double-end Angle Wrenches in Sets: Frank Mossberg Co., Attleboro, Mass. This firm provides its double-end angle wrenches in sets put up in a neat compartment canvas case, to be used for machine equipment, automobile kits, and standard engineers' and machinists' sets. The wrenches are carefully proportioned and made of a high grade of material. The five wrenches, being double ended, fit ten sizes of bolts and nuts.

Ball Bearing Hanger: Hess-Bright Mfg. Co., Philadelphia, Pa. This firm has devised a special form of hanger particularly adapted to the application of ball bearings to line shaftings. The hanger frame is of box section, and the bearing is provided with adjustments both vertically and horizontally. The design is such as to make the hanger simple in construction and easy to erect and adjust. The line comprises five sizes, practically covering the field for work of this character.

Independent Pump Hydraulic Jack: Duff Mfg. Co., Pittsburg, Pa. This jack, which the makers call the "Duff-Bethlehem," is of the type in which the pump is independent of the ram cylinder, being connected therewith by an 8-foot length of flexible copper tube. This construction permits the use of the jack in confined places and at any convenient angle. It is possible to use one pump for operating several jacks. It may also be employed for general shop work as a small hydraulic press. This apparatus is made in various capacities from 100 to 500 tons, with strokes ranging from 6 to 12 inches.

"Vulcan" Auto Tool: J. H. Williams & Co., Brooklyn, N. Y. This tool is a solid one-piece forging, which combines in itself a remarkable number of functions. It may be used as a hammer, tire lug wrench, cotter pin puller, gas tank wrench, wire insulator scraper, air tank wrench, spark plug wrench, alligator wrench, cotter pin spreader or screw-driver. As a screwdriver it should be particularly effective for confined places, as three blades are provided, set in three different positions. The category of its useful qualities would not be complete without mentioning also the provision of a bottle opener.

"Arpeco" Pipe and Nut Wrenches: Rogers, Printz & Co., Warren, Pa. These wrenches are of unusually simple construction, being formed only of two drop forgings, a drawn steel sleeve of seamless tubing, and a small screw, which serves to hold the parts together. The adjustment consists of the simple sliding of the parts on each other by the fingers of the hand which operates the wrench. A wedge action locks the jaws as soon as the operating pressure is applied. A special thin model is furnished of only ¼-inch thickness for the purpose of getting in small spaces.

Motor-driven Combined Vertical Milling and Slotting Machine: R. M. Clough, Tolland, Conn. This well-known machine is primarily a vertical miller, provided with a simple slotting attachment operated by a worm and worm-gear connection with the milling spindle. It is especially adapted for diemaking and similar work. It has recently been provided with a single motor drive; the connection between the machine and motor is made by a Morse silent chain. A 1½-horsepower, 120 volt Ridgway motor is used for the No. 2 size of machine.

Hydraulic Cold Tire-setting Machine: West Tire Setter Co., Rochester, N. Y. The well-known tire-setting machine made by this firm has recently been adapted to automobile work. When this machine is to be used, the tire is forged large enough so as to be strained beyond the elastic limit when pressing it on the wheel. The forcible compression has been found to densify and improve the metal. A recent machine was provided with 18 hydraulic rams, capable of exerting a pressure of 100 tons each, with a supply pressure of 2,000 pounds per square inch. For an ordinary automobile rim for a 4-inch tire, not more than 15 tons pressure for each ram would be required.

Combined Hand and Power Pipe Machine: Crane Co., Bridgeport, Conn. This machine has a capacity for pipe from ⅛ inch to 2 inches diameter, inclusive, and may be furnished with bolt threading dies as well in sizes ranging from ¼ to ½ inch. The main frame, consisting of the base and bed, is cast in one piece. Compactness for the electric drive is secured by mounting the motor under the rear overhang of the headstock, so that it requires no additional floor space. The action of the motor is by a belt or chain drive. Three speed changes are effected by a geared mechanism, controlled by a single lever. A rotary oil pump is provided for giving continuous lubrication to the dies.

Horizontal Riveting Machine: H. P. Townsend Mfg. Co., Hartford, Conn. The Townsend riveting machine (which was described in a note in the department of New Machinery and Tools in the February, 1909, number of Machinery) is now furnished in horizontal form as well as in the vertical design then described. It is intended for long or bulky work which it is inconvenient to handle in a vertical position. The action of the machine causes a series of disks to strike the end of the riveting hammer, giving a great number of blows per minute, the variation in blows being obtained by variation in speed. The machine will handle rivets from 1/64 up to 5/64 inch in diameter.

MULTIPLE SPINDLE MILLING MACHINE: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. This machine was built for special work, but involves a number of new features which might, perhaps, be applied to advantage in a great many general shop operations. The machine is of the planer type, with a horizontal spindle, having a driving head on one column and an outboard support on the other. The cross-rail carries two heads with vertical spindles. These heads are, however, adjustable, so that the spindles may be set at any angle out of the vertical desired, permitting the cutting of angular surfaces with ordinary end and face mills. The machine will mill work up to 16 feet long and 30 inches wide.

COMBINED BENCH CENTER AND CENTERING MACHINE: Artisan School, Syracuse, N. Y. This machine as indicated by its name serves the double purpose of indicating the truth of work mounted on centers and drilling center holes in rough stock with the standard form of combination center drill. The machine is provided with a graduated indicating pointer for showing the amount by which the work runs out of true. An adjustable V-block is provided for supporting work which otherwise would require a "third hand." The rod for knocking out the center drill or center (as may be required) is permanently mounted in the machine. The design of the framework and the general construction of the tool is unique, but of convenient and rational form.

COMBINATION BENCH AND VISE STAND: New Britain Machine Co., New Britain, Conn. This device consists of a 5-inch vise, mounted on a solid iron tripod, either alone or in combination with a tray or bench top. The whole arrangement is compact and occupies a minimum of floor space. It is sold as a unit and is ready for service as soon as it is attached to the floor, on which it rests firmly no matter how uneven it may be. Any make of vise preferred by the customer will be furnished. When one of the swivel base type is used, the binder for locking it operates in a pocket in the front of the tripod rod. When a pipe vise is used, the shelves form a convenient place for dies, cutters or tongues. The size of the table is 20 by 40 inches. The weight complete is 375 pounds.

TAPPING ATTACHMENT FOR SENSITIVE DRILL: Taylor & Fenn Co., Hartford, Conn. We have previously described a number of designs of this make of drill press (see, for instance, the department of New Machinery and Tools in the May, 1909, number of MACHINERY). In this machine the speed changes for the spindle are obtained by a geared change mechanism in the base of the adjustable spindle column. The improved tapping attachment consists of a reversing mechanism, located at the same point and operated by a small projecting lever. The reverse of the spindle is effected by a clutch in combination with a set of bevel gears. The vertical movement of the spindle and its reverse can be controlled by the same hand, though a positive connection between the two movements will be furnished if desired.

ELECTRIC TACHOMETER: Industrial Instrument Co., Foxboro, Mass. This device is essentially an electrical generator, positively connected (by silent chain or otherwise) with the part whose speed is to be measured, and electrically connected with a special volt meter calibrated directly in revolutions per minute. The generator is of the alternating type, so that the uncertain action of brushes and other sliding contacts is avoided. Irregularities in the voltage and consequent vibration of the meter needle are avoided by driving the generator through a fly-wheel, whose connection with the motive power is through a coil spring, which absorbs momentary speed changes. As many indicating dials as may be desired can be attached to a single generator, so that information as to speed may be given in a number of places simultaneously.

INSERTED LATHE TOOL-HOLDERS: G. R. Lang Co., Meadville, Pa. These tools are made in a variety of designs, one of which is particularly interesting in obviating the use of the regulation spherical ring and tilting shoe. The tool is clamped solidly down onto a block on the cross-slide, no adjustment for height of tool being furnished or required, owing to the fact that the point of the tool is ground on the end and not at the top, thus keeping the height constant at the right position. Tools of this design are used for turning, side facing, cutting off, etc. A special cutting-off tool-holder (another new product) permits the use of a blade having flat top and bottom, the proper gripping force being provided without dove-tailing these surfaces as usual. Side clearance is provided so that the blades cut as well as a properly forged tool of the old style.

HAND-FEED AND AUTOMATIC THREAD ROLLING MACHINES: Waterbury Farrel Foundry & Machine Co., Waterbury, Conn. This firm has redesigned its line of reciprocating thread rolling machines, and has introduced a number of improvements. An offset crank is used in place of the former quick return movement for giving a slow, powerful threading stroke. A new device is applied to prevent the possibility, in the automatic feed machines, of getting a blank into the feeding guides in a wrong position, and thus clogging the feed. Extra long dies are used, and provision is made for an extra length of thread as well. The six sizes have a maximum capacity for work from 1/4 to 1 inch in diameter, and for a depth of die ranging from 1 to 3 inches. They are built in horizontal form with automatic feed for small and medium work, and hand feed for the heaviest; and in an inclined form for automatically feeding headless blanks. All the mechanism of the machine is thoroughly guarded.

MICRO-ADJUSTABLE BORING HEAD: Porter-Cable Machine Co., Syracuse, N. Y. This tool is intended for use in connection with the maker's sensitive high-speed universal milling attachment, but may be applied to milling machines and drill presses in general. It consists of a shank mounted in the spindle of the machine, carrying a head with cross-slide ways formed in it, on which the tool-holder is adjusted. This adjustment is effected by a micrometer screw with graduations reading to thousandths of an inch. The tool head is provided with a split chuck for holding the cylindrical shanks of the boring tools, and has suitable clamping arrangements for binding it firmly to the tool when the adjustment has been made. The tool itself has a 1/2-inch shank, and the draw-in chuck furnished is fitted for boring tools of 1/4-inch shank. The cross adjustment is 3/8 inch, making it possible to enlarge a hole 3/4 inch without change of tool. This device will be found very useful in the accurate boring of small holes in jigs, fixtures, dies, etc.

TELESCOPING INSIDE GAGE: L. S. Starrett Co., Catalogue 18D, Athol, Mass. This gage is intended for use in measuring the exact size of holes or slots by the use of an outside micrometer caliper; the tool is, in fact, a transfer gage, very solid and accurate in construction. In general form it resembles a T-head wrench in which one of the arms of the T telescopes into the other, against spring pressure. After pressing together, it is locked by a thumb screw at the outer end of the shank and inserted in the hole. Releasing the thumb-screw allows the measuring arm to spring open to the diameter of the hole being measured. Locking the knurled thumb-screw again clamps the arms in this position, after which the tool is removed and the diameter measured. The end of each of the heads is hardened and ground to the radius of the smallest hole the tool enters. The instrument possesses advantages over the inside caliper in the matter of stiffness and accuracy. The gages are made in five sizes, having a range from 1/2 to 6 inches.

FAN DYNAMOMETER FOR TESTING GASOLINE AND OTHER MOTORS: Joseph Tracy, 116 West 39th St., New York City. We have illustrated various arrangements of fans for absorbing the power when testing engines. These appliances have all been of the home-made order. The above manufacturer has now placed on the market a well-designed and compact apparatus for this purpose which offers several improvements over the home-made construction, the most noticeable of which is the provision of a tachometer directly connected with the spindle so as to give speed readings at all times. The resistance blades on the arms of the fan are radially adjustable to absorb more or less power. For any given position of these blades the tachometer dial may be calibrated to read directly for the power appropriate to a given speed. A series of dials is provided for different positions of the blades, so that the machine will read the power absorption directly over a range running from 1 horsepower at 180 revolutions to 70 horsepower at 980 revolutions.

END MILLS FOR PRECISION WORK: Porter-Cable Machine Co., Syracuse, N. Y. These end mills are built for high-speed operation on fine work, and range in size from 1/16 inch to 5/8 inch in diameter. The mills from 1/16 to 5/32 inch are provided with but a single tooth, which is cut to the center so that the tool may be fed directly into the work like a drill. The sizes from 3/16 to 1/4 inch have two teeth, also cut to the center. All of these mills have straight teeth. For the sizes from 1/4 to 5/8 inch diameter, four or six teeth are used, cut spirally; the larger sizes are made of high-speed steel. The teeth of the mills are given a peculiar form which greatly increases their strength, effecting a large saving in the matter of drill breakages. The unusually small number of teeth used has been found by the makers of exceptionally great advantage. Each tooth has a much stronger backing and is much less liable to break. Their metal-removing capacity is as great as in the older multiple tooth styles, since it has been found that in most cases but one tooth at a time would work anyway. While these tools were designed particularly for the maker's high-speed milling attachment, they are applicable as well to any high-speed milling machine built for accurate work.

AUTOMATIC TEMPERATURE REGULATOR FOR GAS FURNACES: American Gas Furnace Co., 24 John St., New York City. This device is designed to work in connection with a thermo-electric pyrometer, and it is so constructed that the exceedingly delicate movements of the needle of that instrument control a mechanism for opening and closing the gas and air valves without interfering to the slightest degree with the sensitiveness of the operation of the indicating mechanism. It will be admitted that this is something of an achievement in mechanical construction. The power for the valve movements is furnished by a small fan motor connected by a 1/4-inch pipe

with the regular air supply of the furnace, so that no special motive power connections are required. The mechanical control of this motor by the needle is effected by a system of interferences, which that needle offers to members driven by the motor. This interference is effected without restraining to the slightest degree the movements of the needle itself. The instrument is designed to hold the temperature control steady within five or ten degrees of a given point of temperature. It may be instantaneously adjusted to any point on the temperature scale, and it is so constructed and enclosed as to be durable and fool-proof.

ENGINE FOR FAN AND GENERATING SETS: B. F. Sturtevant Co., Hyde Park, Mass. This firm has for many years built a line of engines for driving either by belt or direct connection the fans and generators which they manufacture. They recently placed on the market a new model of vertical single engine for this work, which incorporates all the improvements which their past experience in this line has suggested. It is of the high-speed, closed type, having openings fitted with dust-proof covers which can be easily removed. A distance piece is provided between the cylinder and the frame which permits access to the stuffing box, and provides, as well, a watershed for keeping the oil from the frame out of the cylinder, and for keeping the water of condensation from the cylinder out of the frame. An oil reservoir is mounted on the frame, from which the oil flows to all the bearings, through piping equipped with sight feed regulators. A reservoir cast in the base receives the oil, where it is filtered through a fine screen and then pumped back to the reservoir. The pump may be dispensed with by keeping the reservoir at the top full, drawing off the excess from the bottom. The Rites inertia governor is used, and provides for a maximum variation of speed between no load and full load of not more than 1½ per cent. For direct connection with a pump, fan or similar apparatus, the base is extended so as to make the whole installation a complete unit. These engines are carefully tested before leaving the works. Particular stress is laid on compactness, economy, dependability and smooth running features, making the engines particularly adapted to isolated electric plants.

WAGE RAISE RECOMMENDED BY N. M. T. A

Commissioner Robert Wuest, of Cleveland, Ohio, in his monthly letter for January to the members of the National Metal Trades Association, recommends that the members raise wages of their employes wherever possible to keep pace with the great increased cost of living. He says in part:

"To increase wages as the demand for labor increases is good business. That it is doubly good business when an era of great prosperity is at hand cannot be denied. Let us see what would follow this increase of wages of our employes: First, it will keep them in their shops instead of driving them into other shops; second, it will keep them contented and ready to work with hearty good will; third, it will keep our products up to the standard of practice of the times because it will enable us to retain efficient workmen.

"Speaking generally, it is fair to say that the wise policy of manufacturers is to pay their employes the best wages that they can afford to pay. Voicing the sentiment which pervades the councils of the National Metal Trades Association, we wish to impress upon our members the importance of remembering this. The more it is remembered and practiced, the longer we will be immune from strikes and their consequences.

"The papers of the country at this time are full of talk about the increased cost of living. The reasons assigned for this increase are many and varied. . . . But be the reasons what they may, the fact is undeniable that a dollar does not go nearly so far to-day as four or five years ago. It would seem to be good business for all our members to take to heart the foregoing on the wage question. Good wages, the proper education of employes—especially apprentices—the adoption of practical and equitable profit-sharing systems are important factors in the solution of the labor problem."

TENTH INTERNATIONAL AUTOMOBILE SHOW

The Tenth International Automobile Show was held in the Grand Central Palace, New York City, December 31, 1909, to January 7, 1910, under the management of the American Motor Car Manufacturers' Association. There were over eighty exhibitors of vehicles, and a great number of exhibitors of accessories, the exhibition being distributed over the main floor and the two balconies. The American Motor Car Manufacturers' Association numbers forty-three members, and it is of some interest to note the principal features of the cars brought out by the members of the association. In all, there are 183 different pleasure cars and 86 commercial vehicles made by the members of the association and specified as 1910 models. Of the pleasure cars, only 6 are one-cylinder cars, 14 are two-cylinder cars, one is a two-cycle three-cylinder car, 19 are six-cylinder cars, and the remaining 143 are four-cylinder cars. Of the commercial vehicles the smaller sizes in general are two-cylinder cars, these numbering 50, while 36 are four-cylinder cars. Of the pleasure vehicles only 12 are specified as air cooled, one is either air- or water-cooled, while 170 are water-cooled. Of the commercial vehicles 4 are air-cooled, 7 are either air- or water-cooled and 75 are water-cooled. As regards the approximate power of the cars, 12 of the pleasure cars are of less than 15 H. P.; 30 are between 20 and 25 H. P.; 38 are of 30 H. P. or thereabouts; 21 of 35 H. P.; 20, 40 H. P.; 14, 45 H. P.; 25, 50 H. P.; and 18, 60 H. P. or more. Of the commercial vehicles, 10 are of 20 H. P. or less; 9 of about 25 H. P.; 29 of about 30 H. P.; 4 between 30 and 50 H. P.; 33, 50 H. P.; and one 60 H. P. As regards price, 27 of the pleasure vehicles are priced at less than $1,000; 29 between $1,500 and $2 000; 45 between $2,000 and $2,500; 29 between $2,500 and $3,000; 24 between $3,000 and $4,000; and 29 at over $4,000. Of the commercial vehicles 11 are specified at a price below $1,000; 10 between $2,000 and $3,000; 9 between $3,000 and $4,000; 17 between $4,000 and $5,000, and 10 above $5,000. The price of a number of commercial vehicles is furnished only on application, so that the figures above do not include the whole list of all makes.

TENTH A. L. A. M. AUTOMOBILE SHOW

The Tenth National Automobile Show took place under the auspices of the Association of Licensed Automobile Manufacturers at the Madison Square Garden, January 8 to 15. There was a total of 56 exhibitors of complete cars, 21 motor-cycle exhibitors, and 246 exhibitors of accessories and parts. The tremendous growth of the automobile industry in the last few years was plainly in evidence to anyone who has had an opportunity to see the National Automobile Show from year to year. On the main floor and on the elevated platform were placed only gasoline pleasure cars, while electric pleasure vehicles were exhibited in an exhibition floor of their own. The basement was occupied by commercial vehicles and motorcycles, while the concert hall and balconies accommodated the exhibitors of accessories. The Madison Square Garden was exquisitely decorated for the event, it being stated that more than $35,000 was spent on decorations. In all, there were 91 gasoline pleasure cars, 2 steam pleasure cars, 22 gasoline commercial cars, and 23 electric pleasure cars exhibited. Of the gasoline pleasure cars 65 were four-cylinder cars and 26 six-cylinder cars. Of the gasoline commercial cars one was a one-cylinder car, 4 were two cylinder cars, and 17, four-cylinder cars. All the pleasure cars, with the exception of five, and all the commercial cars, with the exception of six, were water-cooled. As regards the power of the cars 2 of the gasoline pleasure cars were of less than 20 H. P., 29 were between 20 and 30 H. P., 20 were between 30 and 40 H. P., and 20 were between 40 and 50 H. P., while 18 were 50 H. P. and over. The power of two of the gasoline pleasure cars was not specified. Of the commercial cars 5 were under 20 H. P., 10 were between 20 and 40, and 6 were 40 H. P. and over. As regards price, 3 of the exhibited cars were priced at less than $1,000, 10 between $1,000 and $1,500, 12 between $1,500 and $2,000, 7 between $2,000 and $2,500, 10 between $2,500 and $3,000, 27 between $3,000 and $4,000, 31 between $4,000 and $5,000, and 30, $5,000 and over.

A. L. Pfitzner recently made an exhibition flight at Hammandsport, N. Y., with a monoplane equipped with a new balancing device which, it is claimed, does not infringe upon the Wright patents on the warped plane principle. The Pfitzner device consists of two sliding panels at the outer ends of each wing. These panels are mounted on tracks under the wings, and are controlled by cords leading to the operator's seat. Changing the position of the panels accomplishes the same results in the balancing of the monoplane as warping the wings in the Wright models.

Don't think you are a machinist until you can take a set of drawings and produce from them what the draftsman wants made.

A METHOD FOR LOCATING THE DECIMAL POINT IN SLIDE RULE CALCULATIONS

CHAS. G. RICHARDSON*

The location of the decimal point in the results of multiplication and division has proven a vexatious problem to most users of the slide rule. The formulas heretofore given have proved cumbersome and confusing; inapplicable, practically, to examples of any length. It is believed, therefore, that the following easily remembered method will commend itself to all interested. Bearing in mind that when the words "left-hand figures" are used, *the number of figures to the left of the decimal point* (or in the integral portion of the number) is meant, there are two short rules which must be thoroughly memorized.

RULE No. 1. *Multiplication.* The left-hand figures in the product equal the sum of the left-hand figures in the factors, *except* that one left-hand figure must be subtracted for each time the slide projects to the right.

RULE No. 2. *Division.* The left-hand figures in the quotient equals the left-hand figures in the dividend minus the left-hand figures in the divisor, *except* that one left-hand figure must be added to those in the dividend for each time the slide projects to the right.

These two rules embody the whole method, and once having been learned, there only remains their application. Note that absolutely no reference is made to slide projections to the left.

The "left-hand figures" would be

3 in 843.210
2 in 41.189
1 in 6.922
0 in 0.632
—1 in 0.028
—2 in 0.003 etc.

The use of the two rules will now be illustrated by examples chosen at random, leading from simple problems to those more complex. The calculations are given in detail, but after a little practice the decimal point can be determined mentally with great rapidity.

(Note: It is understood that the lower scales on the slide rule are used.)

Example: $8 \times 5 = 40$.

The slide does not project to the right, therefore add the left-hand figures of the factors, giving two in the product.

Example: $8 \times 5 \times 12 = 480$.

The slide projects once to the right, therefore add left-hand figures of factors and subtract 1, giving 3 units in product.

Example: $8 \times 5 \times 12 \times 0.16 \times 0.08 = 6.14$.

The slide projects twice to the right, therefore $(1 + 1 + 2 + 0 - 1) - 2 = 1$ left-hand figure in the product.

Example: $123.1 \times 132.16 \times 14 \times 11 \times 0.008 \times 0.61 = 12720$.

The slide projects three times to the right, therefore $(3 + 3 + 2 + 2 - 2 + 0) - 3 = 5$ left-hand figures in the product.

Example: $\dfrac{140}{20} = 7$

The slide does not project to the right, therefore subtract the divisor's left-hand figures from the dividend's, or $3 - 2 = 1$ figure in the quotient.

Example: $\dfrac{360}{24} = 15$.

The slide projects once to the right, therefore add 1 to the dividend's left-hand figures and then subtract the divisor's, or $(3 + 1) - 2 = 2$ left-hand figures in the quotient.

Example: $\dfrac{3600}{24 \times 12} = 12.5$.

The slide projects twice to the right; therefore $(4 + 2) - (2 + 2) = 2$ left-hand figures in the quotient.

Example: $\dfrac{3600}{24 \times 0.12 \times 0.004 \times 18} = 17360$.

The slide projects three times to the right, or there are $(4 + 3) - (2 + 0 - 2 + 2) = 5$ left-hand figures in the quotient.

In formulas involving a combination of multiplication and division, the value of the method especially asserts itself.

Example: $\dfrac{12 \times 8}{16 \times 2} = 3$.

Alternately dividing and multiplying to save unnecessary settings, gives one projection to the right in *division*, but none in multiplication. Therefore, adding 1 to the dividend's left-hand figures and subtracting the divisor's, we have $(2 + 1 + 1) - (2 + 1) = 1$ left-hand figure in the result.

Example: $\dfrac{16 \times 14 \times 24}{30 \times 72 \times 0.8} = 3.11$.

Here we have one projection to the right in *multiplication*, but none in division and consequently $(2 + 2 + 2 - 1) - (2 + 2 + 0) = 1$ left-hand figure in the result.

As we proceed to longer examples it becomes rather difficult to separate *mentally* the number of projections to the right in multiplication from those in division. Short vertical lines may be used to keep this score, as it might be called, these marks being placed either above or below the division line according to whether the operation is respectively one of multiplication or division. Inasmuch, however, as a projection to the right in multiplication *subtracts* 1 and a projection to the right in division *adds* 1 to the left-hand figures in the dividend, it is unnecessary to score every projection to the right, as such a projection in division often may be immediately balanced by moving the runner to the next number in the dividend. In other words, it is only the *unbalanced* projections to the right which it is necessary to record.

To illustrate:

$$\text{Score}\begin{cases}\mathrm{I} \\ \mathrm{II}\end{cases} \quad \frac{114 \times 232 \times 1.98 \times 0.0006 \times 188}{196 \times 0.064 \times 72 \times 0.12 \times 14 \times 12.6} = 0.309.$$

Taking the solution step by step

114 ÷ 196	......slide is to left	
Multiply by 232	......slide is to left	
Divide by 0.064	......slide is to left	
Multiply by 1.98	......slide is to right	(mark above line)
Divide by 72	......slide is to left	
Multiply by 0.0006	......slide is to left	
Divide by 0.12	......slide is to right	} balance
Multiply by 188	......slide is to right	} balance
Divide by 14	......slide is to right	(mark below line)
Divide by 12.6	......slide is to right	(mark below line)

Now the excess of the lower group of "marks" over the upper is 1, therefore the slide has gone to the right once more in division than in multiplication, and 1 is to be added to the dividend's left-hand figures before subtracting the divisor's, or $(3 + 3 + 1 - 3 + 3 + 1) - (3 - 1 + 2 + 0 + 2 + 2) = 0$.

It makes no difference as to the order in which the problem is solved; the *excess* of one group of projections over the other will be the same. Gratifying "results" will certainly follow a little careful study and practical application of the simple principles enumerated.

* Address: Builders' Iron Foundry, Providence, R. I.

* * *

A new 14-inch gun for battleships is being constructed at the Washington Navy Yard. This gun will have an extreme range of 25 miles, although the range at which it will be fired in regular action will be about 5 miles. The projectile from this new gun leaves the muzzle at the velocity of 2,000 feet per second, and when fired with a full charge of 365 pounds of powder it will penetrate 22.7 inches of Krupp steel armor plate, when leaving the muzzle. The projectile weighs 1,400 pounds and the total length of the gun is 53½ feet.

* * *

A prize of 50,000 francs has been offered by the Turin (Italy) Chamber of Commerce, in connection with the Turin Exposition of 1911, for that invention or discovery, made before 1908, that has proved in practice of the greatest advantage in promoting national economy. Applications are to be made, in Italian or French, before April 1, 1911, to "Commissione per il Concorso a Premis, Camera di Commercio, Torino, Italia."

NEW SHOPS AT PURDUE UNIVERSITY

The new buildings which are now under way for the Department of Practical Mechanics at Purdue University, Lafayette, Ind., are worthy of notice as representing a notable advance in the efficiency of practical instruction at that institution.

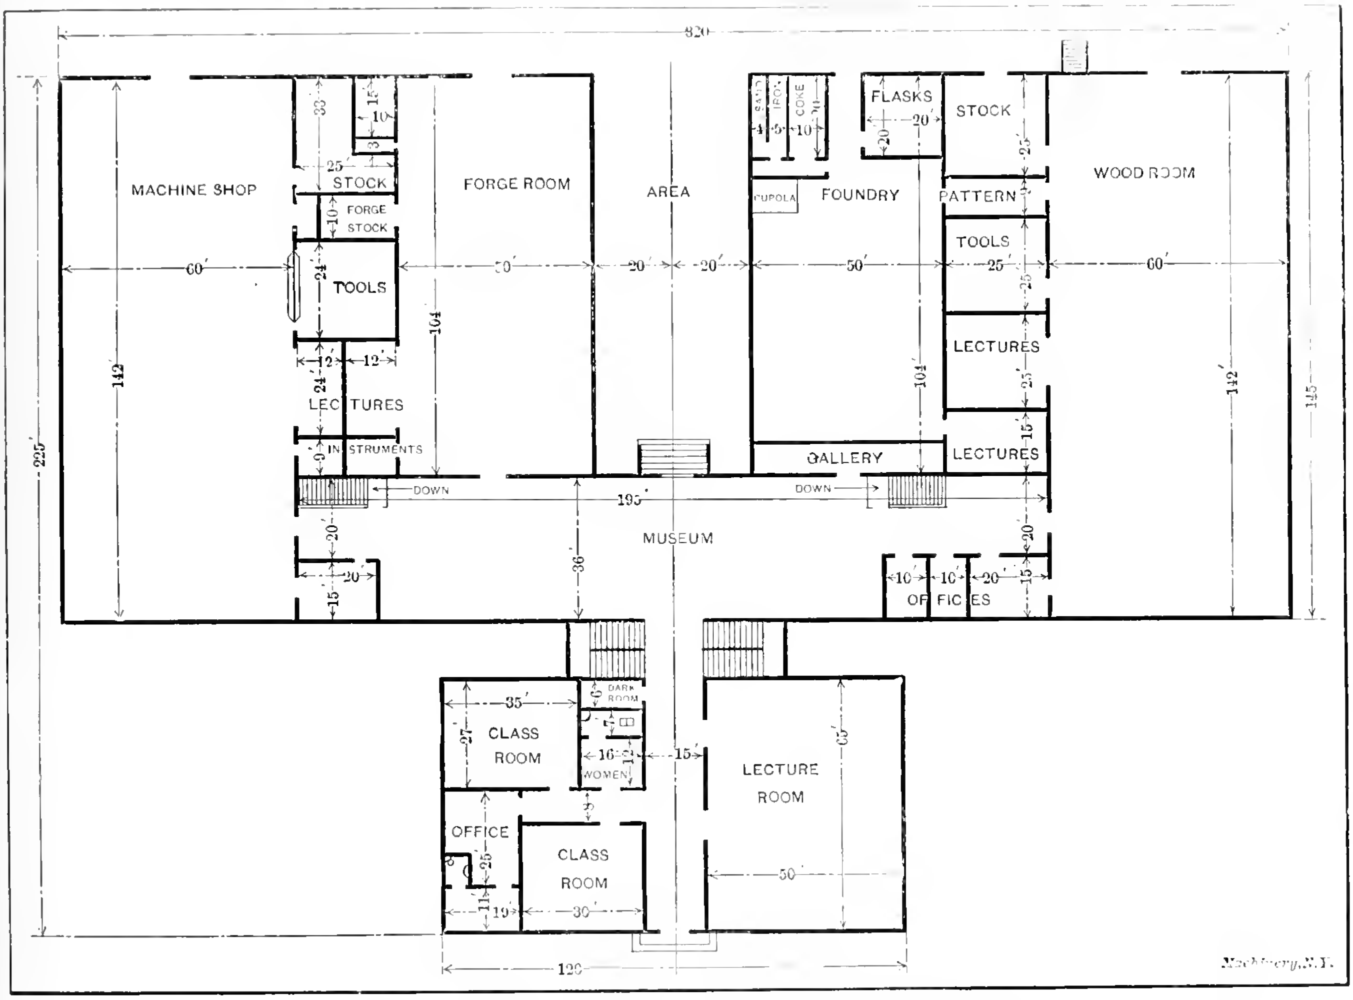
The organization of this branch of work at Purdue is somewhat different from that in most other technical schools. The department of Practical Mechanics stands by itself, independent of the School of Mechanical Engineering and bearing to the latter somewhat the same relation as do the departments of Mathematics or Applied Mechanics. The department is in charge of a staff of professors and instructors and covers the work done in elementary mechanical drawing, descriptive geometry and shop instruction.

In 1909 the State Legislature recognized the crowded condition of the present shops and drawing rooms and appropriated the sum of $170,000 for new buildings and equipment. Plans and specifications were prepared, contracts let and in May of that year work was begun on the new plant.

As may be seen from the outline plan, the buildings form a connected group containing a front or main building, a longitudinal corridor and transverse wings. The general construction is of the factory type with concrete foundations, brick walls and roofs lighted from above. The main building, 65 by 120 feet, three stories high, furnishes accommodations for class-room instruction and for drawing. On the ground floor are offices, class-rooms and a lecture room 50 by 65 feet. The second and third floors each contain two large drawing rooms and the necessary offices, blue-print rooms, etc.

The remaining buildings are one story in height. A long corridor joining the shops proper has in the basement the heating plant and space for lockers and wash-rooms, while its ground floor contains offices and cases for exhibits and models. The wood shop, 60 by 142 feet, and the foundry, 50 by 104 feet, each under a separate roof, form one wing with an intermediate space of 25 feet used for tools, stock and demonstration rooms. Each building is lighted from overhead as well as from the sides and is capable of indefinite extension in the rear. A basement under the wood shop accommodates stored lumber and contains the shafting and motors for driving the machinery on the main floor. A similar group on the south side contains the machine shop, the foundry and the connecting store rooms and demonstration rooms. The basement of the machine shop will be used for storage.

The buildings will be lighted throughout by electricity and heated by a combined radiation and blower system, insuring uniform temperature and thorough ventilation. The machinery in the shops will be driven by electric motors, both group and independent drives being employed. Alternating and direct currents will be available for the two classes of transmission used.



Plan of New Shops for Department of Practical Mechanics Purdue University

We are indebted to Prof. Charles H. Benjamin, dean of the Schools of Engineering and Director of the Engineering Laboratory for the foregoing information.

LUBRICATION AND LUBRICANTS

At the regular monthly meeting of the American Society of Mechanical Engineers, January 11, papers on the subject of lubrication and lubricants were read and discussed. The authors of the papers were Dr. Charles F. Mabery, professor of chemistry at the Case School of Applied Science, of Cleveland, Ohio; Prof. F. H. Sibley, of the University of Alabama, and Dr. P. H. Conradson, of the Galena Signal Oil Co.

Dr. Mabery's paper dealt especially with laboratory tests of lubricants containing deflocculated graphite, but contained also considerable matter of direct practical application. The various fields of usefulness of different lubricants were referred to. Greases compounded with graphite, for example, are of particular advantage on low-speed bearings, under heavy load, while natural graphite serves an excellent purpose in cast iron bearings, where it appears to smooth the surface of the porous metal. On close grained surfaces highly finished, however, care must be exercised so that it does not collect and scratch and abrade the journals and bearing

Some of the tests on the deflocculated graphite gave very interesting results. It was found that a very small amount of graphite suspended in water serves its purpose as an efficient lubricant. For example, an amount of only 0.35 per cent of graphite in water will sustain a pressure of 70 pounds per square inch in the bearing, and a larger amount than that is superfluous. Experiments were also carried out with graphite deflocculated in kerosene and various lubricating oils. It was found that one cubic inch of graphite in three gallons of oil is sufficient to give excellent results and materially reduce friction. Experiments were also undertaken with a view to determine the rise in temperature with the various lubricants, and the most remarkable result in this direction was that graphite suspended in water is an excellent lubrication means for keeping the temperature of the bearings constant. The increase in temperature when testing with this lubricant did not exceed 5 degrees F.

Prof. Sibley's paper described experiments undertaken to determine the relation between viscosity and the wearing and lubricating qualities of oils, and the effect of the constituents of various oils on the lubricating qualities. Twenty-two oils were tested, the method of procedure being to find the chemical composition and viscosity of each oil, and then use it as a lubricant in a journal bearing. The viscosity of an oil is measured by its resistance to flow, a strong resistance to flow indicating a high viscosity. The experiments showed that the viscosity of an oil affects its lubricating quality in the following way: If the oil is adapted to the load put upon it, then the lower the viscosity the better the oil as a lubricant. The oil, however, must conform to the character of the load, a light oil being unsuitable for heavy loads.

While the two previous papers dealt particularly with laboratory tests of oils, Dr. Conradson's paper dealt more directly with practical conditions, and oils suitable for steam turbine plant lubrication, railroad journal lubrication, etc., were discussed by him, as well as several other practical considerations affecting lubricants.

In the discussion following the reading of the papers, Mr. Henry Souther made some interesting remarks relating to the lubrication of automobile cylinders. He had found by practical experiments that a high flash-point oil is not desirable, because of the gum and residue that always results from oils of this kind. These oils give good lubrication while running, but make it difficult to start the engine after it has been standing. The most desirable lubricant for an automobile cylinder is an oil which will take care of the main shaft bearing and the main pin bearings of the piston, and then passing up the piston into the explosion chamber, will disappear as much as possible, so as not to leave any considerable amount of residue oil. Such oils have viscosity of 40 to 50 seconds at 210 degrees F., as measured by the Saybolt viscosimeter, and a specific gravity of from 28 to 31 Beaume.

* * *

PERSONALS

The present address of P. L. Joselevitsch, formerly of 733 E. 16th St., Minneapolis, Minn., is desired by the editor.

W. B. Engler, formerly assistant chief engineer of the Reliance Motor Truck Co., Owosso, Mich., has now been made superintendent of that company.

John J. Grant has been made consulting engineer of all the constituent plants of the Everitt-Metzger-Flanders Co., automobile builders, Detroit, Mich.

Oscar Stegeman has associated himself with Messrs. Landau & Golden, consulting engineers, New York, as a western engineer. He will be located in Milwaukee, Wis.

George H. Hall was recently transferred from the Boston office of the Sprague Electric Co. to its motor and generator department in the company's general office, New York City.

John J. Murphy, blacksmith foreman for the Wabash R. R. at Moberly, Mo., has been appointed to a similar position at Decatur, Ill., succeeding Christopher Jackson, resigned.

Joseph J. Reid has taken charge of the eastern sales department of the Harris Automatic Press Co., with the title of eastern manager. He succeeds E. E. Barney, resigned.

Christopher Jackson, blacksmith foreman at the Wabash Car Shops, Decatur, Ill., left January 1 for Dayton, Ohio, to become superintendent of forges for the Barney & Smith Car Co.

H. C. Fay, of the engineering department of the Remington Arms Co., Ilion, N. Y., has been appointed foreman of the chucking and punch press department to succeed W. H. Dotzauer, resigned.

W. J. Greer, better known as "Genial Jack" Greer, is back again among his own in Pittsburg representing the interests of the Van Dorn Electric and Mfg. Co., maker of electric drills and reamers.

C. E. Chambers has been appointed superintendent of motive power of the Central Railroad of New Jersey, with office at Jersey City, N. J. Mr. Chambers succeeds Mr. William McIntosh, who was superintendent of motive power for many years.

Cyrus F. Raymond, organizing engineer and industrial expert recently employed by the Warner & Swasey Co., Cleveland, Ohio, and later by the Coe Mfg. Co., Painesville, Ohio, has been made superintendent of the Davis-Bournonville Co., New York.

George S. Brown has resigned the position of foreman of the screw department of J. Stevens Arms and Tool Co., to take the management of the Mellor Mfg. Co., Springfield, Mass., a recently established plant for making screw machine products.

Paul Stoner has joined the selling force of the American Emery Wheel Works, Providence, R. I. Mr. Stoner was connected with the Landis Tool Co. for several years, and later with the Allis-Chalmers Co. and the Cleveland Automatic Machine Co.

W. R. Lathrop, who for several years has been connected with the Niles-Bement-Pond Co.'s New York and Birmingham office, has severed his connection and has associated himself with M. E. Dewstoe of Birmingham, Ala., forming the Dewstoe-Lathrop Machinery Co.

George W. Johnson, who lately resigned the superintendency of the Chapman Valve Mfg. Co., Springfield, Mass, has established the Springfield Equipment Co. to do a general mill and factory supply business. He will locally represent the Heller Bros. Steel Co., Newark, N. J.

P. J. Illing, manager of Ludw. Loewe & Co.'s commercial department, sailed for New York the latter part of January on the *Kaiser Wilhelm der Grosse*. He intends to visit the principal machinery manufacturing plants with the object of renewing and opening business connections.

W. H. Dotzauer, foreman of the chucking and punch press department of the Remington Arms Co., Ilion, N. Y., and who has also held the position of foreman in several other departments for the last fifteen years, has resigned to take the position of superintendent of the automobile hub department of the Weston-Mott Co., Flint, Mich.

H. E. Frentzel, for many years superintendent of the shops of Pawling & Harnischfeger, Milwaukee, Wis., retired January 1. He was succeeded by Otto A. Ruemelin, for several years past assistant superintendent. Mr. Frentzel was presented with a handsome silver service by his associates in the shop and office as a mark of their friendship and esteem.

W. R. Wilson, formerly general superintendent of the Columbus Brass Co. and the Columbus Iron Fittings Co., Columbus, Ohio, is now general manager and receiver for the Standish Machine & Supply Co., of that city, manufacturer of the Robinson right angle drive. Under Mr. Wilson's efficient management it is expected that the company will soon be in first-class shape.

J. D. Cox has been elected president of the Cleveland Twist Drill Co., Cleveland, Ohio, to succeed Mr. F. F. Prentiss, who resigned on account of ill health. Mr. Cox is the founder of the business, and has always been the practical man of the concern. He has probably had more experience and been closer in touch with the manufacture of twist drills than any other man now living.

F. A. Hall, who for the past twelve years was manager of the chain block and hoist department of the Yale & Towne Mfg. Co., New York and Hartford, has resigned to take the position of vice-president and treasurer of the Cameron Engineering Co., Brooklyn, New York. Mr. Hall is succeeded by R. T. Hodgkins, who for several years was his chief assistant and who is thoroughly qualified by experience and ability to fill the position.

Henry J. Smith has been promoted from the position of assistant foreman to the foremanship of the Water Shops of the United States Armory at Springfield, Mass. Mr. Smith was promoted from machinist to assistant foreman in 1898. The position of assistant foreman in the Water Shops is practically the same as that of foreman in civilian shops, the term being applied to the heads of departments such as milling, drilling, drop forging, etc.

J. W. Coyle, who was connected with the W. N. Best American Calorific Co. until its retirement from business, is now with the Rockwell Furnace Co., New York, and is giving special attention to oil and gas furnaces for railroad work. Mr. Coyle is an experienced railroad man, having formerly been master blacksmith for the Lehigh Valley R. R. at Wilkes-barre, and later was in charge of the drop hammer and machine department at the forge shops of the Philadelphia & Reading Ry., Reading, Pa.

George Walworth Hayden has been appointed general plant manager of the works of the Pratt & Cady Co. at Hartford, Conn. Mr. Hayden was for nineteen years with the Crane Co. of Chicago working in all departments and rising to be general manager of all its factories, having been chief draftsman, foreman, superintendent and general manager of all the brass, malleable and cast iron departments. He was also in the employ of the United States Steel Corporation and of the McNab & Harlan Co. as works manager at Newark, N. J.

C. H. Ladd has retired from the position of foreman of the Water Shops of the United States Armory at Springfield, Mass., after serving in that capacity for seventeen years. Previous to going to the Water Shops Mr. Ladd was at the Smith & Wesson revolver factory for fourteen years holding the position of foreman and superintendent. He is a Civil War veteran. In civilian shops the position he filled would be called superintendent. He had about five hundred men under him in several departments, including tool-making, hand, drop and rolled forging, milling, drilling, rifling, etc.

At a meeting of the board of directors of the Pennsylvania R. R., January 12, F. E. Abercrombie, superintendent of the New York division, C. F. Dabney, superintendent of the Central division, and W. A. Bannard, superintendent of the Maryland division, were delegated to the general manager's office at Philadelphia to assist in exhaustive investigations of various transportation problems. These men, who are to be known as special agents on the staff of the general manager, are well fitted for their duties on account of long experience in the operating department, especially divisional work, of the railroad.

Charles Kirchhoff, who recently retired from the editorship of the *Iron Age*, was given a tribute of regard in a luncheon at the Engineers' Club, New York, January 16, just prior to sailing on a cruise to the West Indies. The luncheon was attended by about 120 manufacturers, professors, editors, chemists, etc., prominent in the business world and their professions. Letters of regret were read from Andrew Carnegie, Ambrose Swasey, John Hayes Hammond, H. G. Prout, Prof. Henry M. Howe and others. Mr. Kirchhoff was presented with a bronze statue by Picault entitled "La Source du Pactole," by his colleagues on the *Iron Age*, as an evidence of regard and admiration. Mr. George W. Cope, who made the presentation, said in part referring to the gift: "It is emblematical of your profession as well as of the cause in which you have so long employed your energies and your talents. The engineer holding in one hand the dividers and in the other a hammer, contemplates the Pactolian stream, and as he muses we can well believe that he exults in the thought that his labor is also productive of wealth. How much and how effectively your labors have contributed to the material benefit of those who have for years used the *Iron Age* as an important factor in the conduct of their business is beyond my power to estimate."

* * *

OBITUARIES

Samuel E. Riendeau, assistant foreman of the screw department of the J. Stevens Arms and Tool Co., Chicopee Falls, Mass., died at his home December 21, aged thirty-eight years.

George S. Taylor, treasurer of the Belcher & Taylor Agricultural Tool Co., Chicopee Falls, Mass., since its incorporation in 1864, died of pneumonia at his home in Chicopee Falls, Mass., January 3, after an illness of four days, aged eighty-eight.

William Baxter, Jr., died at his home in Jersey City, January 12, after a brief illness with pneumonia, aged fifty-six years. He was born in Troy, N. Y., and was given an academic education. He acquired considerable valuable experience in designing steam and hydraulic machinery between 1860 and 1880 with his father, William Baxter, Sr., who was a well-known builder of engines and machinery and an inventor of considerable reputation. William Baxter, Jr., inherited the inventiveness of his father and made several inventions of merit in electrical apparatus, elevators, etc. He entered the electrical engineering field in the early eighties and afterwards devoted himself largely to this work and elevator improvements. He was a pioneer motor inventor and manufacturer. He invented the first enclosed arc lamp about 1882. He put stationary motors on the market in 1886 and railway motors in 1890. He was the first to design and place on the market the single reduction type of railway motors now universally used on trolley cars. Previous to Mr. Baxter's improvement, motors were double reduction with intermediate shaft between the motors and car axle. This arrangement was used to obtain sufficient power to operate the car without making the motor too heavy. Since 1895 Mr. Baxter had acted as a consulting engineer and writer. He wrote extensively for various mechanical and electrical journals on nearly all the industrial applications of electricity, and on elevators of all kinds. His series, "Electrical Railway Machinery and Apparatus," recently published in the railway edition of MACHINERY, is a case in point.

Don't grind a lot of clearance on one side and no clearance on the other side of a thread tool.

COMING EVENTS

April 13-14.—Annual convention of the National Metal Trades Association at the Hotel Astor, New York. Robert Wuest, commissioner, 605 New England Building, Cleveland, Ohio.

April 17-June 1 (April 4 to May 19, O. S.).—International exhibition of internal combustion motors under the auspices of the Imperial Russian Technical Society of St. Petersburg on the premises of the society Panteleimonskaia No. 2. The object of the exhibition is to acquaint the consumer as well as the general public at large with the development and present condition of internal combustion motors, and to show the comparative advantages of each of the existing systems. The exhibit will be divided into sections as follows: Motors for agricultural purposes, motors for artisan in small industries, and domestic use, motors for factories, motors for marine, railway, tram car, automobile, aeronautical and similar purposes, motor details and accessories, literature on motors, drawings, diagrams, etc.

May 4-5.—Annual meeting of the Iron and Steel Institute at the Institution of Civil Engineers, London. G. C. Lloyd, secretary, 28 Victoria St., London.

May 31-June 3.—Spring meeting of the American Society of Mechanical Engineers, Atlantic City, N. J.

June 1-August 31.—American Exposition in Berlin, under illustrious auspices, to stimulate trade relations between Germany and America. This will be the first all-American exposition ever held in a foreign country and will be of interest to all Europe as well as America. It will be held during three of the best months of the year for an exposition, being at the full tide of the foreign travel, when people will be attracted in large numbers. Max Vieweger, American Manager, 50 Church St., New York.

June 6-10.—Convention and exhibition of the Foundry & Manufacturers' Supply Association, Detroit, Mich., C. E. Hoyt, secretary, Lewis Institute, Chicago, Ill. Cadillac Hotel, Detroit, headquarters of the association convention week.

June 7-9.—Convention of the American Foundrymen's Association and American Brass Founders' Association, Detroit, Mich. Headquarters, Hotel Ponchartrain. Richard Moldenke, secretary. American Foundrymen's Association, Watchung, N. J. W. M. Corse, secretary. American Brass Founders' Association.

June 13-16.—National Gas and Gasoline Engine Trades Association convention at Cincinnati, Ohio, Hotel Sinton, headquarters. Albert Stritmatter, secretary.

June 23-28.—International Congress of Mining, Metallurgy, Applied Mechanics and Practical Geology at Dusseldorf, Germany. For information apply to G. C. Lloyd, 28 Victoria St., London.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in Birmingham and London, England.

SOCIETIES AND COLLEGES

OHIO SOCIETY OF MECHANICAL, ELECTRICAL AND STEAM ENGINEERS, organized in 1901, elected the following new officers at the last annual meeting at Lima, Ohio, November 19-20: president, O. F. Rabbe, Toledo, Ohio; vice-president, Grant Miller, Toledo, Ohio; secretary and treasurer, Prof. F. E. Sanborn, Columbus, Ohio; managers, Ira Cole, Lima, Ohio, C. F. Baker, Covington, Ky., E. M. Adams, Akron, Ohio.

SOCIETY OF ENGINEERS, 17 Victoria St., Westminster, S. W. England will award a status prize each year for the next four years ending 1913 for the best paper written by any person on the subject "How to Improve the Status of Engineers and Engineering with Special Reference to the Consulting Engineer." The prize will be books or instruments or both to the value of three guineas selected by the author of the winning essay. Essays should be written in the third person and should contain not fewer than 4,000, or more than 6,000, words.

STEVENS ENGINEERING SOCIETY, Hoboken, N. J. Program of lectures for the season 1909-10. The society is affiliated with the American Society of Mechanical Engineers. The speakers yet to appear are Samuel Whinery, February 8, subject, "Pavements for City Streets;" David S. Jacobus, February 15, subject, "Power Plant Economics;" Henry L. Gantt, February 21, subject, "The Engineer as a Manager;" John F. O'Rourke, March 1, subject, to be announced; Hermann F. Cuntz, March 8, subject, "Automobiles;" William J. Hammer, March 15, subject to be announced; Charles R. Richards, March 22, subject "Art and Industries of the Orient;" George V. Wendell, March 31, subject, "The Gyrostat and its Application;" Lewis A. Martin, April 5, subject, "The Theory of Gyrostatic Motion;" Frank B. Gilbreth, April 12, subject, "Methods and System in Relation to Handling Concrete Work;" John C. Ostrup, April 19, subject, "Notable Examples in Modern Construction;" David Watson Taylor, April 26, subject, "Development of the New Navy;" Charles F. Kroeh, May 3, subject, "Immortality;" John A. Brashear, May 10, subject, "The Contribution of Photography to our Knowledge of the Stellar Universe."

NEW BOOKS AND PAMPHLETS

GOOD ROADS. Bulletin No. 20. 53 pages, 6 x 9 inches. Published by the University of South Carolina, Columbia, South Carolina.

OCCLUDED GASES IN COAL. Bulletin 52. By S. W. Parr and Perry Barker, 28 pages, 6 x 9 inches. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill.

PROCEEDINGS OF THE FOURTEENTH ANNUAL CONVENTION OF THE NATIONAL ASSOCIATION OF MANUFACTURERS. 270 pages, 6 x 9 inches. Issued from the secretary's office, 170 Broadway, New York.

PROCEEDINGS OF THE SEVENTEENTH ANNUAL CONVENTION OF THE TRAVELING ENGINEERS' ASSOCIATION HELD AT DENVER, COLO., September 7-10. 396 pages, 6 x 9 inches. W. O. Thompson, secretary, Buffalo, New York.

PROCEEDINGS OF THE SEVENTEENTH ANNUAL CONVENTION OF THE INTERNATIONAL RAILROAD MASTER BLACKSMITHS' ASSOCIATION AT NIAGARA FALLS, N. Y. August 17-19, 1909, 189 pages, 6 x 9 inches. A. L. Woodworth, secretary, Lima, Ohio.

INDUSTRIAL PEACE AND INDUSTRIAL EFFICIENCY. 30 pages, 5¼ x 8 inches. Published by the Anti-Boycott Association, 27 William St., New York.

This pamphlet is a reprint from an English publication giving the terms of Sir Christopher Furness' co-operative scheme, or "The Treaty of the Hartlepools."

FUEL TESTS WITH HOUSE-HEATING BOILERS. Bulletin No. 31, by J. M. Snodgrass. 108 pages, 6 x 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

The bulletin reports 139 tests of anthracite, Pocahontas, coke and Illinois coal made in connection with two types of house-heating boilers. The efficiency obtained varied from 44 to 66 per cent.

LOCOMOTIVE BREAKDOWNS. By George L. Fowler and William W. Wood. 292 pages, 4¼ x 6½ inches, illustrated. Published by Norman W. Henley & Son, New York. Price $1.00.

This work, which was first published in 1903, has passed into the sixth revised and enlarged edition. It is in catechism style, the questions selected being based on the experience of engineers, air brake inspectors, and others connected with locomotive operation and maintenance. The contents by chapters are: Defective valves; accidents to the valve

motion, Stephenson link gear; accidents to cylinders, steam, chests, and pistons; accidents to guides, crossheads, and rods; accidents to the valve motion, Walschaerts radial gear; accidents to running gears; truck and frame accidents; boiler troubles; defective throttle and steam connections; defective draft appliances; injector troubles; accidents to cab fixtures; tender accidents; miscellaneous accidents; accidents to compound locomotives; tools and appliances for making engine repairs; locating and remedying air-brake troubles; the Pyle National electric headlight; rules, tables and other information. The details of the Pyle National electric headlight are illustrated on a folding plate.

PRACTICAL ENGINEER POCKET-BOOK AND DIARY FOR 1910. 684 pages, $3\frac{1}{2}$ x $4\frac{1}{2}$ inches, in addition to which are many pages of advertising and blank pages for the diary. Published by the Technical Publishing Co., Ltd., 55-56 Chancery Lane, London, England. Price, leather, 1s. 6d.; cloth, 1s.

A great fund of useful engineering information is contained in the limits of this convenient pocket-book, as is shown by the following partial statement of contents: Standard of weights and measures, areas of small circles advancing by decimals, areas of circles up to six inches diameter advancing by thirty-seconds and sixteenths, areas of circles advancing by tenths from 1 to 100 inclusive, tables of squares, logarithms, chords, wire gage and metric conversion, steam boilers and furnaces, chimneys, boiler fittings, feed water, boiler joints, boiler trials, steam consumption, properties of saturated steam, indicator dimensions, steam engine details, sizes of steam pipes, relative strength of solid and hollow shafts, heating of buildings, condensers, steam engine regulation, springs, beams, steam turbines, gas producers, gas engines, refrigeration, water turbines and Pelton wheels, pumps, gearing, belting, chain driving, rope driving, emery grinding, limit gages, speed of cutting tools, power required for machine tools, pyrometry, cranes, ball bearings, roller bearings, reinforced concrete, strength of materials, etc.

ANNUAL REPORT OF THE SMITHSONIAN INSTITUTION, 1908. 801 pages, 6 x 9 inches; illustrated. Published by the Smithsonian Institution, Washington, D. C.

This well-known publication contains the report of the Smithsonian Institution and, as has been the custom for some years, a series of valuable technical articles on various phases of scientific development, as follows: "The Present Status of Military Aeronautics," by Major George O. Squier; "Aviation in France in 1908," by Pierre-Roger Jourdain; "Wireless Telephony," by R. A. Fessenden; "Phototelegraphy," Henri Armat; "The Gramophone and the Mechanical Recording and Reproduction of Musical Sounds," by Lovell N. Reddie; "On the Relations Between Matter and Ether," by J. J. Thomson; "Development of General and Physical Chemistry, during the past Forty Years," W. Nernst; "Development of Technological Chemistry during the last Forty Years," by O. N. Witt; "Twenty Years' Progress in Explosives," by Oscar Guttmann; "Recent Researches in the Structure of the Universe," by Prof. Dr. J. C. Kapteyn; "Solar Vortices and Magnetism in Sun Spots," by O. G. Abbott; "Climatic Variations: Their Extent and Causes," by Prof. J. W. Gregory; "Uranium and Geology," by Prof. John Joly; "An Outline Review of the Geology of Peru," by George I. Adams; "Our Present Knowledge of the Earth," by E. Wierchert; "The Antarctic Question—Voyages Since 1898," by J. Machat; "Some Geographical Aspects of the Nile," by Capt. H. G. Lyons; "Heredity, and the Origin of Species," by Daniel T. MacDougal; "Angler Fishes: Their Kinds and Ways," Theodore Gill; "The Birds of India," by Douglas Dewar; "The Evolution of the Elephant," by Richard S. Lull; "Life and Work of Lord Kelvin," by Silvanus P. Thompson, etc.

THE GAS TURBINE. By Henry Harrison Suplee. 262 pages, 6 x 9 inches. 93 illustrations and diagrams. Published by J. B. Lippincott Co., Philadelphia, Pa. Price, $3.

The intention of the author in publishing this work was to place in the hands of engineers and experimenters such theoretical and practical data as are now available in the solution of the problems of the gas turbine. The historical chapter describes early experiments and illustrates some early forms of gas turbines. Papers read before the Institute of Mechanical Engineers are digested, as well as a paper presented before the Society of Civil Engineers of France. Chapter V discusses the actual behavior of gas engine nozzles, giving account of experiments of Dr. Charles E. Lucke, and describes and illustrates the practical work of Messrs. Rene Armengaud and Charles Lemale. In the last chapter the author draws some general conclusions. So far as predictions may be made, it appears that the most immediate results are to be expected from the so-called "mixed" turbine, that is the type in which the injection of water for cooling purposes causes the machine to partake of the combined nature of the gas and steam turbine. Also, the turbine of the explosive type appears to have arrived at the practical stage already, notwithstanding its low thermal efficiency. Its efficiency, however, is about the same as that of the steam engine of the same capacity. The advantages of the turbine type are so great for certain purposes that Prof. Langley is quoted in speaking of the engine of his flying machine, whereof he said: "It might burn gold, if necessary, so long as it fulfills all the other requirements of the problem." In short, the mechanical advantages of the gas turbine may outweigh its disadvantages, in thermal efficiency and other respects. In this connection it is interesting to note that a new development in gas turbines will soon be announced that will startle the aeronautical world because of the simplicity of the motor and propeller.

MODERN GAS ENGINES, AND THE GAS PRODUCERS. By A. M. Levin. 485 pages, 6 x 9 inches. 100 illustrations. Published by John Wiley & Sons, New York. Price, $4.

The literature on the gas engine is rapidly assuming the importance and profuseness of that on the steam engine. It is fitting that it is so, for the internal combustion engine undoubtedly is the coming motor. It, with the gas producer, will gradually displace the steam engine for the majority of power-producing purposes. The thermal efficiency of the gas engine is higher than that of the steam engine; in certain industries, as the steel manufacture, it offers means of directly converting waste gases into power without the loss and complicated apparatus inseparable from the steam engine. The author in his foreword speaks of the importance of economy in national fuel resources and points to the gas engine as being one means of conserving them. The contents by chapters are as follows: Introduction to Thermodynamics; Design Constants and Formulas; Theoretical Analyses of Gas Engine Cycles; Power, Size and Speed of Gas Engines; Fuels and Combustion; the Proportioning of Mixtures and the Relation of these to the Size of the Engine; Alcohol Fuels; Features of Practical Gas Engine Cycles; the Fly-wheel; the Crankshaft; Engine Details; Governing; Engine Auxiliaries; Various Gas Engine Types; Producer Gas and Gas Producers. The work treats of gas engines with particular reference to the stationary types for general power purposes. While automobile engine design is not neglected, the importance of this specialized type would seem to have merited considerably more attention than the author gave it, especially when it is conceded that the automobile development has had a great improving influence on small internal combustion motor design. Space will not permit of a more detailed reference to the otherwise excellent phases of the work, except to say in conclusion that it is essentially a book for the designing engineer. The treatment of stresses in crankshafts, thermodynamics, etc., should give the average designer bases on which to work in almost all phases of gas engine design.

GAS, GASOLINE AND OIL ENGINES. By Gardner D. Hiscox. 476 pages, 6 x 9 inches. 370 illustrations. Published by Norman W. Henley & Son, New York. Price, $2.50.

This book, which was first published in 1897, has passed into the eighteenth edition. It was revised and extended by the author before his death. In the foreword he says that the gasoline engine has almost superseded the windmill for farm and suburban use and many manufacturers are employing it in preference to electricity for portable machines. It is estimated that there are about 10,000 manufacturers of gas, gasoline and oil engines in the United States. The author gives an account of the historical progress of the internal explosive motors, and follows with the theory of gas and gasoline engines, isothermal and adiabatic law, formulas and examples, tables, utilization of heat and its efficiency in explosive motors, temperatures and pressures, formulas and examples, retarded combustion, wall cooling and compression efficiencies, advanced ignition, compression in explosive motors and its work, causes of loss in efficiency in explosive motors, form and influence of combustion chamber, economy of gas engine for electric lighting, merits of the two- and four-cycle type, gas engine fuels, carbureters and vaporizers, cylinder capacity of gas and gasoline engines, governors and valve gear, explosive motor ignition, cylinder lubrication, constructive details and dimensions, measurement of power, gas engine testing, marine gas engines, motor bicycles, producer gas and its product, etc. The automobile and marine types of internal combustion motors are exhaustively treated, a large number of forms and constructions being illustrated and described. This section makes this work particularly acceptable to many designers concerned with the design of small motors. Practical hints on assembly are given in the chapter of construction and details and parts of explosive motors. The well-known method of using strips to set the piston rings when entering the piston into the cylinder, is illustrated and described. The author saw fit to give credit for it to a gas engine designer, but as a matter of fact, this method was in common use long before the engineer named was born. The work as a whole is heartily commended.

CATALOGUES AND CIRCULARS

UNIVERSITY OF ILLINOIS, Urbana, Ill. Circular of information of the Department of Mining Engineering.

SPRAGUE ELECTRIC CO., New York. Bulletin No. 110 superseding bulletin No. 107 on Sprague electric generators.

SARGENT STEAM METER CO., 271-285 East Madison St., Chicago, Ill. Catalogue of Sargent automatic gas calorimeter.

CINCINNATI-BICKFORD TOOL CO., Cincinnati, Ohio. Circular R-50 illustrating and describing the Bickford $2\frac{1}{2}$-, 3- and $3\frac{1}{2}$-foot plain radial drill.

CLEVELAND PUNCH & SHEAR WORKS CO., Cleveland, Ohio. Handbook and stock list of machines and small tools for the fabrication of iron and steel.

PAWTUCKET TOOL CO., Pawtucket, R. I. Circular of Thompson automatic tapping chuck, which is made in both reversing and non-reversing types.

HUNTER SAW & MACHINE CO., 37th and Butler Sts., Pittsburg, Pa. Circular and price list C of circular metal-cutting saws, saw sharpening machines, etc.

LEIMAN BROS., 62 John St., New York. Circulars of pressure blowers (see MACHINERY, January, 1909), sand blast apparatus, melting furnaces, etc.

WESTERN ELECTRIC CO., 463 West St., New York. Bulletins No. 5131 and 5132 on motors and generators, type IL, and interpole motors, type ELC.

ECK DYNAMO & MOTOR CO., Belleville, N. J. Circular of Eck motors and dynamos of protected, enclosed, Manchester, back geared, vertical, variable speed and worm gear types.

HOWELL & MURRAY, Waverly, N. Y. Circular of the Howell adjustable work clamp for clamping work to lathe faceplates, boring mill tables, planer platens, etc.

SPRAGUE ELECTRIC CO., New York. Circular of Sprague "multilets." These junction boxes for electric service are made of stamped steel in two sizes with a set of covers for each size.

RICHARD W. JEFFERIS CO., Camden, N. J. Folder illustrating the Jefferis pressed steel lockers, unit construction, for use in armories gymnasiums, factories, clubs, stores, schools, offices, etc.

COMMERCIAL MOTOR CAR CO., Times Building, New York. Circular of commercial motor vehicles of gasoline and electric types for transportation systems, comprising light and heavy express wagons, trucks, etc.

E. C. BLISS MFG. CO., 91 Sabin St., Providence, R. I. Circular of the Bliss milling attachment for upright drills and drill presses. With this attachment, the ordinary drill can be converted into a vertical milling machine.

BROWN & SHARPE MFG. CO., Providence, R. I. Pamphlet on differential indexing, containing formulas and examples for differential indexing, and tables giving gears and index moves from 2 to 382 divisions, inclusive.

WHEELER CONDENSING & ENGINEERING CO., Carteret, N. J. Booklet entitled "A Radical Improvement in Jet Condensers," being a reprint of the article published in the *Iron Age* on the improved condenser made by the company.

NAYLOR BROS., 50 Church St., New York. Price list No. 1 of power transmission apparatus comprising Naylor adjustable ball and socket shaft hangers made with double brace parting hanger, wick oiling and babbitted bearings.

VILLINGER MFG. CO., Williamsport, Pa. Circular of the Williamsport 14-inch friction drill with quick-change speed device. The machine will drill to the center of a $14\frac{1}{2}$-inch circle and its spindle is fitted with No. 1 Morse taper.

WESTERN ELECTRIC CO., 463 West St., New York. Bulletins Nos. 1001, 1002, and 1105 on magneto non-multiple switch-board with manually restored line signals, magneto multiple switch-board with self-restored line signals, and intercommunicating telephone system, respectively.

KINKEAD MFG. CO., 7 Water St., Boston, Mass. Pamphlet describing the Kinkead method of aligning and leveling shafting, including setting up machinery, countershafts, grading steam and water pipes, and the common method in indoor and outdoor surveying for manufacturing plants of all kinds.

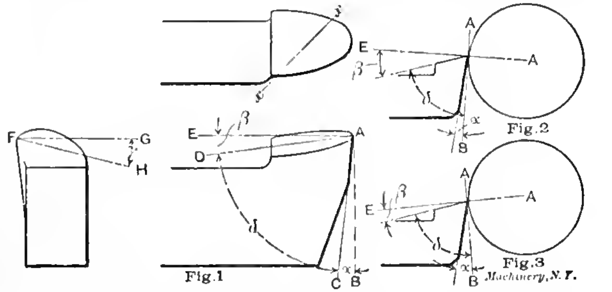
CHARLES GREINER, New Haven, Conn. Card advertising high-speed elastic blow combined riveting and spinning machine which is especially adapted for the assembly of general hardware, typewriters, etc. The machine strikes 6000 blows per minute, and is claimed to rivet faster than work can be handled.

Supplement to MACHINERY, March, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Tool Grinding"

SHOP OPERATION SHEET NO. 127

Franklin D. Jones MACHINERY, March, 1910



Meaning of Terms Used in Tool Grinding

NOTE.—In order that the tools which are used in turning or planing may work efficiently, they must be properly ground, but before considering the shape of the tool point, we shall first explain the meaning of the terms used in connection with tool grinding.

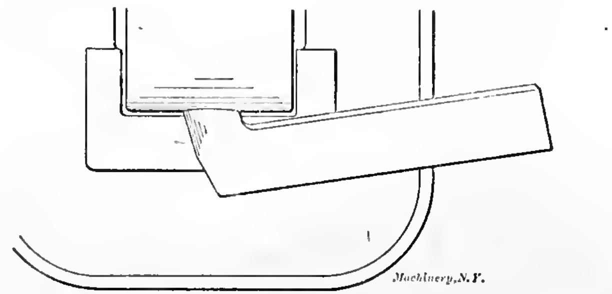
1. The clearance angle of a tool is the angular distance α between a line A-B, which is at right angles to the tool shank and the flank A-C of the tool. The angular distance β between a line A-E, which is parallel to the shank, and a line A-D, is known as the angle of back slope. When the top of the tool slopes to one side as well as backward, the angle γ between the lines F-G and F-H, is the angle of side slope. When a tool is without side slope, the angular distance δ represents the lip angle or the angle of keenness. If, however, the tool has both back and side slopes, the lip angle would more properly be the angle between the flank and the top of the tool when measured diagonally along a line x-x, as at this point the lip angle would be the most acute.

2. The base-lines A-B and A-E from which the angles of clearance and back slope are measured, do not always occupy the position with relation to the tool shank, shown in the engraving. The base line A-E, for a lathe tool which is being used, coincides with the point of the tool and the center of the work. Therefore, the position of this base-line is different from that shown in Fig. 1, when the tool point is either above or below the work center. This is illustrated in Figs. 2 and 3, where the tool is shown in different positions. As the line A-B is always at right angles with A-E, the former is also changed when the tool is presented differently to the work. It is evident then, that as the tool point is raised above the work center, as in Fig. 2, the effective angle β of back slope increases and the clearance angle α diminishes; whereas the lowering of the tool, as in Fig. 3, has the opposite effect. The effective angle of keenness also changes as the height of the tool point varies, as this angle, when the tool is in use, is the angular distance δ.

3. As the point of a planer or shaper tool usually acts along a line at right angles to the tool shank, the tool being clamped in one position, it will be seen that the angles of clearance and back slope when the tool is in action, are the same as the theoretical angles, or those of the tool alone. If, however, the tool were clamped in an inclined position, obviously the effective angles of clearance, keenness, and back slope would be affected.

SHOP OPERATION SHEET NO. 128

Franklin D. Jones MACHINERY, March, 1910



Grinding a Lathe Roughing Tool—1

NOTE.—The shape of the cutting end of a tool is governed by the particular work for which it is intended. While tools for different machines and intended for different purposes are shaped differently, the various forms are largely based on certain underlying principles, which will be briefly considered in the following description of the grinding of a lathe roughing tool.

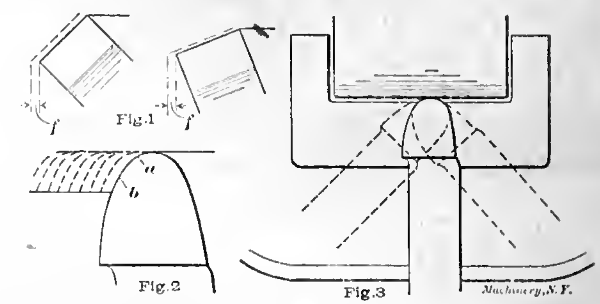
1. The top of the tool is first ground by holding it against a wet emery wheel or grindstone in the position shown in the engraving. By inclining the tool with the wheel face, it will be seen that both the back and side slopes may be ground simultaneously. With a given amount of clearance, the lip angle will depend on the angles of back and side slope; and, obviously, a given lip angle may be obtained by grinding the tool so that it has back slope without side slope, or *vice versa*, or by a combination of these two angles. It has been demonstrated that the latter method is the best, and also that the lip angle should be obtained principally by side slope. The advantage in having considerable side slope is that the chips run from the side of the tool and do not come in contact with the tool shank or the holder; in addition there is less side pressure on the tool and less resistance to feeding. A certain amount of back slope is needed, however, as otherwise the chips tend to push the tool away, thus impairing the finish and accuracy of the turned part. The angles of back and side slope should, for most work, be approximately as follows:

2. Tools for turning soft steel should be ground with a back slope of 8 degrees and a side slope of 22 degrees. Tools intended for cast iron and steel of medium hardness should have a back slope of 8 degrees and a side slope of 14 degrees. For hard material, such as tire steel, the angle of back slope should be 5 degrees, and the side slope 9 degrees. It will be seen that as the metal becomes harder, the angles of back and side slope decrease, and, consequently, the lip angle increases and the tool is more blunt; this is to give it increased strength at the cutting edge to prevent the edge from crumbling. If the lip angle is too great, however, it will affect the cutting speed and result in an excessive chip pressure on the tool.

NOTE.—There is great danger of burning tools when grinding them, that is, drawing the temper, even when the wheel used is provided with water. The tool, particularly when grinding the top, should be slightly but frequently drawn away from the stone to prevent it from becoming overheated.

SHOP OPERATION SHEET NO. 129

Franklin D. Jones MACHINERY, March, 1910



Grinding a Lathe Roughing Tool—2

NOTE.—Experiments have shown that the thickness of the chip severed by a lathe tool, greatly affects the cutting speed. When the chip is thin, the speed of the work may be much higher than for a thicker chip, without injury to the cutting edge of the tool. The thickness of the chip, for a given feed, may be varied by changing the angle that the cutting edge of the tool makes with the axis of the work. This is illustrated by the dotted lines in Fig. 1, where a broad-nosed tool is shown in different positions. When the tool is set as shown to the right, the chip is thinner for the same feed, f, and the speed may be increased. It is principally this relation between the angle of the cutting edge and the cutting speed, that adapts a tool having a rounded cutting edge so well to rough turning. With the rounded edge, the thickness of the chip removed by a point a (Fig. 2) on the tool, is much less than at b, as is illustrated by the dotted lines. Because of this thinness of the chip toward the tool point, the cutting speed that will dull the part b, will not affect the part a or the point to the same extent. We see then that the part of the cutting edge which sizes the work, remains keen after the rest of the edge has become dulled, provided the tool is ground with a curved cutting edge.

1. When grinding the flank of the tool, it should be held on the tool rest of the emery wheel or grind-stone, as shown in Fig. 3. In order to form the curved cutting edge, the tool is turned about the face of the stone while it is being ground, as indicated by the dotted lines. This rotary movement can easily be effected by supporting the inner end of the tool with the left hand while the shank is being moved to and fro with the right. The curve of the cutting edge should be approximately like that shown in Fig. 2. If the radius of the tool point is too large, the tool, while capable of a higher cutting speed, is liable to cause chattering.

2. It will be seen that at this grinding, the cutting edge is given both its shape and clearance. Generally speaking, the clearance of any metal-working tool should be just enough to ensure that the tool will cut freely. If the clearance is unnecessarily great, the tool, because of its decreased lip angle, is weakened. As a lathe tool traverses a spiral path, there must be sufficient clearance below the cutting edge to prevent the tool flank from rubbing. A turning tool should have approximately eight or nine degrees of clearance. Six degrees is sufficient, but unless a tool grinding machine is used, it is not advisable to grind too close to the limit.

Diagram 13.

Connections for Alternating Current Induction Motors.

Single-phase motors are not self-starting. Diagram 9 shows connections for small motors of this type. They are started by giving the belt a few quick pulls. Large single-phase motors are made self-starting by acting as two-or three-phase machines in starting; when up to speed, connections are changed to single-phase. They are also arranged to start as repulsion motors, and when running at nearly full speed, connections are automatically changed to single-phase induction motors. Diagram 9 shows connections for large motor arranged to start as repulsion motor. Diagram 10 shows connections for single-phase motors arranged to start as three-phase motors. To change to single-phase, move down the starting switch lever (which is thrown upward to start).

Motors starting as repulsion machines are made reversible by using a reversing switch, with connections as shown in Diagram 11. Small two-and three-phase induction motors are connected with the mains in the way shown in Diagrams 12 and 13.

Contributed by William Baxter, Jr.

TYPICAL A. C. INDUCTION MOTOR WIRING DIAGRAM.

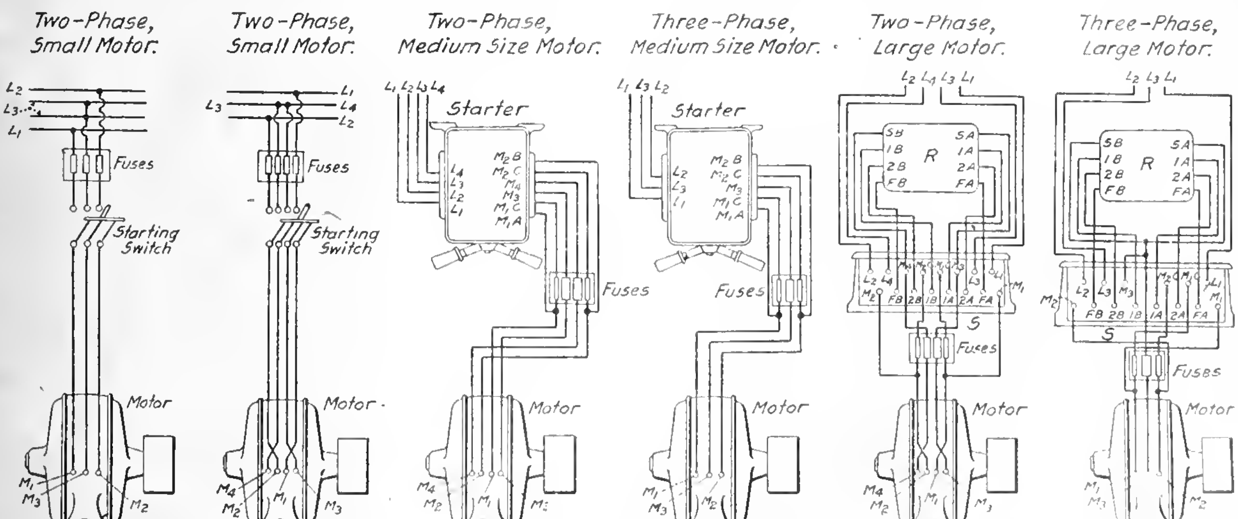

Diagram 14. Diagram 15. Diagram 16. Diagram 17. Diagram 18. Diagram 19.

When a three terminal motor is connected with four main wires, connections are made as shown in Diagram 14, one of the motor terminals being connected with two line wires.

When the motor has four terminals and three line wires, connections are made as in Diagram 15, two motor terminals being connected with one of the line wires. In medium size motors, regulator and starting switch are combined in one, the connections with the motor and line being as shown in Diagram 16 for two-phase, and in Diagram 17 for three-phase motors. When the motor is large, regulator and starting box are made separate, and are located as near to each other as possible. Connections are made between the mains, the starter, the regulator, and the motor. These connections are made as shown in Diagram 18, for two-phase motors, and in Diagram 19 for three-phase motors. The starting switch is marked "S" and the regulator "R".

March, 1910

METAL SPINNING—1*

By WILLIAM A. PAINTER†

THE principal object of this article is to describe in detail the various operations of spinning metal so that a tool-maker or machinist who has not access to a metal spinner, will be able to make his own tools, rig up an engine or speed lathe, and make the simple forms or models that are required in experimental work. To do this intelligently, it is necessary to follow in detail every step in metal spinning from the circular blank to annealing, pickling, dipping, burnishing, etc., and also to know how to make the simpler forms of spinning tools, what lubricants to use on the different kinds of metals, what material to make the spinning chucks of, and how far the metal can be worked before annealing.

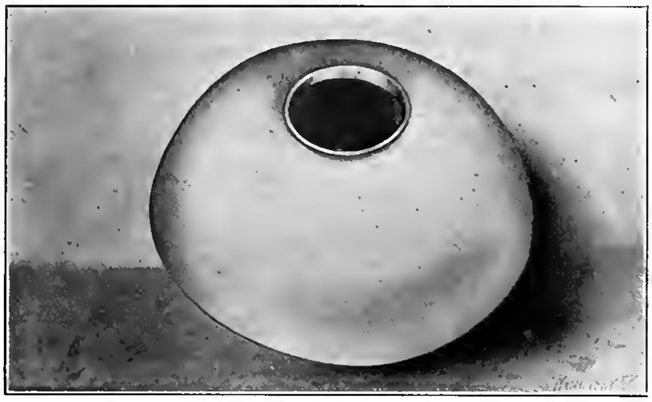

Fig. 1. Zinc Lamp Shade Spun in One Operation without Annealing

Spinning metal into complicated and elaborate shapes, is an art fully as difficult as any craft, and the man is truly an artist that can make artistic and graceful outlines in metal, especially when only a few pieces are required and the cost will not allow of making special chucks to do the work on and with no outline chucks to govern his design, the forms being made by skill and manipulation of tools alone. Such skill is far superior to that of the Russian metal worker, who, instead of making a vase or ornament of one piece, cuts up several sections and soft solders them together, after covering them with crude "gingerbread" work to disguise his poor metal work.

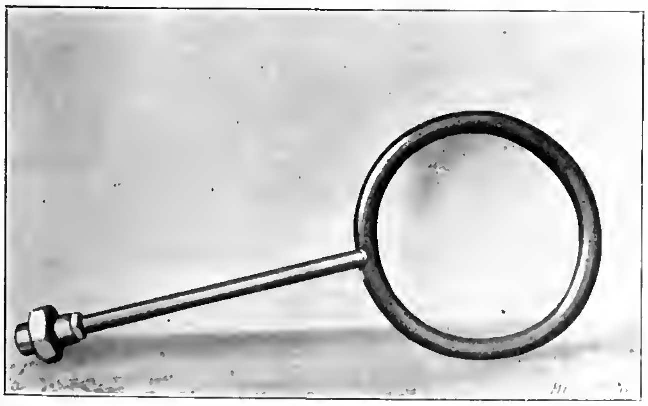

Fig. 2. Gas Burner for Heating Spinning Chuck

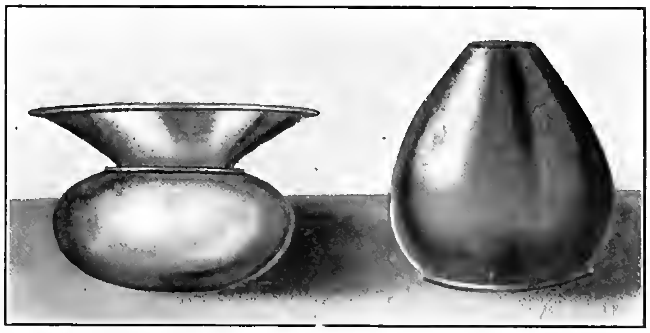
The amateur can imitate the Russian work, but never the work of the skilled spinner. There are several grades of spinners, most of them never attaining the skill of the model-maker or the facility for handling the different metals. A man that has had several years of experience spinning brass or copper would not be able to spin Britannia or white metal without stretching it to a very uneven thickness. As brass or copper is harder than the other metals mentioned, they resist the tool more and require more pressure in forming, and if the operator used the same pressure on the softer metals, he would stretch or distort them, so that they would be perhaps one-quarter of the original thickness at angles and corners where the strain in spinning would be greatest, which would ruin the articles. The best test for skill in ordinary spinning, is to take a long difficult shape, after being finished, and saw it in two lengthwise, and if the variation in thickness is less than 25 per cent of the original gage, it is good practice. Some spinners can keep within 10 per cent of the gage on ordinary work, but they are scarce.

The spinning trade in this country is mostly followed by foreigners, Germans and Swedes being the best. The American that has intelligence and skill enough to be a first-class spinner, will generally look around for something easier about the time that he has the trade acquired. It is an occupation that cannot be followed up in old age, as it is too strenuous, the operator being on his feet constantly, and having to use his head as well as his muscles.

General Remarks on Metal Spinning Chucks

For common plain shapes, a patternmaker's faceplate, with a tapered center screw, is sufficient for holding the wood chuck. The hole in the wood should be the same taper as the screw, thus giving an even grip on the thread. If a straight hole only is used, and it is not reamed out before screwing to the plate, it will only have a bearing on one or two threads, and if the chuck is taken off and replaced on the faceplate, it will not run true. Care should also be taken to face off the end of the chuck flat, or to slightly recess it, so that it will screw up evenly against the faceplate, as a high center will cause it to rock and run out of true.



Figs. 3 and 4. Examples of Aluminum and Copper Spinning

In large chucks (over five inches) it is best to have three or four wood screws, besides the center screw. The holes for these can be spaced off accurately on a circle in the iron faceplate, and drilled and countersunk. It is best to have twice as many holes as screws; that is, if four screws are used there should be eight holes, so that if the chuck has to be replaced at any time and the wood has shrunk, it can be turned one-eighth of a revolution further than the original chucking.

Where a chuck has to be used several times, it is better practico to cut a thread in the wood and screw the chuck directly to the spindle of a lathe, not using the faceplate. This thread can be chased with a regular chasing tool, where the operator has the skill, and, if not, the wood can be bored out and a special wood tap used. Such a tap has no flutes and it is bored hollow, there being a wall about 3/16 inch thick. One tooth does all the cutting, that being the end of the thread. The chips go into the hollow part of the tap. The end of the tap for about 1/4 inch should have the same diameter as the hole before threading to act as guide for the cutting tooth.

* See also the article, Methods and Tools Used in Metal Spinning, published in the December, 1909, number of MACHINERY.

† Address: 1515 Franklin St., Pittsburg, Pa.

It is essential that a chuck should run very true and be balanced perfectly, as the high speed at which it runs will cause it to vibrate and run out of true, causing the finished metal to show chatter marks. The best wood for chucks is hard maple, and it should be selected for its even grain and absence of checks and cracks. It is best to paint the ends with paraffine or red lead, or to immerse the chucks in some vegetable oil after turning. Cotton seed oil is very good for this purpose, but care should be taken not to soak the chucks too long.

For a man not skilled in spinning, it is better to use metal chucks than wood, for if there are many shells of a kind, the operator is liable to bear too hard on the tool, thus compressing the chuck and making the last shells smaller than the first. Corners and angles that are not well supported might also be knocked off. I prefer cold rolled steel for chucks up to 6 inches in diameter and cast iron for the larger ones, but where good steel castings can be obtained a good chuck can be made by turning roughly to shape a wood pattern, allowing enough for shrinkage and finishing, and hollowing

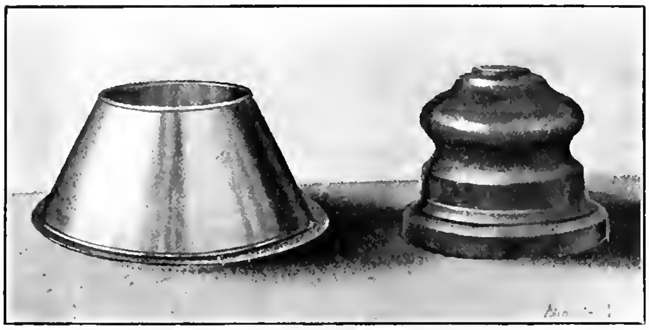


Fig. 5. German Silver Reflector Fig. 6. Open-hearth Cold-rolled Steel Shell

out the back to lighten it. When the casting is finished all over in the lathe, it should balance much better than a cast iron one as there are not the chances of having blow holes in the iron thus throwing the chuck out of balance.

Annealing

The distance that metal can be drawn without annealing, can only be learned by experience. A flat blank rotated on the lathe, being soft, will offer little resistance and it can be gradually drawn down by a tool held under the chuck and against the blank. This tool is pushed from the center outward and forward at the same time, and every time it passes over the blank or disk the metal becomes harder by friction and the change of formation and the resistance at the point of the tool greater. This can be felt as the tool is under the operator's arm. When the spring of the metal is such that the tool does not gain any but only hardens the metals, the shell should be taken off and annealed. If the metal has

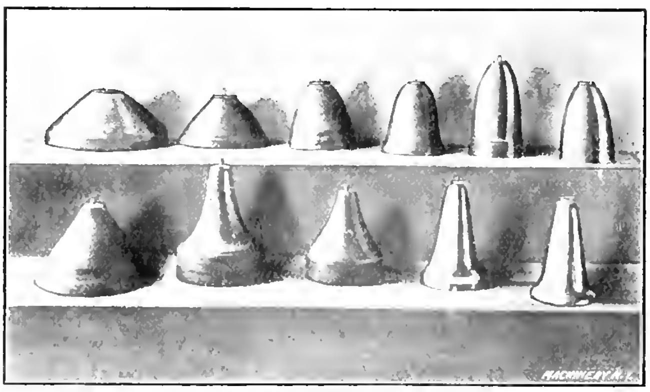

Fig. 7 Various Steps in Spinning the Two Brass Shells at the Right

been under a severe strain, it should be hammered on the horn of an anvil or any metal piece that will support the inside. The hammer should be a wood or rawhide mallet, but never metal, the object being to put dents or flutes in the metal to relieve the strain when heating to anneal; if this is not done the shell will crack.

After annealing the shell it should be pickled to clean the oxide or scale from the surface; otherwise the metal will be pitted. Where the scale is crowded into the metal and when it will not finish smooth after spinning to shape, the metal can be finished by skimming or shaving the outer surface which cuts out all tool marks; it can then be finished with medium emery cloth or the shell can be bright dipped, and be run over with a burnishing tool before buffing. Burnishing can be done on the spinning chuck, but the speed should be

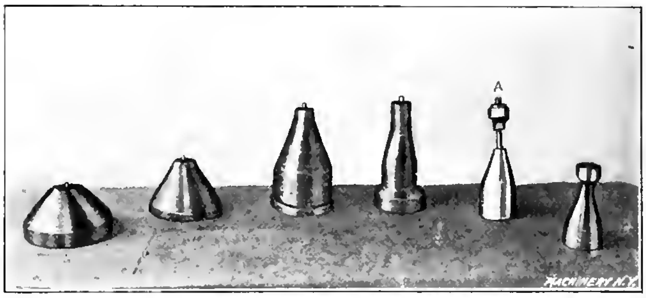

Fig. 8. Another Brass Spinning Operation; the Chuck used is shown at A

higher than for spinning; this requires some skill for a good job, and it can be done only on metal chucks.

Annealing is best accomplished in a wood or gas oven, where a forge fire is used. The metal should never touch the coke or other fuel but it should be held in the flame above the fire. Where only part annealing is required, the shell can be immersed in water, the part to be annealed being exposed above the water, and a blowpipe used on it. The remainder of the shell will then be hard. This way of annealing is sometimes necessary on special shapes.

Brass should be heated to a cherry red, and held at that point for a few minutes, in a muffle furnace. If an open furnace is used, just bring the metal to a cherry red and then dip it in water; this method anneals better than waiting for it to cool, the action being just the opposite to that of steel. Brass such as the common yellow brass is not suitable for spinning there being but 55 per cent copper and 45 per cent

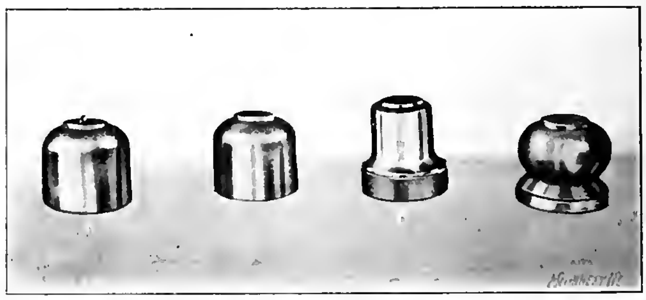

Fig. 9. An Example of "Air Spinning" and the Chucks used

zinc. There are two grades of brass suitable for spinning. These are known as "spinning and drawing," having 60 per cent copper and 40 per cent zinc, and "extra spinning and drawing" having 67 per cent copper and 33 per cent zinc. There is also a better grade known as "low brass" having from 75 to 80 per cent copper; it has the color of bronze and is only used on very deep and difficult spinning.

The scale, after annealing, should be pickled off in an acid bath (described further on in this article), and the part thoroughly washed in running water. Brass, German silver and the harder metals should be hammered before annealing; it is not necessary to hammer zinc, copper, aluminum, etc.

A pyrometer in an annealing furnace would be an advantage where quantities of the softer metals such as zinc, aluminum, etc., are being heated. Copper is annealed the same as brass and is also pickled. Zinc is coated with oil before being put in the oven, and when the oil turns brown, which occurs when the temperature is about 350 degrees, the metal is ready to take out; it should then be plunged in water to shed the scale but not pickled. The melting point of zinc is 780 degrees F. Aluminum can be annealed the same as zinc, as the melting point is 1,140 degrees F.

Steel should be annealed by heating to a cherry red and then allowing it to cool slowly; it should be scaled in a special pickle, thoroughly washed, and then put back in the fire long enough to evaporate every particle of acid that may have remained from the pickling operation. Any acid remaining

on the steel will neutralize any lubricant that is applied when spinning. Annealing should be avoided wherever possible. Open hearth steel only should be used. It should be free from scale and preferably cold rolled. Bessemer steel is not suitable, except for very shallow spinnings. Tin plate made from open hearth steel can be spun about one-half as deep as its diameter where the shape is not too irregular. German silver is difficult to spin, especially when it is over 15 per cent nickel; it has to be hammered before annealing, the same as brass, to avoid cracks.

Lubricants

Common yellow soap cut up in strips about ½ inch or ¾ inch square is a good lubricant for spinning most metals. It should be applied evenly to the disk or blank while it is revolving, by holding the soap in the hand and drawing it across the surface. Beeswax is the best for spinning steel, but it is expensive. Lard oil mixed with white-lead is a fair substitute. Either mutton or beef tallow applied with a cloth swab is very good on most all metals; also vaseline and graphite mixed to a paste and applied the same as tallow.

Fig. 10. Miscellaneous Collection of Spinning Chucks

Examples of Spinning with Various Metals

The different metals are malleable, ductile and tenacious in the following order: white metal or Britannia, aluminum, zinc, copper, low brass, high brass, German silver, steel, tin plate. White metal does not harden in spinning, but it requires special skill in handling, or the metal will be of very uneven gage. The best metal for an amateur to start on is copper, as it is both tenacious and ductile, and will stand much abuse in the fire and on the lathe. One of the peculiar properties of zinc is that it has a grain or texture, and when spinning, the two sides that went through the rolls lengthwise will be longer than the sides that have the cross grain, requiring the shell to be trimmed off quite a distance to even the edge.

To show the possibilities of working the different metals, and their relative spinning values, a number of articles made from different materials are illustrated herewith.

A zinc lamp shade is shown in Fig. 1 that is 14¼ inches in diameter and 4¾ inches deep. This shade was spun in one operation, without annealing, from a flat circular blank. All zinc should be warmed before spinning, either over a gas burner at the lathe or in hot soap water, and the chuck also should be heated, as otherwise the blank will soon chill, if spun on a cold metal chuck, as the chuck absorbs the heat long before the operation is finished. Of course this does not apply to wooden chucks. The chuck may be heated by using the burner shown in Fig. 2, which is located around the spindle of the lathe. The size of the burner should, of course, be in proportion to that of the chuck used. The burner illustrated is 8 inches in diameter. It has several small holes drilled for the gas on the side facing the chuck. The heat of the chuck is regulated by varying the supply of gas to the burner. The blank is heated before it is put on the chuck and the friction of the spinning tool helps to keep it warm until it comes in contact with the chuck. The metal retains its heat until the job is finished, and this sometimes saves an annealing operation.

In Fig. 3 is shown an example of aluminum spinning. The article illustrated is a cuspidor having a top 7¾ inches in diameter, a neck with a 4-inch flare, a diameter at the top of 9½ inches, and a height of 6½ inches. This shell was spun without annealing, which shows the extreme ductility of aluminum. The copper shell shown in Fig. 4, has a maximum diameter of 7 inches, and a depth of 8 inches; it was spun with four annealings. A German silver reflector, which is 10 inches in diameter at the largest end and 5 inches deep, is shown in Fig. 5. The spinning of such a reflector, when made from this material, is quite difficult. An open hearth cold-rolled steel shell with a maximum diameter of 3 inches and a depth of 4 inches is shown in Fig. 6. This shell was spun without annealing which shows that the grade of steel used is well adapted for this work.

In Fig. 7 two finished brass shells are shown to the right, and also the number of operations required to change the form of the metal. The upper shell is 6 inches long and 3½ inches in diameter at the large end, while the lower one is 7¼ inches long by 3¾ inches in diameter. It was necessary to anneal these shells between each operation, the upper shell being annealed four times and the lower one three times. These pieces were made in quantities sufficient to warrant the making of chucks for each operation, which enabled them to be spun with less skill than would be required if a finishing chuck only were made. When a single finishing chuck is used, the various operations in spinning a shell of this kind would be left to the judgment of the spinner, who would decide the limit of the stretch of metal between the operations before annealing.

A brass shell that is made in five operations and with four annealings is shown in Fig. 8. The finishing chuck used is a split or key chuck on which it is necessary to cut out the end of the shell in order to withdraw the key after the shell is spun. This shell, which is shown finished to the right, is 5½ inches long. It is spun smooth on a machine steel chuck, and is not skimmed, but gone over with a planishing tool at the last operation. The two pieces shown in Fig. 7 were also finished in this way.

Fig. 9 shows a brass shell, which is a good example of "air spinning," so called because the finishing or second operation on part of the shape is done in the air, thus avoiding the use of a sectional or split chuck. The shell shown is about 5½ inches in diameter. The first or breaking-down chuck is shown at *A*. The neck or small part of the piece, and also a portion of the spherical surface, is formed by the spinning tool without any support from the chuck. After the shell is spun, or broken down on chuck *A*, it is annealed and pickled. It is then put back on chuck *A* and planished or hardened on the part that is to retain its present shape. The work is then placed on the chuck *B* and the soft part is manipulated by the tool until it conforms to the shape shown to the right. While this soft part of the metal is being formed, the part which was previously hardened retains its shape.

Fig. 11 Another Group of Spinning Chucks. Those in the Upper Row are of the Split or Key Type

Various Types of Metal-spinning Chucks and Their Construction

A miscellaneous collection of spinning chucks is shown in Fig. 10. As will be seen, the larger ones are machined out in the back to lighten them, and also to give them an even balance. The larger of those illustrated measure about 9½ inches in diameter, and they are made of cast iron, while the smaller chucks shown in this view are of machine steel. The chuck marked *A* is a key chuck. Another collection of spinning chucks of various shapes is shown in Fig. 11. Those in the upper row are all key or split chucks, and the keys are shown withdrawn from the sockets. All these chucks, up to 6 inches in diameter, are made of machine steel; those seen in the lower row are shapes which are comparatively easy to spin.

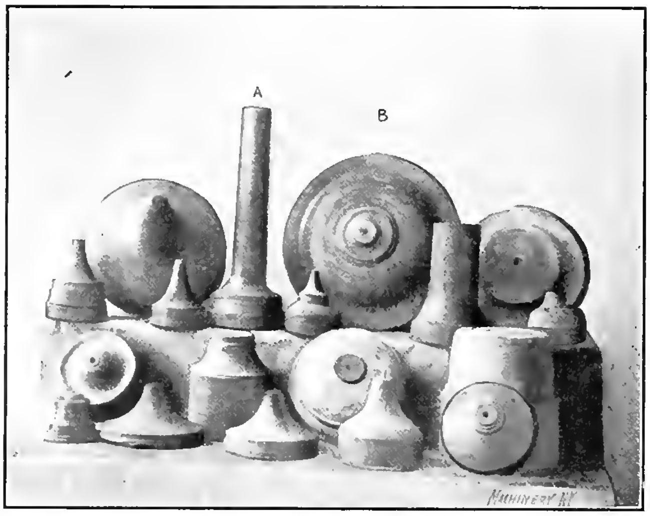

Fig 12. Various Forms of Spinning Chucks made from Hard Maple

A collection of hard maple chucks is shown in Fig. 12, some of which represent shapes that are difficult to spin. The chuck *A* is 15 inches long, and the maximum diameter of *B* is 12½ inches. These figures will serve to give an idea of the proportions of the other chucks. All of the chucks shown have threads cut in them and they are screwed directly to the spindle of the lathe, the faceplate being dispensed with. Some of the larger wooden chucks used measure approximately 5 feet in diameter. A chuck of this size is built up of sections which are glued together.

A number of bronze sectional split chucks are shown in Fig. 13. When spinning over a sectional chuck, it is first necessary to break down the shell as far as is practicable on a solid chuck. Care should be taken, however, to leave sufficient clearance so that the work may be withdrawn. The shell is then annealed, after which it is put on the sectional chuck and the under cut or small end is spun down to the chuck surface. When the entire surface of the shell is spun down to a bearing, the shell is planished or skimmed to a smooth surface; the open edge is also trimmed even and the shell is polished with emery cloth.

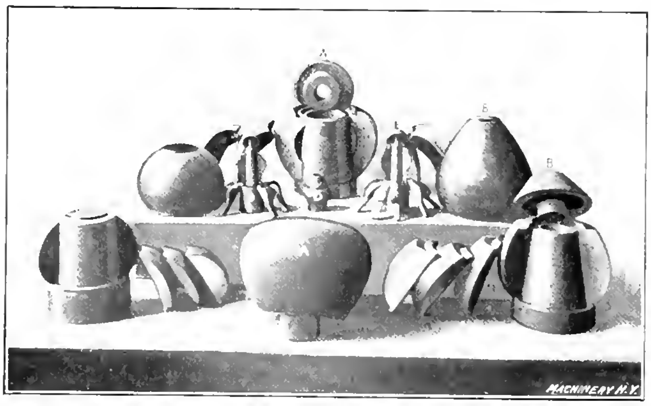

Fig. 13. A Group of Bronze Sectional Chucks

A large bronze chuck of seven sections, one of which is a key section, is shown at *A*. The largest diameter of this chuck is 10 inches. It has a cast iron center hub and a steel cap at the top for holding the sections in place. This cap, when in place in the retaining groove shown, is flush with the top of the chuck. Another large chuck having five sections and one key section is shown at *B*. The retaining cap in this case is of a different form. The lower part of the sections of all these chucks fit in a groove at the bottom of the hub. A chuck of five sections, that is without a binding cap, is shown at *C*. This is not a good design as the hub or center is too straight, and all of the grip or drive is from the bottom groove, which is not sufficient. The shape shown at *D* is more difficult to spin than any of the others, as it is smaller at the opening in proportion to its size. This chuck also requires more sections in order that it may be withdrawn from the shell after the latter is spun. The chuck *E* is intended for a small shell that is also difficult to spin. The drive pins which prevent the segments of the chuck *E* from turning, may be seen projecting from its base. The centering pins at the outer end of chucks *D* and *E* and the binding caps may also be seen. The chuck *A*, because of its size, is hollowed out to reduce the weight. All of these chucks were made for hard service, and they have been used in spinning thousands of shells.

Another group of sectional chucks is shown in Fig. 14. There are mostly made from hard maple. The sections of chuck *A* are planed and fitted together and thin pieces of paper are glued to these sections before they are glued collectively for turning. By using the paper between the joints, the sections may be easily separated after they are turned to the proper size and form. If the different sections were glued without paper between them, the joint formed would be so good that the separation of the sections could not be controlled, and parts from opposite sections would be torn away. The use of the paper, however, between the glued joints, controls the separation of the sections. The chuck shown at *D* is also made with the paper between the sections. Chucks *B* and *E* are turned from the solid, care being taken to have the grain of the wood lengthwise. After they are turned to the required form, they are split into sections with a sharp chisel. Before doing this, the key-section should first be laid out. There should be as few sections as possible, the number being just sufficient to enable the withdrawing of the chuck from the shell after the latter is spun to shape. This method of making a chuck, while quicker than the other, is not good practice, except for small work.

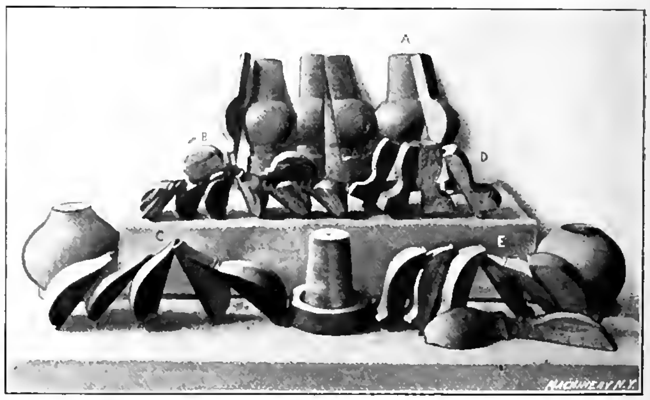

Fig 14. Sectional Chucks made from Wood

A lignum vitæ chuck is shown at *A* in Fig. 15 that was made with paper between the sections. The key-section is shown on top. This wood, while being more durable than hard maple, costs sixteen cents a pound in the rough and, counting the waste material, is not any cheaper than bronze, and is less durable. The hard maple chucks *B* and *C* were turned from the solid, after which the sections were split. The segments shown in the center of the illustration did not split evenly, owing to a winding or twisting grain.

The construction of a sectional spinning chuck is shown in Fig. 16. This illustration also shows the proper proportion for the central hub and its taper. This hub should never be straight, but should have from 5 to 7½ degrees taper on the central part. There should also be a taper of 1½ degree on the other binding surfaces as indicated. These parts are made tapering so that the shell can be released from the

lathe after spinning, without hammering or driving; when straight surfaces are used the work has to be pried off, and it is also harder to set up the sections for the next shell. Another disadvantage is that with straight fittings the wear cannot be taken up. An end cap or binder should be used wherever possible as it steadies the chuck. A drive pin should also be used and the hole for it drilled in the largest

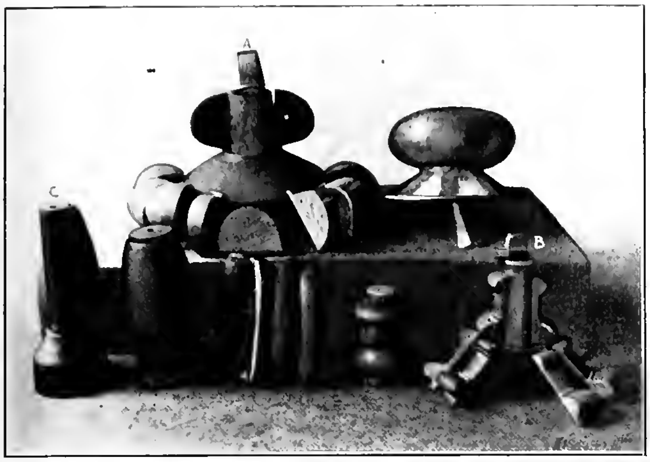

Fig. 15. Other Examples of Wooden Sectional Chucks

section; this is important, as it gives the sections a more positive drive. If they slip they will soon wear themselves loose and leave openings at the joints.

The plan view shows the method of laying out the various sections. The key should be laid out first. One key is enough for the particular form of chuck illustrated, but it is often necessary to use two key sections when the shell opening is small.

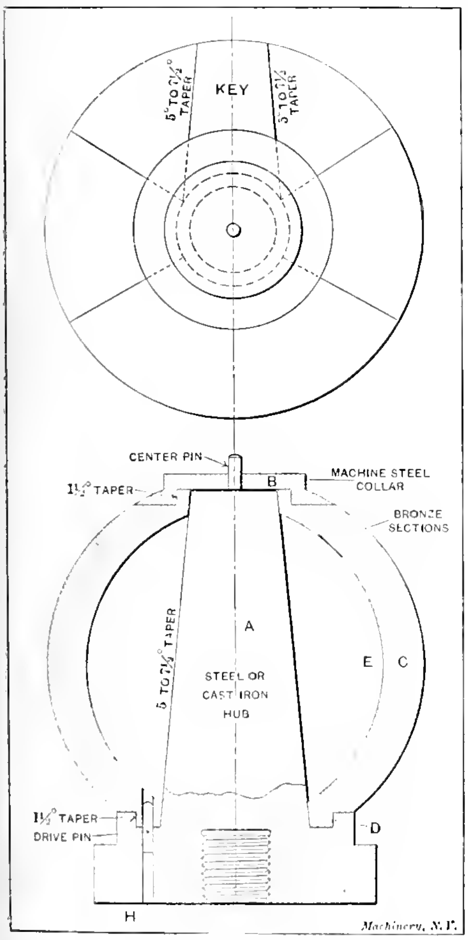

Fig. 16. Elevation and Plan showing Construction of Sectional Chuck

When a sectional chuck is to be made, it is important to decide first on the size of the central hub A, the number of sections C, and also the design of the cap or binder B. This cap must not exceed in size the opening in the finished shell, as it would be impossible to remove it after the chuck sections were taken out. After the size of the hub A has been decided upon, a wooden form should be turned that is a duplicate of A, except that a spherical surface E should be added. This spherical part should be slightly smaller than the inner diameter of the bronze sections in order to allow for machining them. In turning this wooden pattern on which the plaster patterns for the sections are to be formed, the shoulder D should be omitted, as a removable metal ring will take its place.

When the wooden hub is ready, two metal partitions or templets of the same outline as the chuck, though about one-half inch larger than its total diameter, for shrinkage and finishing, are fastened to the hub in the correct position for making a plaster pattern for the key section. These patterns should have extension ends so that the sections when cast, may be held by them while they are being turned. The templets should be banked around with a wad of clay, and they should also be coated on the inside with sperm oil to keep the plaster from sticking. There should be two brads driven in the hub for each section of plaster to hold the sections in place while they are being turned. After the plaster for the key section has hardened, the templets should be located, one on each side of the key section, so that the two adjacent sections may be made. In this way all the sections are finished. After about forty-eight hours the plaster will be hard enough to turn in the lathe with a hand tool. The form should be roughly outlined and plenty of stock left for shrinkage, as bronze shrinks considerably. Before taking the sections off the wooden frame, the metal band D should be removed to allow the sections to be separated. This should not be done, however, until they are numbered, so that they can be again placed in their proper positions. After the sections are cast, they should be surfaced on a disk grinder, or finished with a file, care being taken to remove as little metal as possible. Each section is next tinned on both contact faces, and then all are assembled and sweated or soldered together by a blow-pipe. It is sometimes necessary to put a couple of strong metal bands around the sections to hold them firmly in place when soldering and also to support them during the turning operation.

The central hub A should be machined first; then the assembled outside shell should be machined to fit the hub A, both on the taper part and at the point D. While the segments are being bored and faced, they are held by the extension ends (not shown) which were provided for this purpose. This outer shell should also be machined all over inside so that it will be in balance. It is then taken out of the chuck and a hole is drilled in the largest section for drive pin H. The hub A is then caught in the lathe chuck with the assembled sections on it, and a seat is turned for the cap B. After this is done the binder bands can be removed, but not before. The chuck can be finished with a hand tool and file after the roughing cut is taken. After the sections are removed from the hub and numbered at the bottom or inner ends, they can be separated by heating them. If the joints are properly fitted there will be only a thin film of solder which can be wiped off when hot.

* * *

A new iron has been produced and sold for a short time past by the American Rolling Mill Co., of Middletown, Ohio. It is a product of the open-hearth steel furnace, but in chemical composition and in mechanical properties it is so closely similar to wrought-iron that the term "steel" can no longer be applied to it properly. The makers have given it the trade name "American Ingot Iron." This ingot iron differs from steel in having its carbon, manganese and silicon contents reduced to small fractions of the amounts found in ordinary soft steel. A typical analysis is as follows: Carbon, 0.02 per cent; manganese, 0.01 per cent; phosphorus, traces; sulphur, 0.02 per cent, and silicon, traces. The metal is to all appearances identical with dead soft steel, or a good wrought-iron, though its fracture lacks the ropy fiber seen in the latter. Its strength is closely the same as that of wrought-iron. Several tests indicate an ultimate tensile strength of from 47,000 to 49,000 pounds per square inch. Its ductility is remarkably high, and the metal is rolled into sheets and the sheets used for drawing in the drawing press with good results. The prime quality of this ingot iron, however, is its resistance to corrosion. This was the object for which it was originally produced as an experiment, and when trials against steel in sulphuric-acid solutions showed the hope of high corrosion resistance to be borne out, it made the metal at once the most interesting appearance in iron metallurgy of the present time.

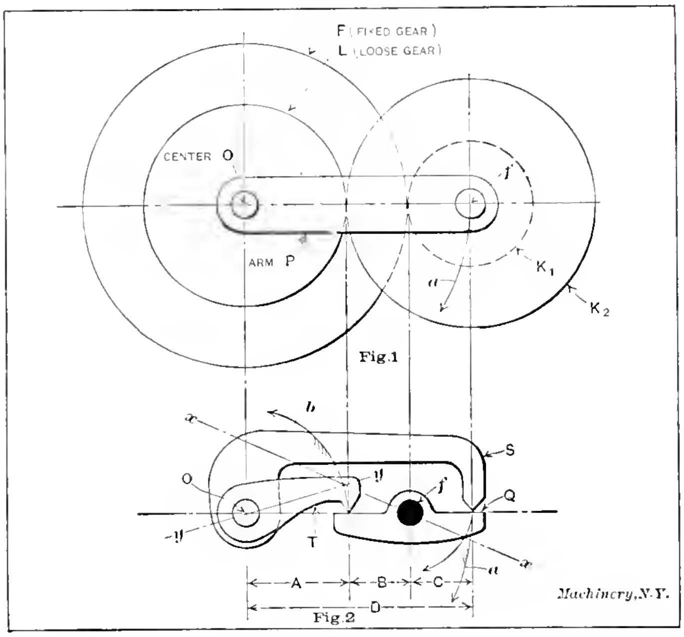
* * *

Don't forget that it is a high point in economy to put all necessary information and data on all drawings.

SOLUTION OF EPICYCLIC GEARING BY THE METHOD OF LEVERS*

By JOHN S. MYERS†

The solution of epicyclic, planetary, or as it is sometimes called, differential gearing, is often rather confusing. This is especially the case to the person who approaches the subject for the first time, and, unless some correct and systematic method be pursued, two different men working independently on the problem are quite likely to get entirely different results as to the velocity ratio, and resultant direction of rotation. The method which is probably most generally known is that of separate motions, and the only drawback to this method is the liability of getting the signs (+ and —) mixed.



Figs. 1 and 2. Diagram for the Solution of Problem in Epicyclic Gearing by the Lever Method

In the following problems the writer has illustrated the application of this method, at the same time applying a method which he has termed *the lever method*, in each case checking the latter by the former to prove the work.

The principal advantages of the lever method are: 1. That the resultant direction of rotation can be determined without calculation by a simple process of inspection, thereby reducing the chances of error to a minimum, and offering a ready means of checking the result obtained by some other method. 2. It facilitates finding the directions and amounts of the tooth pressures.

When applying the lever method for velocity ratios, instead of taking the actual radii of the various gears, these radii may be taken as the number of teeth in the respective gears if all the gears in the train are of the same pitch. If the gears are not all of the same pitch, take the number of teeth equivalent if they were all of the same pitch. For example, if in Fig. 1 the gears F and K_1 are 1-inch pitch and have 40 and 20 teeth, respectively, while gears L and K_2 are ¾-inch pitch and have 48 and 32 teeth respectively, we could reduce them all to the equivalent number of teeth at 1-inch pitch; when the number of teeth in L would be $\frac{3}{4} \times 48 = 36$, and in K_2, $\frac{3}{4} \times 32 = 24$. We would then consider these numbers as the radii of the respective gears. This eliminates slight errors due to dropping decimals when working out an actual pitch diameter and using it in the equations for velocity ratios.

Examples of Planetary or Epicyclic Gearing

In Fig. 1 is shown a train of planetary gears, in which F is the fixed or stationary gear, sometimes termed the sunwheel. K_1 and K_2 are the planetary gears which are keyed together and rotate about the center f at the same time as they are rotated bodily about the center O in the direction indicated by the arrow a, the arm P actuating the motion. The gear L is free to turn on its axis.

Problem 1.—a. What is the direction of rotation of gear L? b. What is the angular velocity of gear L as compared to that of arm P? ....

a. For a small fraction of a revolution, the action of a lever and a gear are similar, as far as direction and velocity ratios are concerned. Hence we may replace the gears and the arm P by a system of levers as shown in Fig. 2. The teeth of the fixed gear will always constitute the fulcrum of one of the levers, corresponding to the fulcrum f of lever Q in Fig. 2. The arm P in Fig 1 corresponds to the lever S in Fig. 2, while gear L corresponds to lever T, and gears K_1 and K_2 to lever Q.

Now assume that motion is imparted to lever S in the direction indicated by the arrow a; then lever Q will be inclined in the direction indicated by the line xx and being in contact with lever T it will cause this lever to move to the position indicated by the line yy, or to rotate in the direction of the arrow b. This arrow then shows the direction of rotation of gear L, which was to be determined. The answer to question (a) is, therefore, that gear L rotates in a direction opposite to that of arm P. This answer is arrived at by a very simple process, thus presenting the minimum chance of error..

b. It is now required that we find the ratio of the angular velocity of gear L to that of arm P. Referring to Fig. 2, we find that if lever S made one complete revolution, the end in contact with Q would move a distance equal to $2\pi D$, and consequently cause that end of lever Q which is in contact with lever T to impart motion to the latter lever, the amount of which would be $\dfrac{2\pi DB}{C}$

One turn of lever T would require this end to be moved a distance of $2\pi A$. It, therefore, revolves, for one turn of S, a number of revolutions equal to $\dfrac{2\pi DB}{C \times 2\pi A} = \dfrac{BD}{AC}$.

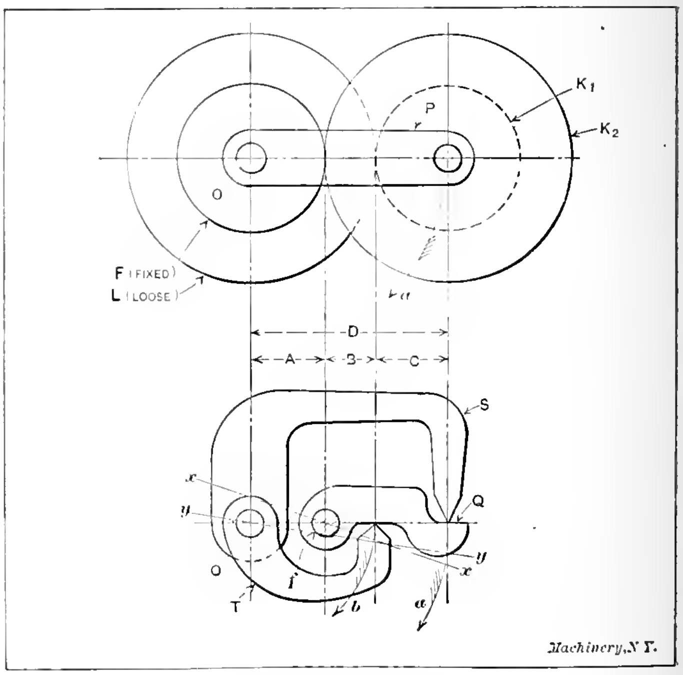


Fig. 3. Diagram for Problem 2

The gear ratio may therefore be stated thus:

Revolutions of P : revolutions L : : $1 : \dfrac{BD}{AC}$;

or since P is the driving and L the driven member, we would say that the gear reduction is $1 \div \dfrac{BD}{AC}$, or simply $\dfrac{AC}{BD}$. If this quantity be less than unity it indicates an inverse speed reduction.

The results obtained may be verified by a common method of separate motions. First lock the gears together and turn the entire mechanism one revolution to the right; call this direction positive (+).

* For additional information on epicyclic gearing, see the following articles previously published in MACHINERY: Epicyclic Gearing, August, 1899; May, 1900, and August, 1900; and Some Applications of Epicyclic Gearing, September, 1900. See also MACHINERY'S Data Sheet No. 102, Simple and Compound Epicyclic Trains.

† Address: 2436 Almond St., Philadelphia, Pa.

Second, hold arm P stationary and turn gear F back one turn in the negative (—) direction. The net or combined result on gear F is zero, or "no motion," while for gear L we have:

1st condition: Revolutions of $L = +1$.

2nd condition: Revolutions of $L = -1 \times \dfrac{A+B}{C} \times \dfrac{B+C}{A}$.

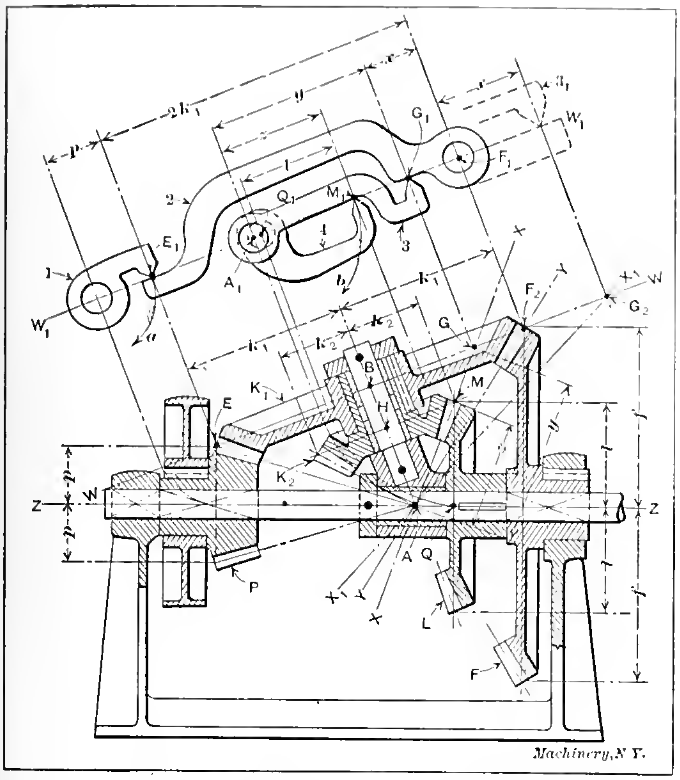

Fig. 4. Compound Bevel Gear Epicyclic Train

Adding these results, we have the number of revolutions of gear L for one positive (+) turn of arm P:

$$1 - \frac{(A+B)\ (B+C)}{AC} = -\frac{B\,(A+B+C)}{AC}$$

and since $A + B + C = D$, the number of revolutions $= -\dfrac{BD}{AC}$.

which is the same result as that obtained by the lever method, the minus sign only serving to show the direction of rotation of L, which is opposite to that of P.

Problem 2.—In Fig. 3 the small gear F is fixed and the

Fig. 5. Diagram for the Solution of Epicyclic Train in Fig. 4

larger gear L loose. Arrow a indicates the direction of motion of arm P, while arrow b shows the direction of rotation of the driven wheel L, or lever T, which for this case is the same as the direction of driver P. By the method of levers the revolutions of L for one revolution of P equals

$$\frac{2\pi BD}{(B+C) \times 2\pi\,(A+B)} = \frac{BD}{B\,(A+B+C)+AC} = \frac{BD}{BD+AC}$$

By the usual method of separate motions we would have the number of revolutions of L =

$$1 - \frac{AC}{(B+C)\ (A+B)} = \frac{B\,(A+B+C)}{B\,(A+B+C)+AC} = \frac{BD}{BD+AC},$$

thus showing that both methods are correct analyses of the conditions, as they both give the same results.

Compound Bevel Gear Epicyclic Train

In the train of bevel gearing shown in Fig. 4, P is the prime mover, L is the loose or driven gear, K_1 and K_2 are keyed together, and F is fixed. The action of gears P, K_1, K_2, and L is represented by levers 1, 2, 3 and 4 respectively. Point F_2 of gear F constitutes the fulcrum F_1 of lever 2. Points A and Q are projected upon line W_1W_1 at A_1 and Q_1. These points (A_1 and Q_1) form the fulcrums of levers 3 and 4, respectively. Now let:

T_P = any given number of revolutions of gear P,

T_L = resulting revolutions of gear L,

$R = \dfrac{T_P}{T_L}$ = gear reduction of entire train.

By reference to the leverage diagram it is seen that if gear P rotates in the direction of arrow a, gear L will rotate in the direction indicated by arrow b. Gears P and L thus rotate in the same direction. We further have, by the principle of levers:

$$T_L = T_P \frac{2\,\pi\,p\,x\,z}{2\,k_1\,y\,2\,\pi\,l} = T_P \frac{p\,x\,z}{2\,k_1\,l\,y} \qquad (1)$$

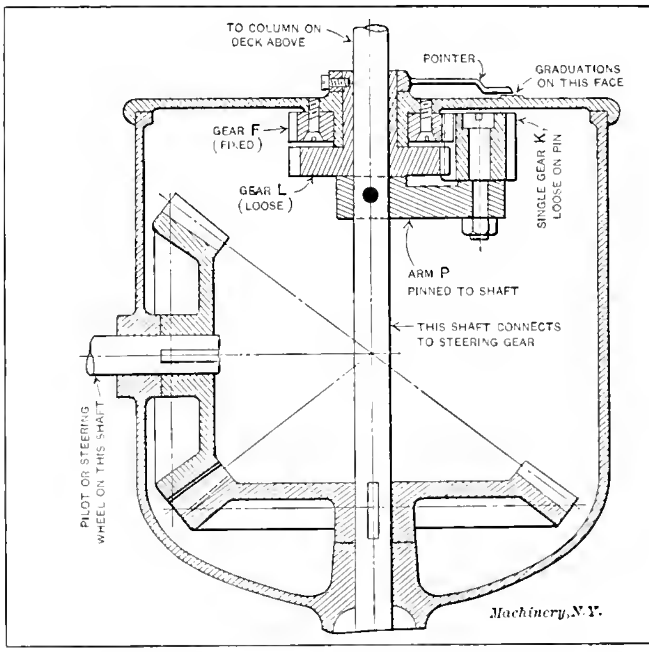

Fig. 6. Planetary Geared Indicator used on Steering Columns

It can be shown by the principles of geometry (see below) that

$$\frac{x\,z}{y} = \frac{2\,k_1\,l - 2\,k_2\,f}{f+p} \qquad (2)$$

Then

$$T_L = \frac{T_P\,p}{k_1\,l}\left(\frac{k_1\,l - k_2 f}{f+p}\right) \qquad (3)$$

from which

$$R = \frac{T_P}{T_L} = \frac{k_1\,l}{p}\left(\frac{f+p}{k_1\,l - k_2\,f}\right) \qquad (4)$$

The results obtained may be verified by the method of separate motions as follows:

First: turn the entire mechanism + 1 turn (arm locked).

Second: hold arm, and turn F back — 1 turn.

1st condition { revolutions of $P = +1$; revolutions of $L = +1$

2nd condition { revolutions of $P = +\dfrac{f}{p}$; revolutions of $L = -\dfrac{f\,k_2}{k_1\,l}$

Summing up the results of these two conditions:

Revolutions of $P = 1 + \frac{f}{p} = \frac{f+p}{p} = T_P$

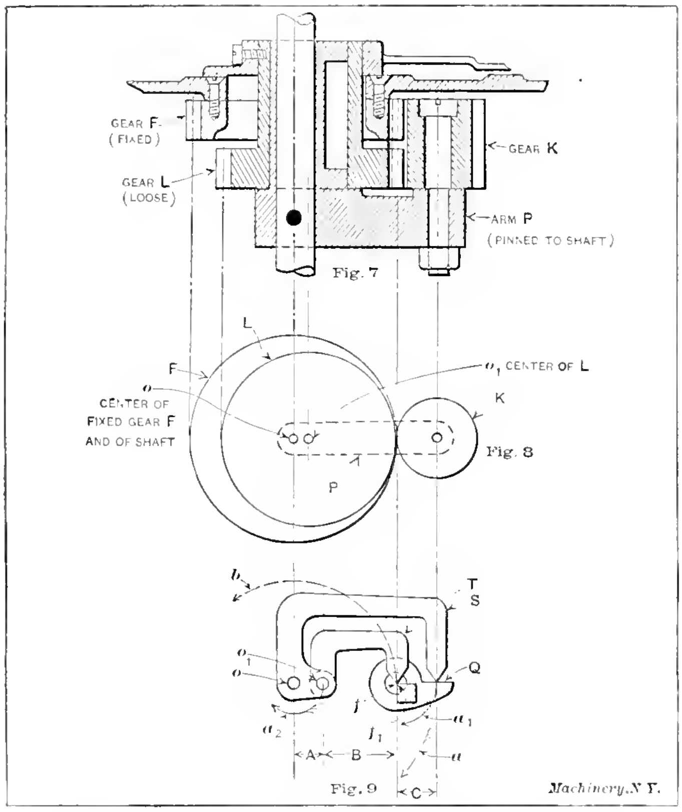
Revolutions of $L = 1 - \frac{f\,k_2}{k_1\,l} = \frac{k_1\,l - k_2\,f}{k_1\,l} = T_L$

Now

$$R = \frac{T_P}{T_L} = \frac{(f+p)\,k_1\,l}{p\,(k_1\,l - k_2\,f)} = \frac{k_1\,l}{p}\left(\frac{f+p}{k_1\,l - k_2\,f}\right)$$

It will be seen that this last equation is the same as equation (4). If the quantity $k_1 l - k_2 f$ is positive, then gear L will revolve in the same direction as gear P. If this quantity is negative, then gear L rotates in a direction opposite to gear P. If, however, this quantity equals zero, then there is no rotation of gear L, no matter what the velocity of gear P is. This is caused by the fact that the gear reduction R is then infinite.

These same deductions can be drawn from an inspection of Fig. 4. If gear K_2 be increased in size, line XX will incline more and more towards line YY, thus increasing the gear ratio in consequence of the decrease in dimension x. When line XX



Figs 7, 8 and 9. Diagrams for Solution of Gear shown in Fig. 6

coincides with line YY, point G has been moved to F_2, $x = 0$ and R = infinity, and there is then no motion imparted to gear L. If gear K_2 is further increased until line XX comes into a position outside of line YY, as indicated by X_1X_1, then the dimension x becomes negative, and gear L will rotate in a direction opposite to that of gear P. By the lever method of analysis, this condition becomes at once apparent, for if point G falls outside of point F_2 as at G_2, lever 3 would be located as shown in dotted lines at 3_1. It is seen then that levers 3 and 4 would rotate in a direction opposite to that of lever 1.

When the shafts are at right angles to each other $f = p$ and

$$R = \frac{T_P}{T_L} = \frac{2\,k_1\,l}{k_1\,l - k_2\,p} \qquad (5)$$

The method of obtaining equation (2) may need some further explanation (see Fig. 5).

$$EF = 2\,k_1;\ ET = f - p;\ BD = \frac{f+p}{2}$$

$$CS = TF = \sqrt{EF^2 - ET^2} = \sqrt{4\,k_1^2 - (f-p)^2}$$

$$AB = \frac{EF}{CS}\,BD = \frac{k_1\,(f+p)}{\sqrt{4\,k_1^2 - (f-p)^2}}$$

$$\sin a = \frac{ET}{EF} = \frac{f-p}{2\,k_1};\quad MJ = k_2 \sin a = \frac{k_2\,(f-p)}{2\,k_1}$$

$$HN = JQ = l - MJ = l - \frac{k_2\,(f-p)}{2\,k_1}$$

$$HA = HN\,\frac{EF}{CS} = \frac{\left[l - \frac{k_2\,(f-p)}{2\,k_1}\right] 2\,k_1}{\sqrt{4\,k_1^2 - (f-p)^2}} = \frac{2\,k_1\,l - k_2\,(f-p)}{\sqrt{4\,k_1^2 - (f-p)^2}}$$

$$\tan b = \frac{k_2}{HA} = \frac{k_2\sqrt{4\,k_1^2 - (f-p)^2}}{2\,k_1\,l - k_2\,(f-p)}$$

$$BG = AB \tan b = \frac{k_1\,k_2\,(f+p)}{2\,k_1\,l - k_2\,(f-p)}$$

$$x = GF = k_1 - BG = k_1 - \frac{k_1\,k_2\,(f+p)}{2\,k_1\,l - k_2\,(f-p)}$$

We further have

$$\frac{z}{y} = \frac{k_2}{BG} = \frac{k_2\,[2\,k_1\,l - k_2\,(f-p)]}{k_1\,k_2\,(f+p)}$$

Then

$$\frac{x\,z}{y} = \frac{2\,k_1\,l - 2\,k_2\,f}{f+p}$$

Indicator with Planetary Gears as used on Steering Columns

Fig. 6 shows a type of indicator used on steering columns. In practice, gear F may have 36 teeth, gear L, 35, and gear K, 18. Theoretically there should be two different sizes of planetary gears in place of the single gear K, in order that the teeth might mesh properly. In practice, however, the single gear is simpler and entirely satisfactory. In order to apply the method of levers to the solution of this problem, let us conceive of the device as constructed along theoretically correct lines. Fig. 7 shows, in section, a construction which would give theoretically correct results. In Fig. 8 is shown a diagrammatical plan view of Fig. 7, showing the pitch circles of the gears. In Fig. 9 is shown a system of levers which would have the same velocity ratio and the same direction of motion of the lever T as the gears in Fig. 7 would give to gear L. It will be noted that lever Q has one arm of the length C, while the length of the other arm is zero. It, therefore, has no influence upon the velocity ratio. The fulcrum of the lever Q is at f, while f_1 is the fulcrum, or more properly the abutment, of lever T. The end of lever T which is in contact with f_1 is stationary.

Now when lever S is rotated through a small arc in the direction indicated by arrow a, then lever Q is rotated as indicated by arrow a_1 and point o_1 and lever T are moved as indicated by arrow a_2. This movement of point o_1 is equivalent to rotating lever T about the point o_1 in the direction indicated by arrow b. Thus arrow b indicates the direction of rotation of lever T or of the gear L, which corresponds to T.

The ratio of the system of levers in Fig. 9, or of the gearing in Fig. 7, may now be arrived at by the method of levers as follows:

In one revolution of lever S, the point moving along the arrow a_2 would travel a distance equal to $2\pi A$. Dimension A has been shown enlarged in Fig. 9, in order to show the existing conditions more clearly. Now as far as the angular motion of lever T is concerned, we may consider this movement $2\pi A$ to have occurred at the end f in the direction of arrow b, and we may treat point o_1 as the center of rotation, which in fact it is for T or L. One turn of lever T about o_1 would require point f to be moved a distance of $2\pi B$; therefore, a movement of $2\pi A$ would revolve T as many revolutions as $2\pi B$ is contained in $2\pi A$; or, for one turn of lever S, lever T will make $\frac{2\pi A}{2\pi B} = \frac{A}{B}$ revolutions; and since S corresponds to arm P, and T to gear L, we may express the ratio thus:

Revolutions of P : revolutions of L : : $1 : \frac{A}{B}$.

Since P is the driver, we may say that the gear reduction is

$$1 \div \frac{A}{B} = \frac{B}{A}.$$

The ratio obtained by the method of separate motions agrees with the above, the final turns of L for $+1$ turn of P being

$$1 - \frac{A+B}{B} = -\frac{A}{B},$$ the minus sign indicating that L rotates in a direction opposite to that of P.

It will be noted that in this last problem the method of levers is rather cumbersome to apply, inasmuch as we are compelled to first make a theoretically correct layout, as was done in Fig. 7, before it was possible to solve the problem. The principal value of the method in a case like this may therefore be that of a check on the calculations. But velocity ratios and directions of rotation are not the only features with which the designer must deal. He must also find the tooth loads, pressures of bearings, etc., if he is to intelligently proportion the various parts. This is, in particular, where the lever method aids the designer. It makes it easier to determine the direction and amount of the various tooth and bearing pressures.

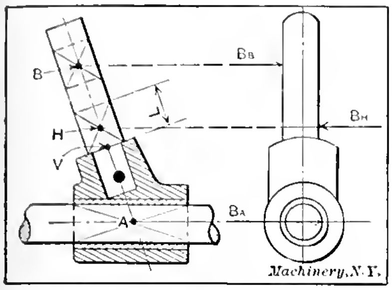


Fig. 10. Diagram for Determining Bending Moments on Main Shaft in Fig. 4

Tooth Loads and Bearing Pressures

Referring now to Fig. 4 let

T_E = tooth load at point E,
T_F = tooth load at point F_2,
T_M = tooth load at point M,
B_A = load on bearings at point A.

The horsepower and revolutions per minute of gear P being known, the tooth load at E will be found as below (p being in inches and N = revolutions per minute):

$$T_E = \frac{33{,}000 \times \text{H P} \times 12}{2\pi p \times N} \qquad (6)$$

In the system of levers this force T_E acts at point E_1 and has a turning moment about the assumed point G_1 equal to $T_E \times (2k_1 - x)$. The resulting force at F_1 is then:

$$T_F = \frac{T_E\ (2k_1 - x)}{x}. \qquad (7)$$

The tooth load T_M is the force acting at point M_1 in the lever system. Taking the moment of T_E about the point F_1 and dividing by x gave the force acting at point G_1. Taking the moment of this force about point A_1 and dividing by z will give the force acting at point M_1. Thus:

$$T_M = \frac{T_E \times 2k_1 y}{xz}. \qquad (8)$$

The load on the sleeve or bearing at point A is the force acting at point A_1 in the lever system and is found in a similar manner. Thus:

$$B_A = \frac{T_E \times 2k_1 (y - z)}{xz} \qquad (9)$$

Similarly the force acting on the bearing at point H is (see Fig. 10):

$$B_H = B_A \frac{AB}{BH}. \qquad (10)$$

and at point B

$$B_B = B_A \frac{AH}{BH}. \qquad (11)$$

Bending Moments

The forces T_E T_F T_M and B_A are now known, and the forces B_T and B_U, acting on the main bearings, may now be determined (see Fig. 11). According to the principles of static equilibrium, the algebraic sum of the moments of all the forces about any point must equal zero. Taking moments about point U, and calling all the upward forces positive (+) and all the downward forces negative (—) gives us:

$$T_F \times US - T_M \times UQ + B_A \times UA + T_E \times UC + B_T \times UT = 0$$

or

$$-B_T = \frac{T_F\ US - T_M \times UQ + B_A\ UA + T_E\ UC}{UT} \qquad (12)$$

Taking moments about point T gives us, in the same way,

$$-B_U = \frac{T_E \times TC + B_A \times TA - T_M \times TQ + T_F\ TS}{TU} \qquad (13)$$

When inserting the actual values and solving for B_T or B_U, if the sign is +, the force acts upwards, and if the sign is —, the force acts downwards, as indicated in Fig. 11.

All the external forces now being known, the bending moments at the various points may be determined. Before doing so, it is well to apply the principle of static equilibrium as a check on the values of B_T and B_U. The algebraic sum of all the external forces must equal zero. Thus for the present case:

$$\pm B_T + T_E + B_A - T_M + T_F \pm B_U = 0 \qquad (14)$$

In this formula, as well as in the following, the sign $\pm$ in front of B_T and B_U indicates that these quantities are to have their proper sign + or — as determined by inserting the actual values in equations (12) and (13).

For the bending moments in the shaft, the moment at any point is equal to the algebraic sum of the moments of all the forces at one side of the point. Let M_C, M_A, M_Q and M_S be the bending moments in the shaft at the respective points C, A, Q, and S. Then:

$$M_C = \pm B_T \times TC \qquad (15)$$
$$M_A = \pm B_T \times TA - T_E \times CA \qquad (16)$$
$$M_Q = \pm B_U \times UQ + T_F \times SQ \qquad (17)$$
$$M_S = \pm B_U \times US \qquad (18)$$

If the mechanism were actually constructed as shown in Fig. 4, account should also be taken of the belt pull on the driving pulley. There would also be torsion in the shaft from the point Q to some point beyond on the right-hand side (not shown in the engraving) where the power is taken off. These torsional stresses should be combined with the bending stresses and the shaft proportioned for the ideal or combined moment (see MACHINERY, July, 1908, engineering edition, "Maximum Stresses, Combined Torsion and Bending").

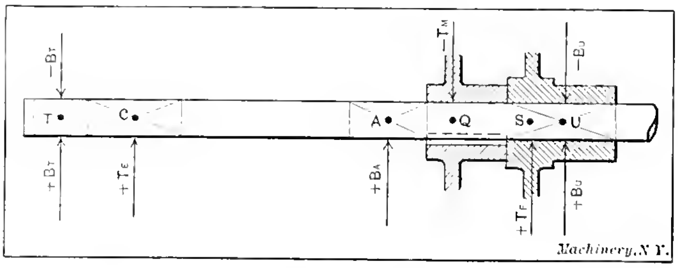

Fig. 11. Diagram for Determining Bending Moments in Stud for Translation Gears in Fig. 4

Referring again to Fig. 10, if points B and H are the centers of the bushings, and the loads are considered as concentrated at these points, the bending moment at H is

$$M_H = B_A \times AH \qquad (19)$$

More correctly the pressures should be considered as uniformly distributed over the whole length L of the bushing. Then the moment is:

$$M_H = B_A \times AH - \tfrac{1}{2} B_H \times \tfrac{1}{4} L$$

The bending moment at the point V is:

$$M_V = B_A \times AV$$

In all the foregoing calculations, the centers of tooth pressure have been assumed to act at the outside pitch diameters of the gears, which, of course, is not strictly correct. For the moments on the shaft in Fig. 11 the forces T_E, T_M, and T_F should be shifted to about the center of the gear faces.

SLIDE RULE FOR HELICAL SPRING CALCULATIONS

By M. E. DAVIS*

The accompanying illustration is a reproduction of the graduations on a slide rule used for calculations of helical springs. The graduations as shown are, in fact, for two slide rules. They have been reproduced in such a scale that they may be cut out and pasted on a wooden slide rule made similar to the regular calculating rules. If desired, they can be pasted directly on top of the regular scales on ordinary slide rules. They have been used for more than two years in the Ordnance Department drawing-rooms at the Washington Navy Yard, and have been the means of considerable saving in time. The chances for errors are also much less than when calculating directly by the formulas. The method of using the slide rule is easily grasped, even by those who are not familiar with the ordinary type. Those who cannot successfully use spring formulas will have no difficulty with this instrument. If one does not care to cut out the scales and paste them on a slide rule, one can use them to advantage by simulating the movement of the slides by means of measurements taken by a pair of dividers, thus arriving at the same results.

The lower set of scales for the deflection of springs was computed with a torsional modulus of elasticity of 12,600,000. If any other modulus is required, a correction for it is provided on the scale, as will be explained later.

In order to describe the use of the slide rule it is best to take a concrete example. The different scales are designated by letters as indicated below:

A	Stress	
B	Load	Slide
C	Diam. of Wire	Slide
D	Mean Diam. of Spring	

E	Load	
F	Deflection per Coil	Slide
G	Diam. of Wire	Slide
H	Mean Diam. of Spring	

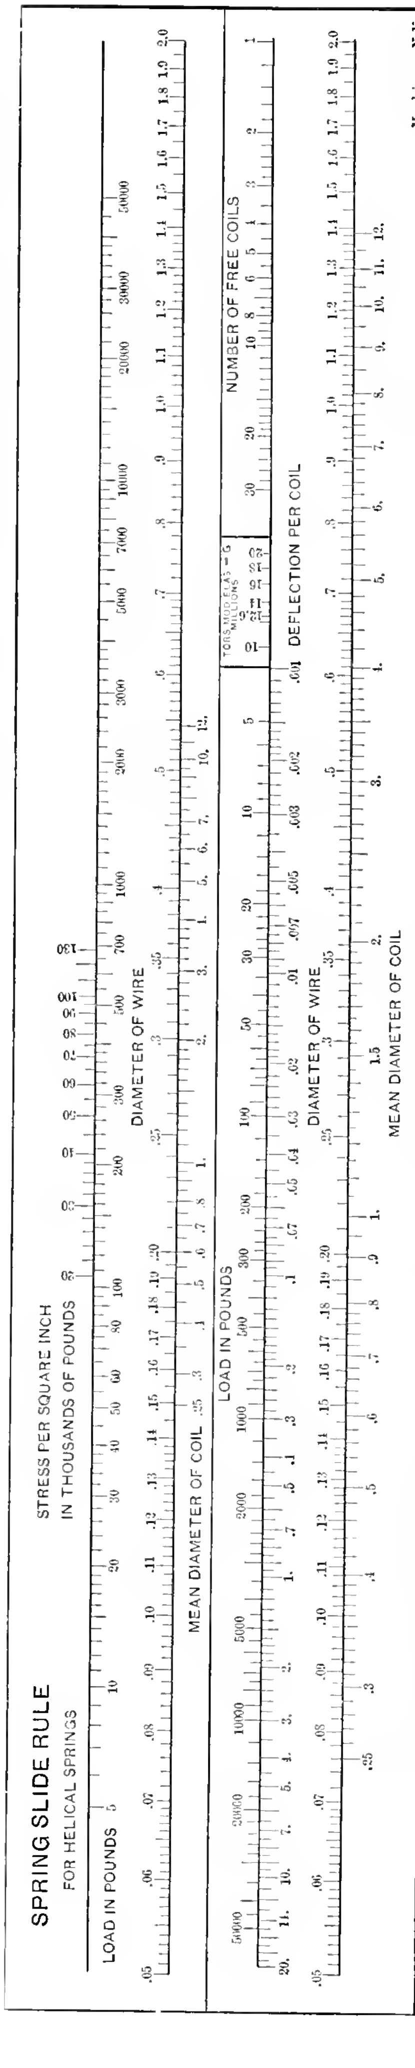
Scales B and C are mounted on a slide and scales F and G are also mounted on a slide. All the other scales are on the stationary part of the slide rule or rules.

Assume that the dimensions of a spring which will sustain a load of 250 pounds when the fiber stress in the material is 80,000 pounds per square inch is required. The graduation 250 on scale B, giving the load in pounds, is brought opposite the graduation 80 on scale A, giving the stress per square inch in thousands of pounds. Scales C and D now give the diameter of wire and the mean diameter of coil, respectively. It will be seen that there is a series of springs that meets the requirements, the mean diameter of coil being in each case opposite the corresponding diameter of wire. Springs of the dimensions given below will be seen, for instance, to fill the conditions:

Mean Diameter of Spring	Diameter of Wire
1.0	0.200
1.5	0.229
2.0	0.252
2.5	0.271
3.0	0.288
4.0	0.317

Assume that the spring having a mean diameter of 2 inches and a diameter of wire of 0.252 inch, is selected. It is required to find the deflection of this spring under a load of 250 pounds. For this the lower set of scales is used. The graduation 0.252 on scale G is brought opposite the graduation 2 on scale H; opposite the load 250 on scale E, the deflection per coil, in this case 0.315 inch, is read off directly

* Address: 107 14th St., N. E., Washington, D. C.



Finding Diameter of Spring and Wire

To find the dimensions of a spring to carry a given load at a given stress per square inch, first find the given stress in thousands of pounds on the *upper stationary* scale. Bring the graduation for the load in pounds on the *upper sliding* scale opposite it. The *lower sliding* scale now gives the diameter of wire required for a spring having a mean diameter as given by the corresponding graduation on the *lower stationary* scale. It will be seen that there are an indefinite number of possible sizes, but there is always one specific size of wire corresponding to a specific mean diameter.

Example:—Given: Stress per square inch, 80,000 pounds; load, 250 pounds.—Found: Diameter of spring 1.0, and of wire 0.200; or diameter of spring 2.0, and of wire 0.252; or diameter of spring 2.5, and of wire 0.271 inch, etc.

Finding Deflection of Helical Springs

To find the deflection per coil when the load in pounds, the diameter of wire and the mean diameter of spring are known, bring the graduation for the diameter of wire on the *lower sliding* scale opposite the graduation for the mean diameter on the *lower stationary* scale; then the deflection is read off on the *upper sliding* scale opposite the given load in pounds on the *upper stationary* scale. The deflection found is for a modulus of 12,600,000. If the deflection is required for any other modulus, move the slide so that the deflection found comes opposite 12.6 on the small scale marked "Tors. Mod. Elas. = G." Then read off, on the upper sliding scale, the deflection for any other modulus opposite this modulus.

Example:—Given: Diameter of spring 2 inches, of wire 0.252.—Found: Deflection for modulus of 12,600,000 equals 0.315; deflection for modulus of 15,000,000 equals 0.264 inch.

on scale *F*. The deflection for any other load can be read off without shifting the slide.

As stated before, the deflection is for a modulus of 12,600,000. If a modulus of 16,000,000 were to be used, a pair of dividers should be set to measure the distance between 12.6 and 16 on the short scale marked "Tors. Mod. Elas. = *G*," and then, by placing one leg of the dividers on the deflection obtained for a modulus of 12,600,000 the deflection for the new modulus, in this case 0.240 inch, will be found at the other point of the dividers, measuring off in the same direction as we measured off from graduation 12.6. The value can also be found directly by bringing the deflection 0.315 opposite the 12.6 graduation on the short scale and reading the new deflection 0.240 opposite the 16 million mark.

[Below the slides in the illustration are shown two sets of directions intended to be pasted on the back of the slide rules, giving in each case in concise language the directions necessary.—Editor.]

IMPROVING THE OUTPUT OF A KEYSEAT CUTTER

During a visit at the shops of the Colburn Machine Tool Co., Franklin, Pa., the superintendent of the firm explained some improvements made in the details of a Colburn keyseating machine, which had greatly improved its output and its accuracy. The improvement in output was estimated by the foreman in charge of the work to be as high as 25 per cent, taking all classes of work together. The accompanying illustrations show the nature of the changes.

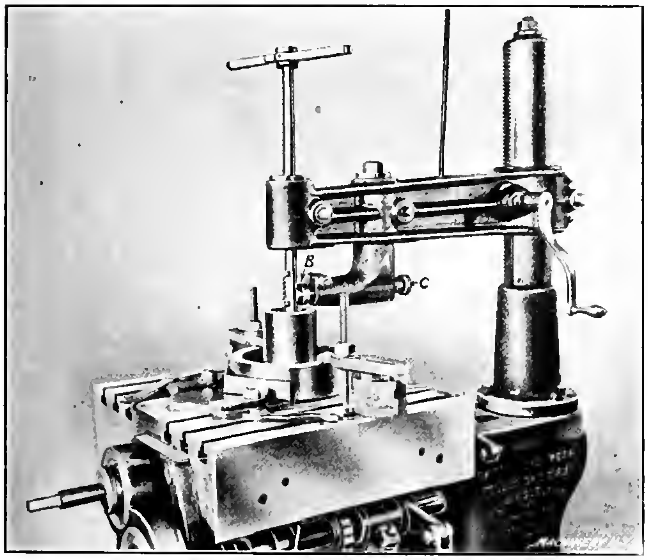

Fig. 1. Colburn Keyseater with Improved Back Support and Multiple Toothed Cutter

In Fig. 1 the keyseating machine is shown set up ready for work in the hub of a clutch member or similar part. Mechanics familiar with the machine will note the addition of a support for the cutter bar. The overhead supporting arm of this machine is regularly provided with two holes for the bushings through which these bars pass, the one on the outside for large diameter work and one further back for work of smaller diameter. In this case, however, the second hole has been utilized for holding the knee casting *A* for the support. This is provided with an iron back-rest at *B*, set up against the cutter bar by the knurled adjusting screw *C*. Clamp-bolts are provided, as shown, for locking the knee casting in the arm, and the back-rest in the knee.

The advantage of this arrangement lies in giving a backing to the bar close down to the work. The supporting bushing in the arm has of necessity to be raised considerably above the work to permit the cutter to clear, so its support is not as effective as it should be, particularly with a slender cutter bar. When a multiple-tooth cutter is used, as shown, the clearance necessary is considerably increased, so the auxiliary support becomes still more necessary.

Fig. 2 shows the construction of this particular form of cutter bar and cutter, which were also designed in this shop. The bar has two slots milled across it connected by the keyway in which the cutter is set. These slots furnish clearance for the keyway to run out into when it is machined, and at the same time they form solid abutments for the ends of the cutter blade, which has simply to be held from dropping out by a small screw, as shown. By providing a number of cutting edges in a blade, thus firmly bedded in the bar, much more rapid cuts can be taken than with the ordinary single-pointed tool.

As shown in Fig. 2, the first blade that strikes the work has the corners well beveled, the next one not quite so much, and so on until the last one, which comes out to sharp corners. This tends to make the tool more durable, as it is only the last cutting edge that gives the finishing shape to the keyway, and this has but a very light cut to take.

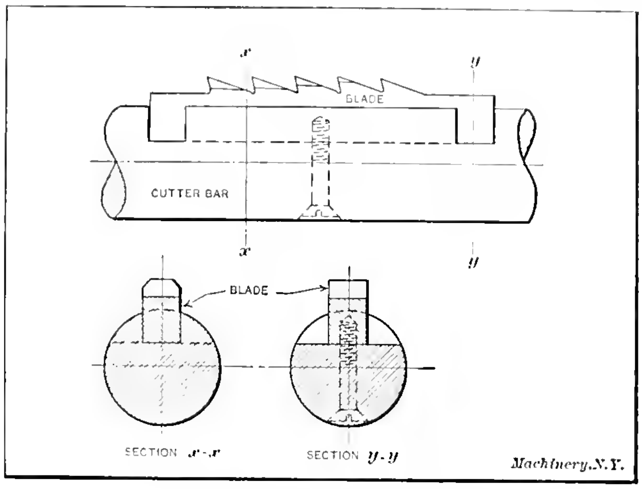

Fig. 2. Details of Multiple Toothed Cutter

Fig. 3 shows how the back-rest is turned around out of the way in removing the work. The cutter bar is withdrawn and the knee casting is loosened and swung around, leaving the table free for the removal and replacing of the work.

The Colburn keyway cutter is, of course, made by the Baker Bros., of Toledo, Ohio, though Mr. L. H. Colburn, of the Colburn Machine Tool Co., was the original inventor. The improvements in the cutter bar and its support, which we have just described, were originated by Mr. B. M. Weller, the superintendent of the latter firm.

* * *

It is stated by the *Scientific American* that Mr. George H. Cove of Somerville, Mass., has constructed a solar-thermo battery which is claimed to produce enough current in ten hours' sunlight to supply thirty tungsten lamps for three days. The apparatus consists of a frame of violet glass, like a large window, below which a number of metallic plugs are set in an insulating material. One end of each plug is constantly exposed to the sun while the other is shaded and cool; the sun's rays thus cause a constant flow of current to the storage batteries.

AIR COMPRESSOR TESTING*

By E. A. FESSENDEN†

Capacities of air compressors are usually stated in terms of the volume of free air compressed per minute or of the volume of air delivered per minute. The capacity of a given compressor may be determined experimentally by several methods among which may be mentioned: (a). The displacement method, and (b) the orifice method. Since these methods are commonly used, a discussion of them may not be out of place.

The Displacement Method

In its simplest form, the displacement method assumes that the volume swept through by the piston in one minute

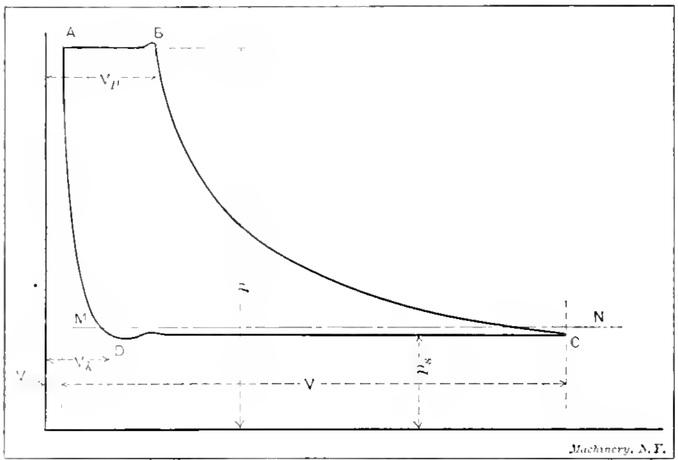

Fig. 1. Typical Air Compressor Diagram

is equal to the volume of free air drawn into the compressor at atmospheric pressure. The formula expressing the capacity under these conditions may be written:

$$Q = \frac{\pi d^2 N s}{4 \times 1728} \qquad (1)$$

where Q = volume swept through by piston in one minute, in cubic feet,

d = diameter of compressor piston, in inches,

s = stroke of compressor, in inches,

N = number of working strokes per minute.

For many purposes this rough method is sufficiently accurate. There are, however, many errors involved in the assumption that the volume of free air drawn into the cylinder is equal to the piston displacement, and these errors make the method unsuitable for accurate work. Before entering into a discussion of the inaccuracies involved in the displacement method together with the means for correcting some of the errors, it may be well to consider briefly the operation of an air compressor.

Fig. 1 represents a typical indicator card from an air compressor cylinder; MN is the atmospheric pressure line; the piston displacement is denoted by V and the clearance volume by V_c. During the suction stroke, air is drawn into the cylinder along the suction line DC. The pressure p_s inside the cylinder during the suction stroke must necessarily be less than the atmospheric pressure, or there would be no flow of air into the cylinder. At C the cylinder is full of air at pressure p_s, and the piston on its return stroke compresses this air along line CB. This compression line may be represented by an exponential equation having the form

$$p_1 v_1^n = p_2 v_2^n \qquad (2)$$

The value of n, according to Peabody,‡ may be as low as 1.2 for a "fluid-piston" compressor, and may approach 1.4 when the air is not effectually cooled during compression. A commonly accepted average value is $n = 1.29$. From this equation there results

$$V_p = (V + V_c)\left(\frac{p_s}{p}\right)^{\frac{1}{n}} \qquad (3)$$

as the volume of high pressure air in the cylinder at the point B. The valves now open and the air is driven out along the line BA until at the end of the stroke, at A, only the clearance volume, V_c, is filled with air at the pressure p. On the suction stroke, no air can be drawn into the cylinder until this clearance air has expanded until its pressure drops to p_s, less than atmospheric pressure, thus allowing the suction valves to open. For simplicity, the slight additional drop in pressure indicated by the wavy line at D, necessary to overcome the inertia of the suction valves, is disregarded. The volume V_k, of the clearance air expanded to the suction pressure p_s, is given by the equation

$$V_k = V_c\left(\frac{p}{p_s}\right)^{\frac{1}{n}} \qquad (4)$$

so that the volume of the new air in the cylinder at the end of the suction stroke is

$$V_s = V + V_c - V_k$$
$$= V - V_c\left[\left(\frac{p}{p_s}\right)^{\frac{1}{n}} - 1\right] \qquad (5)$$

It is evident that the assumption that the volume of free air drawn into the compressor per minute is equal to the piston displacement could only be true in a cylinder having no clearance volume, and also where the temperature and pressure of the air on the suction side of the piston are the same as the temperature and pressure of the atmosphere. A consideration of the temperature and pressure conditions during the suction stroke will, however, show that the actual volume of free air drawn in per stroke is less than V_s. Moreover, it should be noted that no account is taken of the leakage from the high pressure side of the piston to the low pressure side, nor of the leakage through the valves. The air leaking past the piston to the suction end of the cylinder takes the place of free air that would otherwise be drawn into the cylinder, so that the free air capacity will appear greater than it really is.

In order to cause a flow of air into the suction end of the cylinder, the pressure p_s must be less than atmospheric pressure; therefore, the air expands as its pressure drops in entering the cylinder, and the original volume of the free air drawn in is less than the volume V_s, occupied by this air after it is in the cylinder. Furthermore, the temperature of the air inside the suction end of the cylinder is higher than the atmospheric temperature, since the air is heated as it enters, by contact with the walls of the cylinder left warm by the previous compression stroke. This also causes expansion and still further diminishes the volume of air necessary to be drawn in from the outside to fill the suction space. It is possible to correct the errors due to these temperature and pressure differences by assuming that the air acts as a perfect gas, so that the equation

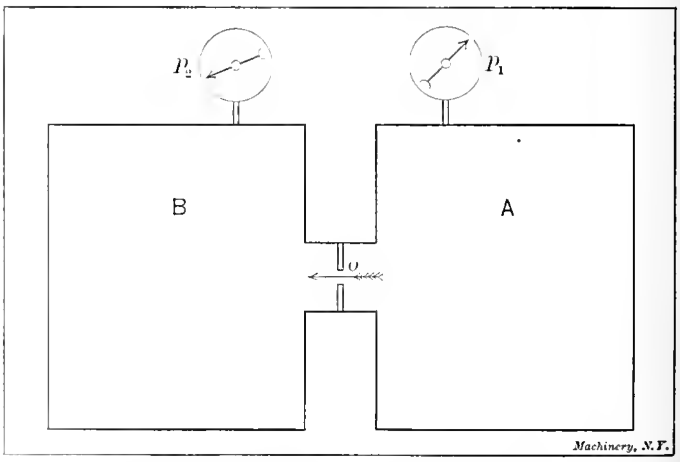

Fig. 2. Illustrating the Flow of Air between Two Reservoirs of Different Pressures

$$\frac{p_a V_a}{T_a} = \frac{p_s V_s}{T_s} \qquad (6)$$

is applicable. In this equation

* See MACHINERY, November, 1909, Engineering edition: Compressor Designing—The Distribution of the Load.

† Assistant Professor of Mechanical Engineering, University of Missouri, Columbia, Missouri.

‡ "Thermodynamics of the Steam Engine," Peabody, 1907 edition, page 361.

p_a = atmospheric pressure in pounds per square inch absolute,
p_s = suction pressure in pounds per square inch absolute, measured from indicator card,
V_a = volume of free air required per stroke, in cubic feet,
V_s = volume of air drawn in after entering cylinder,
T_a = absolute temperature of atmosphere,
T_s = absolute temperature of air in cylinder.

From equation (6) there results

$$V_a = \frac{p_s V_s T_a}{p_a T_s} \qquad (7)$$

It is practically impossible to accurately determine T_s in this equation, but it is probably safe to assume that T_s is about 30 or 40 degrees higher than T_a.

If the value of V_s from equation (5) is substituted in equation (7) there results

$$V_a = \frac{p_s T_a}{p_a T_s}\left\{V - V_c\left[\left(\frac{p}{p_s}\right)^{\frac{1}{n}} - 1\right]\right\} \qquad (8)$$

The clearance volume is usually expressed as percentage of the piston displacement, *i. e.*,

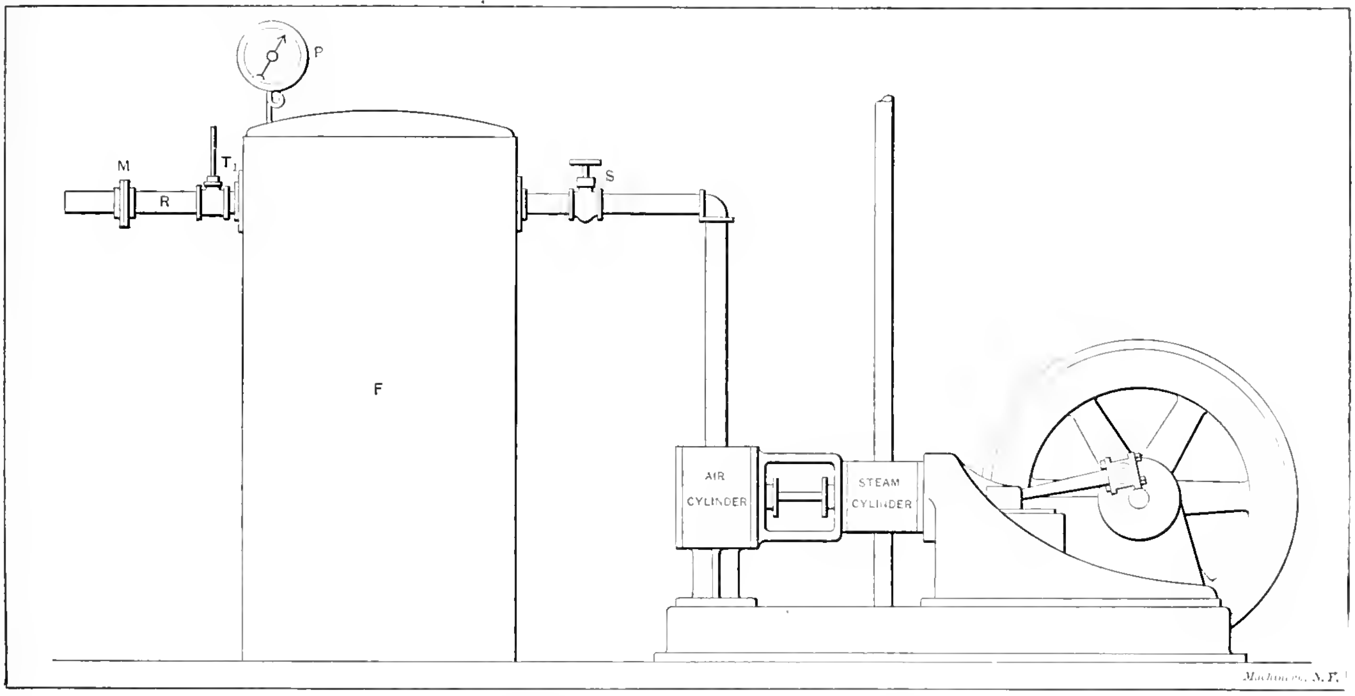

Fig. 3. Air Compressor and Tank arranged for Testing Capacity

$$V_c = \frac{V}{m} \qquad (9)$$

which, substituted in equation (8) gives

$$V_a = \frac{p_s T_a}{p_a T_s}\left\{1 - \frac{1}{m}\left[\left(\frac{p}{p_s}\right)^{\frac{1}{n}} - 1\right]\right\} V \qquad (10)$$

The free air capacity in cubic feet per minute for a given compressor is expressed by the formula

$$Q_1 = \frac{\pi d^2 N s}{4 \times 1728} \times \frac{p_s T_a}{p_a T_s}\left\{1 - \frac{1}{m}\left[\left(\frac{p}{p_s}\right)^{\frac{1}{n}} - 1\right]\right\} \qquad (11)$$

which is the same as equation (1) with corrections applied for clearance volume, and temperature and pressure of suction. Equation (11) may be corrected for leakage by introducing the factor $(1 - k)$, where k represents the per cent of air leaking past the piston, so that finally

$$Q = (1 - k)\frac{\pi d^2 N s}{4 \times 1728} \times \frac{p_s T_a}{p_a T_s}\left\{1 - \frac{1}{m}\left[\left(\frac{p}{p_s}\right)^{\frac{1}{n}} - 1\right]\right\} \qquad (12)$$

Equation (11) gives the free air capacity in cubic feet per minute of any air compressor if we could assume that there were no leakage of air past the piston and valves. This assumption can never be true, and equation (12) is an attempt to correct it. No very close approximation of the value of k, representing the amount of leakage, is possible, since the amount of this leakage is wholly dependent upon the perfection of fit of piston and valves, and this, in turn, is dependent upon the wearing qualities of the materials used in making the compressor and upon the workmanship. Furthermore, the quantities T_s and n in the equation cannot be determined with great accuracy.

The volume of air delivered by the compressor may be obtained from the free air capacity, by assuming that the air acts as a perfect gas and substituting in the formula

$$\frac{p V_d}{T_d} = \frac{p_a V_a}{T_a}$$

$$V_d = \frac{p_a V_a T_d}{T_a p}$$

$$Q_d = (1 - k)\frac{\pi d^2 N s}{4 \times 1728} \times \frac{p_s T_d}{p T_s}\left\{1 - \frac{1}{m}\left[\left(\frac{p}{p_s}\right)^{\frac{1}{n}} - 1\right]\right\} \qquad (13)$$

The displacement method, while it cannot be made entirely accurate with the data now at our command, possesses the advantage that it offers a ready method of quickly estimating the capacity of a compressor with reasonable accuracy without making an elaborate test. It may be applied to multi-stage compressers, in which case the volumes of the low-pressure cylinder alone are concerned in the determination of the free air capacity.

The Orifice Method

In Fig. 2, if a gas is allowed to pass from a vessel A in which the pressure p_1 is high, through a small opening o into a vessel B, where the pressure p_2 is low, it is evident that the volume of gas passing through o in one minute is constant as long as the pressures p_1 and p_2 are unchanged. If desired, the vessel B can be discarded, in which case the gas is allowed to discharge directly into the air, and p_2 becomes the atmospheric pressure p_a. This principle has been thoroughly investigated, and is used as the basis of many methods of measuring both gases and liquids. In all of these orifice methods the volume of air, gas or liquid actually passing through the orifice is measured. Hence, in applying them to testing they take into account all losses due to friction, leakage or other causes in the machine being tested.

Fliegner* has shown experimentally that for a vessel discharging directly into the atmosphere, the rate of discharge is directly dependent upon the pressure p_1 so long as p_1 is more than twice the atmospheric pressure. The results of his experiments have been confirmed by Zeuner and Weisbach. The following equations express the relations deduced from these experiments:

* *Der Civilingenieur*, vol. xx, p. 14

When p_1 is greater than $2p_a$:

$$w = 0.530\, a \frac{p_1}{\sqrt{T_1}} \qquad (14)$$

When p_1 is less than $2p_a$:

$$w = 1.06\, a \sqrt{\frac{p_a\,(p_1 - p_a)}{T_1}} \qquad (14a)$$

in which p_1 = absolute pressure in reservoir in pounds per square inch,

p_a = absolute pressure of atmosphere in pounds per square inch,

T_1 = absolute temperature of air in reservoir, degrees F.,

a = area of orifice in square inches,

w = weight of air discharged in pounds per second.

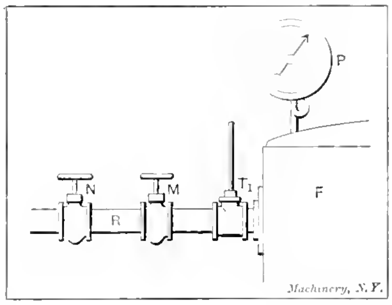

Fig. 4. Arrangement for Testing Capacity by a Modification of the Method shown in Fig. 3

Fig. 3 shows an air compressor arranged for testing by this method. The compressor discharges into a closed tank F, from which extends a pipe R containing an orifice at M. It is important to note that the discharge orifice should be very carefully constructed. It should be short and polished inside so that the friction losses will be reduced to a minimum. The entrance to the orifice must be well rounded and the cross section, preferably, circular. The diameter of the pipe R should be several times that of the orifice and the size of the orifice should be proportioned to the expected capacity of the compressor. A pressure gage P, and a thermometer inserted in a thermometer cup at T_1 show the pressure p_1 and the temperature T_1 of the air delivered to the orifice. Both gage and thermometer should be carefully calibrated, and the diameter of the orifice determined with a micrometer.

If the compressor is operated so that the pressure shown at P is maintained at the required discharge pressure, the speed of the compressor will be about normal if the orifice has been carefully proportioned. It will then be possible to read all

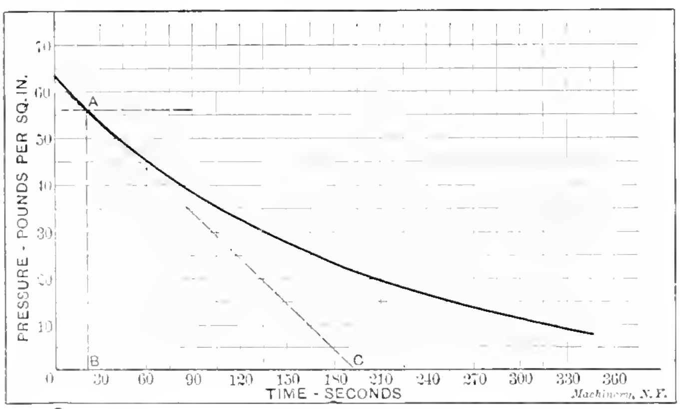

Fig. 5. Diagram plotted from Readings obtained when testing Capacity of Air Compressor

of the quantities required in equation (14), from which the volume of air discharged per minute is

$$Q_d = 60 \times w \times k_d \qquad (15)$$

where k_d = volume of one pound of air at the discharge temperature and pressure.

The value of k_d can be found by finding the volume of one pound of air at atmospheric pressure and at the discharge temperature, from tables published in many handbooks. (See Kent, page 481, 7th ed.); the volume at discharge pressure is then found by the simple rule that the volume of a perfect gas is inversely proportional to the absolute pressure.

Similarly, the volume of free air compressed is

$$Q = 60 \times w \times k_a \qquad (16)$$

in this case k_a being the volume of one pound of air under atmospheric conditions.

The formulas quoted above are for dry air. If much moisture is present a correction will be required for the weight of the water vapor present. This correction is usually disregarded.

Modified Orifice Method

One of the simplest, easiest and most accurate methods of determining the air delivered by a compressor is as follows: The compressor is connected to a receiver tank by an arrangement exactly similar to that shown in Fig. 3, except that an ordinary globe valve replaces the orifice at M, and an additional valve is provided at N as shown in Fig. 4. Since most compressors are furnished equipped with receiver tanks this arrangement should be easily accomplished. The pipe R may be the regular service pipe leading from the receiver. In this case means must be provided for disconnecting this pipe so that the receiver will discharge through the valves M and N directly into the atmosphere. If a receiver is not provided with the compressor equipment, almost any reasonably tight tank capable of holding air at the delivery pressure may be used. The volume should be quite large, the larger the better, and a few slight leaks will not affect the results in any manner whatever.

If it is desired to determine the volume of air delivered by the compressor, it will first be necessary to close off any pipes which may lead from the receiver tank except pipe R which should discharge into the air. Then, with the compressor running at its normal speed, close the valve M until the discharge is throttled down so that the pressure shown at P remains constant at the delivery pressure against which the

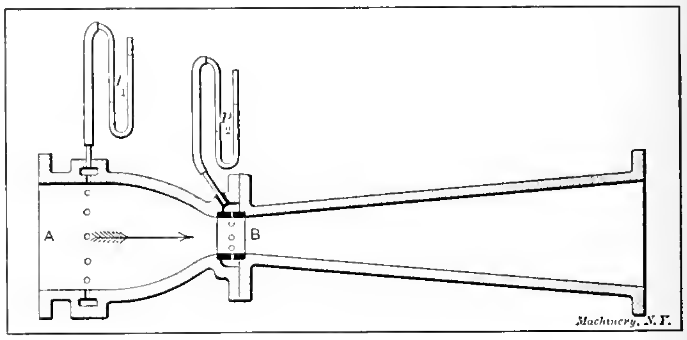

Fig. 6. Venturi Meter for Measuring Flow of Air

compressor is supposed to work. The compressor is now running under its normal working conditions. Now close the valve N tight so that the pressure in the tank rises to a value ten or fifteen pounds higher than the working pressure. Stop the compressor and close the valve S between the tank and compressor so that the tank now stands full of air at a pressure several pounds above the running pressure. Open quickly valve N wide and then take simultaneous readings of time and pressure as the pressure in the tank drops due to the escape of air through the partially opened valve M. This can best be done by two men, one holding a watch (preferably a stop watch) and calling "Read" at short uniform intervals of about fifteen or thirty seconds. The other man should read the pressure shown at P at the instant the signal is given. This should be continued until the pressure has dropped considerably below the working pressure.

Plot the readings just taken, thus obtaining a curve of pressure against time as shown in Fig. 5. (Fig. 5 is the curve taken from an actual test which will be referred to later.) It will also be necessary to determine the volume of the tank, including the piping between valves S and M. This can be done by weighing the amount of water required to fill this volume and then computing the equivalent volume, or the tank volume can be determined by direct calculation.

From the laws of gases we have the general equation

$$p\,V = m\,R\,T \qquad (17)$$

in which p = pressure in pounds per square foot,

V = volume of gas under pressure p, in cubic feet,

m = weight of gas under pressure p, in pounds,

T = absolute temperature in degrees F. of gas,

R = a constant = 53.37 for air.

In the case under consideration, the volume of the tank, V,

and the temperature of the air in the tank are supposed to remain constant. Equation (17) can be rewritten

$$m = \frac{V}{R\,T}\,p \qquad (18)$$

which, differentiated with respect to time gives

$$\frac{d\,m}{d\,t} = \frac{V}{R\,T}\,\frac{d\,p}{d\,t} \qquad (19)$$

in which $\frac{d\,m}{d\,t}$ is the rate of discharge of air in pounds per second. Let A be a point on the pressure-time curve of Fig. 5, corresponding to the working pressure of the compressor, and draw the line $A\,C$ tangent to the curve at A; also draw $A\,B$ parallel to the pressure axis. Then

$$\frac{d\,p}{d\,t} = \frac{A\,B}{B\,C} \qquad (20)$$

in which the values of $A\,B$ and $A\,C$ can be measured directly from the drawing.

It is evident that this method is only a modification of the first orifice method in which the valve M takes the place of the original orifice and the entire apparatus is calibrated at once by the pressure-time curve method. Leaks in the tank will not affect the results since they only serve to increase the area through which the air escapes and the determination is made independent of the area by determining the rate of pressure drop instead. If very accurate results are desired, it would be well to repeat readings for the pressure-time curve and then average the values of $\frac{d\,p}{d\,t}$ obtained.

In recapitulating, the valve M is adjusted to the proper opening to allow just enough air to escape under the working pressure to keep the compressor running steadily at its normal speed and discharging against the normal pressure; then the rate of discharge is found for this pressure and opening. After once adjusting the valve M it must not be moved or changed in any way during the entire test. It is important that the temperature of the air should be the same when the readings for the curve are taken as when the valve M is adjusted. The pressure gage at P must be carefully calibrated.

Example for Practice

As an example of the calculations involved in this method the data for a trial of a small 10 x 7 x 6-inch two-stage compressor are here reproduced. Fig. 5 is the pressure-time curve for this test.

$\frac{p}{144}$ = working pressure in pounds per square inch, absolute,

V = volume of receiver tank = 47.7 cubic feet.

T = temperature of air in tank = 87.1 degrees F. = 546.5 degrees absolute.

From pressure-time curve, Fig. 5, $A\,B = 56 \times 144$ pounds per cubic foot, and $B\,C = 174$ seconds.

The rate of discharge is

$$\frac{d\,m}{d\,t} = \frac{V}{R\,T}\,\frac{d\,p}{d\,t} = \frac{47.7}{53.37 \times 546.5} \cdot \frac{56 \times 144}{174}$$

= 0.0758 pounds per second.

At a pressure of 56 pounds per square inch absolute (42.3 pounds by the gage) and a temperature of 87.1 degrees F. one pound of air has a volume of 3.607 cubic feet. The discharge was therefore

$$0.0758 \times 3.607 = 0.2734 \text{ cubic feet per second,}$$
$$= 16.401 \text{ cubic feet per minute.}$$

One pound of air at atmospheric pressure and 32 degrees F. occupies 12.387 cubic feet, so that the volume of free air compressed, reduced to freezing point, was

$$0.0758 \times 12.387 = 0.9389 \text{ cubic feet per second,}$$
$$= 56.334 \text{ cubic feet per minute.}$$

If it be desired to make an economy test of a compressor under its working load it is only necessary to adjust valve M, determine the rate of discharge of air at the desired pressure as indicated above, and then run the compressor continuously while taking the steam consumption readings, allowing it to discharge into the tank, the air escaping through M. As long as the pressure and temperature of the air in the tank are constant, the volume of air flowing through the tank per second will not change. The pressure in the tank depends on the speed of the compressor, and the governor should keep it constant. The temperature of the discharge air depends largely upon the quantity of jacket water used. If this is kept constant in quantity and temperature, and if the machine is allowed to warm up thoroughly before beginning the test, there is no reason why the temperature of the discharge air should change.

The method just outlined has many advantages. It is rapid, simple, theoretically correct, and can be made very accurate in practice; all leakages and friction losses are taken into account; no expensive apparatus or appliances are required, and in many cases not even a change in piping will be necessary; and the manipulations and calculations are simple.

The Venturi Meter Method

The Venturi meter often used for the measurement of the flow of liquids may also be employed to measure the rate of flow of air or other gas, and very satisfactory results have been obtained, especially under conditions involving the measurement of a large volume of air under comparatively low pressure. A Venturi meter is in effect only a contraction in a pipe line with provision made for determining the difference in the static pressure of the moving fluid at the entrance A, Fig. 6, and at the waist or narrowest part B. The total head causing the fluid to flow through the pipe line is made up of "pressure head" and "velocity head," and if there is no friction in the pipe, the sum of these two is constant over all parts of a closed pipe system. The contraction in the pipe causes the velocity to be much higher at B than at A, consequently the velocity head is increased. An increase in the velocity head could only occur at the expense of pressure head, so that the pressure head indicated at B is less than that at A, and the difference in these two pressure heads is a measure of the increase in velocity. Knowing this change in velocity and the cross sectional areas of the pipe at A and B, we can find the velocity at B and from this the volume of fluid passing through the meter in a given time. When the Venturi meter is used for the measurement of water, the formula for the volume passing through the meter per second is

$$Q = \phi\,A_2\sqrt{\frac{2\,g\,H}{1-\left(\frac{A_2}{A_1}\right)^2}} \qquad (21)$$

where Q = volume passing per second in cubic feet,

H = difference in pressure head between A and B measured in feet of water,

A_1 = area of pipe at A in square feet,

A_2 = area of pipe at B in square feet,

ϕ = frictional coefficient, in most cases about 0.96 to 0.98 for usual construction of meter. (Extremes may be 0.95 to 1.00.)

When used to measure gases the derivation of the formula giving the rate of flow is somewhat complicated. The resulting equation is

$$Q = \phi\,A_2\left(\frac{p_2}{p_1}\right)^{\frac{1}{n}}\sqrt{\left(\frac{2\,g\,n\,p_1\,\gamma_1}{n-1}\right)\left[\frac{1-\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}}}{1-\left(\frac{A_2}{A_1}\right)^2\left(\frac{p_2}{p_1}\right)^{\frac{2}{n}}}\right]} \qquad (22)$$

in which Q = cubic feet of air passing per second,

p_2 = pressure at waist in pounds per square foot,

p_1 = pressure at entrance in pounds per square foot,

n = exponent of v in equation (2); in this case assuming adiabatic expansion, n = 1.41,

γ_1 = density of gas (weight of one cubic foot) at pressure p_1,

g = acceleration due to gravity, in feet per second = 32.2,

A_2 = area at waist in square feet,

A_1 = area at entrance in square feet.

ϕ = frictional coefficient. (Usually negligible in a well-made meter.)

When a Venturi meter is used for measuring the flow of a gas or liquid, precautions must be taken to keep the pressure p_1 constant, and the pressures p_1 and p_2 must be measured with great care. For this purpose water columns are best. The meter tube must be smooth and polished inside in order to reduce the friction losses to a minimum. The shape of the tube must be such as to allow the change in velocity between A and B to be accomplished smoothly and easily with no opportunity for eddies, cross currents or sudden changes in velocity. Venturi meters are sometimes made self-recording so that a continuous record of the volume of gas or liquid passing is available.

HANGING UP REAMERS, STRAIGHTEDGES, ETC., FOR STORAGE

Figs. 1 and 2 show some of the tools used by the Colburn Machine Tool Co., of Franklin, Pa., and illustrate the way in which they are kept when not in use. Fig. 1 shows a row of heavy line reamers, while Fig. 2 shows a set of straightedges and a test-bar. The notion of hanging these tools up after using is a novel one, so far as we know.

The line reamers shown in Fig. 1 are used for finishing the upper and lower bearings for the spindle in the spindle sleeve of the Colburn boring mill. By reaming these two bearings together, assurance is given that they are concentric; this gives further assurance of a good fit on the spindle, if the latter is finished concentric all over as it should be. The I-bolts by which they are hung are primarily intended for suspending the reamers in the hole to be reamed, by means of a chain-block and tackle having a swivel connection. This is done

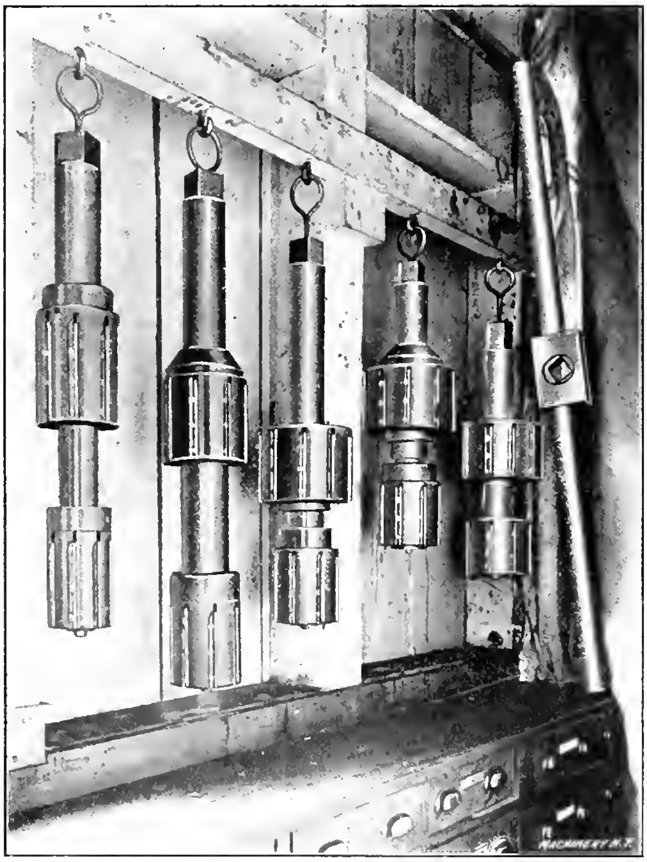

Fig. 1. Large Lining Reamers comfortably hung from Eye-bolts

because the weight of the reamers themselves is so great as to give too heavy a feed, with the very small amount of metal which has to be taken out. The chain-block is employed to lower the reamer gradually while the workmen rotate it.

For turning the reamers, use is made of the double-handled wrench shown at the right of Fig. 1. This is of the ratchet type, with a square socket on the ratchet which fits the squared shanks of the whole line of reamers. By using a ratchet wrench for this, a full revolution is not required, so it is possible to have the handles long enough to be easily manipulated, and still avoid interference with the housings or column of the machine. While the I-bolts were originally intended for use when the reamer is in active operation, as described, this provision naturally suggested hanging them up when they were not in use. When so held they are out of harm's way, as nothing can be laid on top of them and they are kept from contact with each other.

The row of straightedges shown in Fig. 2 is kept at one end of the erecting floor. As shown, a stout cross-beam is mounted on projecting joists, and provided at the top with notches for locating the bent ends of the long hook rods, on which the tools are hung. These grooves space the hook rods evenly and

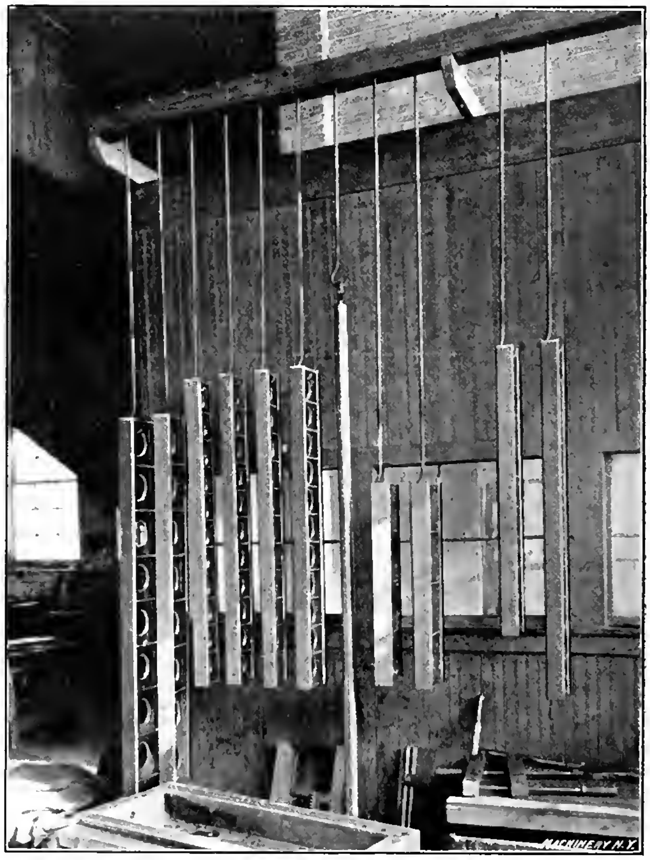

Fig. 2. Suspended Straightedges and Test Arbors, which are thus preserved from Distortion

prevent them from twisting around and dropping out. It might almost be said that these straightedges and test-bars have a *comfortable* look when stored this way. It is said that they preserve their shape better, showing less tendency to warp than when left lying flat in the case as usual. This seems to be a natural position for such tools to take when at rest.

* * *

Electric heat is being employed more and more in the industries. It is, for example, successfully applied in the manufacture of food products. The Natural Food Co. of Niagara Falls manufactures a product called "triscuit," this being a cracker of shredded wheat, baked or toasted by having heat applied on both sides at the same time. The operation consists in passing the product through a machine between two endless belts, enclosed except at the ends. The links of these belts are electric stoves so arranged that the cracker is fed and held pressed between the faces of two of these miniature stoves throughout a complete circuit of the machines. The operation is continuous, and each machine, being provided with about 2,500 stoves, is capable of producing 17,500 triscuits an hour. The company is operating about 10,000 electric stoves, and the failures in operation have been exceedingly small. Another application of electric heat is in the embossing and burning of designs on wood. A form of electric heater is inserted in a hollow cylinder, the outside surface of which has the design engraved on it. The cylinder is slowly revolved, and pieces of soft wood placed between it and a corresponding roller, the wood being fed between the rollers in a manner similar to that of clothes being put through a wringer. In this manner five or six impressions can be burnt per minute.

CIRCULAR FORM AND CUT-OFF TOOLS*—1

PRACTICE FOR THE BROWN & SHARPE SCREW MACHINES

By DOUGLAS T HAMILTON†

When a screw machine is to be fitted up for the making of any given piece of work, the methods of arranging the operations and the tools to be used should be decided upon before designing the cams. One of the first things to consider is the method of applying the circular form and cut-off tools. These methods, of course, will vary to a considerable extent, according to the shape of the piece to be made.

When Circular Form and Cut-Off Tools can be used to Advantage

Forming with circular tools as shown in Fig. 1, when the piece permits, is usually the best and quickest method; it is quicker than using the turret tools, on account of eliminating the necessity of revolving the turret. The tools can also be easily and quickly changed when setting up for another piece. This method is recommended when the length of the work is not more than 2½ times the smallest diameter of the piece when finished. For example, when the smallest diameter *a* in Fig. 1 is ¼ inch and dimension *b* not more than ⅝ inch, it is most economical to use the form and cut-off method. The operations for making this piece would be as follows: The stock is first fed out to the stop, then the form tool *A* is brought in, forming the body *a*, and just as the tool *A* is finishing, the tool *B* is brought in and severs the piece from the bar. Another example is shown in Fig. 2 where a shouldered screw is being made; here the tool *C* is brought in and forms the part c and the neck *e*; then the die threads the screw, and the tool *D* is brought in and severs the piece from the bar, and forms the part *d* for the next screw at the same time; the stock is then fed out to the stop and the operations continued. This order of operations necessitates one complete revolution of the turret, for each screw, and if the time utilized by the tools *C* and *D* is not long enough to allow the turret to be revolved, so as to bring the stop into position for the next piece, extra time would have to be added for revolving the turret.

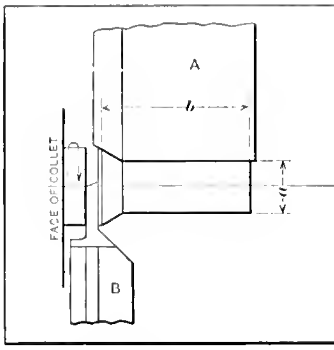

Fig. 1. Illustration showing Relation between Smallest Diameter of Work and Length of Forming Tool

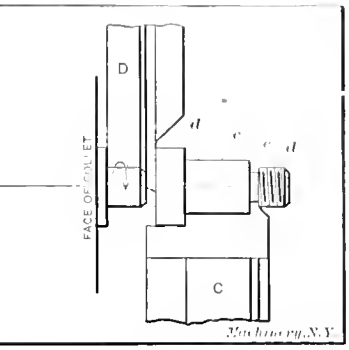

Fig. 2. Illustration showing a Case where the Cut-off Tool forms Part of the Piece

Applications of Circular Tools

When making short screws similar to that shown at *A*, Fig. 3, where the circular form and cut-off tools finish the screw, except the threading, it is good practice to apply the circular tools as shown, and if the time utilized by the tools is not long enough so the turret can be revolved to bring the stop into position for the next piece, two sets of tools, *etc.*, two stops and two die holders, should be used in the turret. The method shown at *B*, Fig. 3, is not commendable, inasmuch as the feeding of the stock varies to such an extent that the form tool will break off the screw when the latter is much reduced at *a*, in case there be an excessive amount to face off the end of the screw. The turret would also require to be indexed, to clear the slotting arm, so that very little time could be saved by adopting a method of this description, except

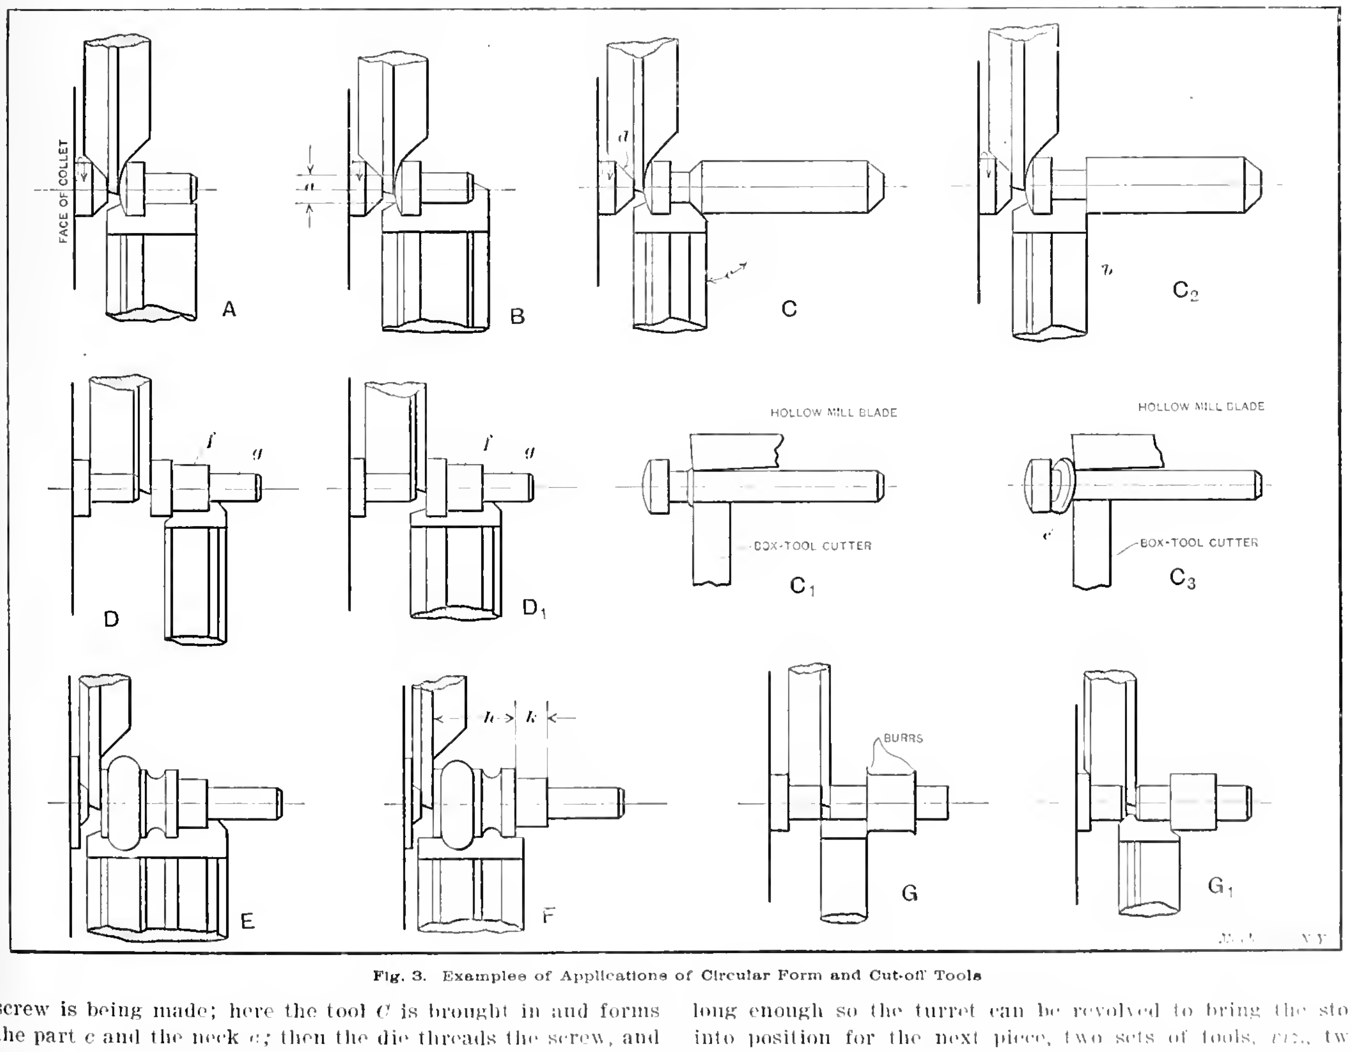

Fig. 3. Examples of Applications of Circular Form and Cut-off Tools

† Address: 169 Querbes St., Outremont, Montreal, Canada

when the part a is large in diameter and the screw is short in length. It is, therefore, obvious that a method of this kind should be avoided if possible.

When a box-tool or hollow-mill follows the forming operation, the forming tool should be beveled, as shown at e in C; this leaves a beveled shoulder on the piece, so that when the box-tool or hollow-mill is fed in as shown at C_1, it completely removes the superfluous material without leaving the objectionable ring which would be produced if the face of the form tool were square, as shown at b in C_2. This ring of metal is shown at c in C_3; it prevents the finishing box-tool or die

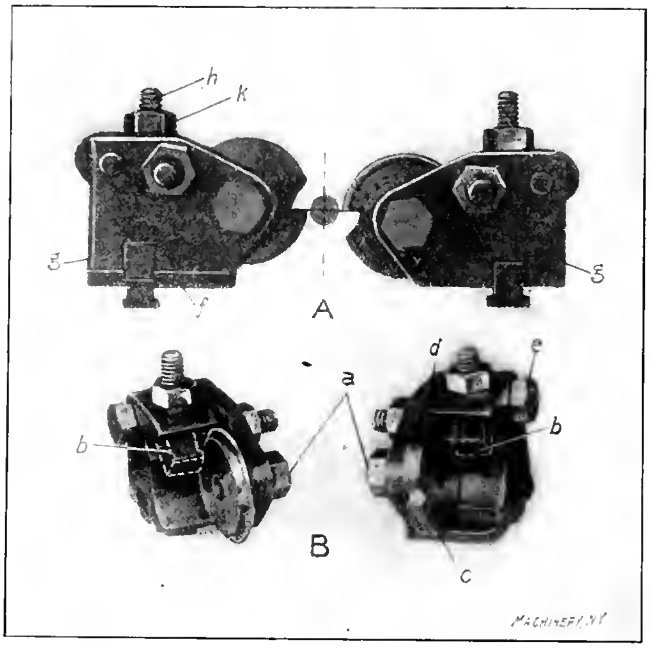

Fig. 4. Holders for Circular Form and Cut-off Tools

from being fed up to the shoulder. It is clearly seen that the ring would have to be removed in any case.

The cut-off tool should bevel the end of the stock, as shown at d in C, in order to permit the starting of the box-tool on a light cut, until the back rests have a good support; the bevel also locates the hollow-mill and equalizes the cutting pressure on the teeth. The previous examples apply to the making of screws, but the principles involved are also, of course, applicable to the forming of other parts. It is obvious that, as the conditions under which the work is done and the limits allowed on same vary widely, it would be impracticable to lay down hard and fast rules in regard to the application of circular tools, but the following suggestions will be found ap-

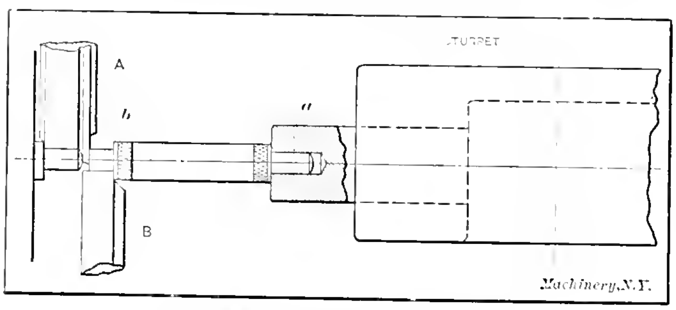

Fig. 5. Method of Supporting Long Work

plicable to general conditions. At D, Fig. 3, is shown a method sometimes used to advantage in making shouldered screws or other pieces of a similar character. This forming operation is not recommended when the piece to be made is required to be very accurate, as a slight eccentricity in the spring collet would cause the part f to be out of true with the part g. In cases where accuracy is required, the part g could be roughed down with the cut-off tool and a light finishing cut taken off with a box-tool. At D_1 is shown an improved method of forming the same piece, as the form tool here removes the burr from the head.

In applying circular tools, the question of gaging the pieces must be carefully considered, as in some cases, when difficult shapes are to be formed, it is advisable, if possible, to use the forming tool for this purpose, thus obviating the making of expensive gages, which is usually necessary when more than one tool is used. The piece shown at E, Fig. 3, will require a box-tool, forming tool and cut-off tool; if made as shown, it will be seen that no gaging will be necessary, except for diameters and over-all length, the latter not requiring great accuracy. At F, a piece of the same shape is shown; three tools are used as before, but the cut-off tool is used to finish part h to the required length and the box-tool to finish the shoulder k to correct length. It will readily be seen that a more expensive gage will be required for gaging the parts h and k; considerable time will be lost in setting up the tools, after grinding, in their correct relation to each other, insuring that part h be formed the correct length.

It is generally necessary that means should be provided to remove the objectionable burrs thrown up by the forming tools, as shown at G, Fig. 3. The burrs are caused by the tools becoming dull and by the rubbing of the forming tools on the sides of the cut due to lack of side clearance on the side of the forming tools. By adding a bevel edge to the tools as shown at G_1, the burrs are removed; this adds slightly to the expense of the tools, but in the majority of cases the results produced warrant the extra expense.

Holding Circular Form and Cut-off Tools

The method by which circular tools are held should be carefully considered; otherwise satisfactory results will not be obtained. If, for instance, the tool-holder is light and improperly supported, chattering will result when long work is

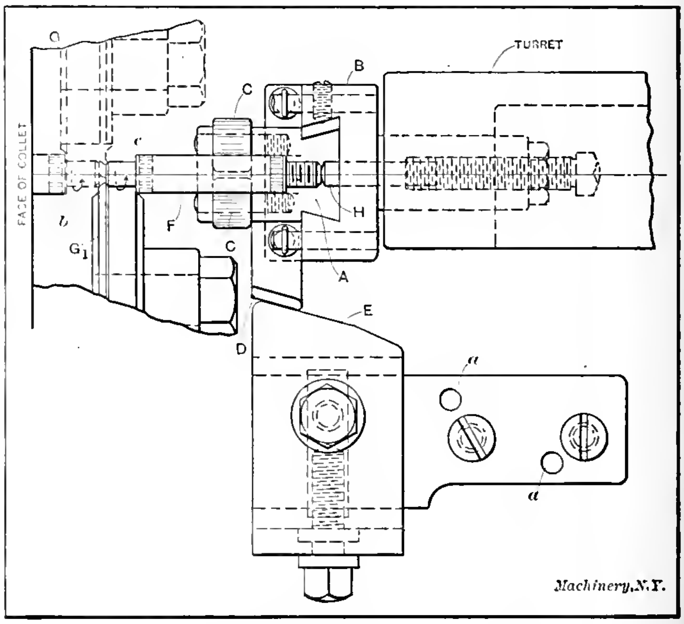

Fig. 6. Improved Method of Supporting Long Work

formed. To prevent this, the tool-holder should be well proportioned and held rigidly upon the cross-slide. The halftones A and B, Fig. 4, illustrate a suitable holder for general work, which is supplied by the Brown & Sharpe Mfg. Co. with their various types of automatic screw machines. This holder embodies all the essential features requisite for obtaining good results, *viz.:* rigidity, means to prevent the tool from rotating while cutting, suitable adjustment, provision for periphery clearance, means for adjusting the tool at right angles to the work, and means for the securing of the holder to the cross-slide.

The form tool is firmly clamped against the face of the holder by means of cap-screw a and clamping bolt b; the latter is used to keep the tool from turning while cutting. Care should be taken when designing the circular tools, so that the clamping bolt b, gets an ample bearing on the side of the tool as otherwise the clamping bolt will in time become bent, as shown by the dotted lines in the half-tone B, which would impair its efficiency as a clamping device. Plate d and eccentric bolt e are provided for obtaining a slight adjustment when setting the cutting edge of the tool in the correct relation to the center of the work, as shown at A. The block f is used for raising the tool when the cutting edge is cut below the cen-

ter. At g are two grub screws, not shown in the half-tone, by means of which the tool can be set at right angles to the work. The holder is clamped to the cross-slide by the bolt h and nut k. Numerous types of holders for holding circular tools have been designed, the principles involved being in most cases similar to those of the one described.

Supporting Long Work while Forming

It is sometimes found necessary to support long work while forming, especially when the piece being formed is turned down on both ends. The work is generally supported by a support held in the turret, which, in the majority of cases, can also be used as a stop. In Fig. 5 is shown a piece which is being supported in this manner. The part a is formed by the tool A and the stock is then fed out into the support

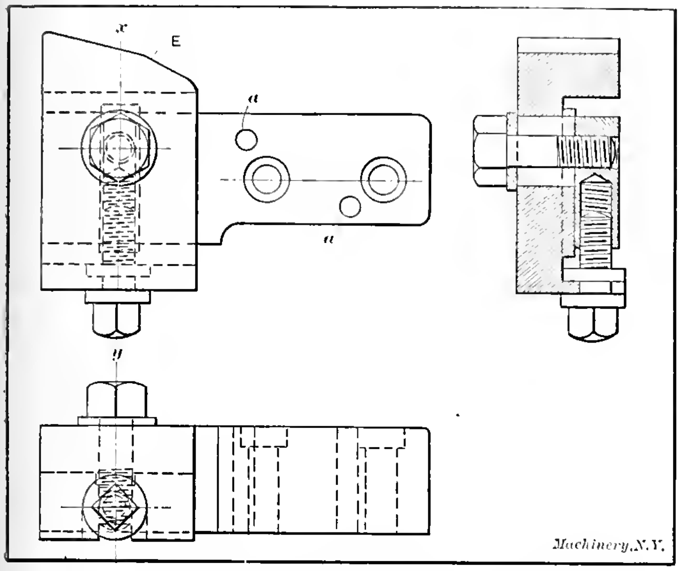

Fig. 7. Cam Attachment used in Connection with the Arrangement for Supporting Long Work shown in Fig. 6

which in this case also acts as a stop; the tool B then forms the part b. This kind of a support works satisfactorily on work which is not required to be very accurate and which is left plain, *i. e.*, not threaded on part a. In some cases both ends would require to be knurled, and then a support of this description could not be used to advantage.

In Fig. 6 is shown a method which will work satisfactorily when the piece is threaded or knurled. The work operated on is shown in position, supported by a movable slide A held in a holder B; slide A carries two hardened and ground supporting rollers C. It is forced up against the work by cam D

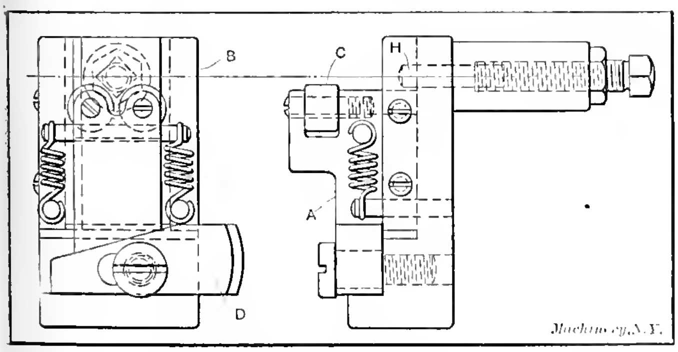

Fig. 8. Combination Stop and Support used in Arrangement for Supporting Long Work shown in Fig. 6

which in turn is operated by the cam attachment E. To fasten the cam attachment to the machine, as shown in Fig. 6, the stop which is used for locating the slotting arm when it is in position to travel onto the work, is removed, and the cam attachment is screwed down in its place. Two dowel pins a have been added to the cam attachment to hold it rigid.

A detailed sketch of the cam attachment is shown in Fig. 7, from which the operating parts can be clearly understood; the combination stop and support is shown in Fig. 8. The operations to produce the piece F, Fig. 6, would be as follows: The part b is left to project out of the chuck far enough so as to allow it to be threaded. To start the operations, the part b is formed and threaded; then, after the die leaves the work, the turret is revolved, the support is brought into position and the stock is fed out and gaged to length by the stop H. The spindle is left running backwards and the tool G_1 forms the part c. After the form tool G_1 has finished its work, a knurl-holder, not shown in the illustration, travels over the work and knurls the ends. The cut-off tool G severs the finished piece from the bar, at the same time forming the part b of the next piece. The support can be withdrawn after knurling, or left in position till the piece is cut off, when the turret is revolved and the piece drops out.

Arrangement of Circular Tools

When applying circular tools to the Brown & Sharpe automatic screw machines, the arrangement of the tools has an important bearing on the results obtained. The various ways of arranging the circular tools, with relation to the rotation of the spindle, are shown at A, B, C, and D, Fig. 9. These are to be considered as being viewed looking from the turret towards the face of the chuck. The arrangement at A gives good results when long forming is to be performed on brass, steel or gun-screw iron, for the reason that the pressure of the cut is downward and hence the work is supported and held more rigidly than when the form tool is turned upside down on the front slide as shown at B; here the stock turning up towards the tool has a tendency to lift the cross-slide, causing chattering on the finished body of the work; therefore, the arrangement as shown at A is recommended when a high finish is desired. The arrangement at B works satisfactorily when forming short steel pieces which do not require a high finish, as it allows the cuttings to drop clear of the work, and also provides for a good supply of oil to reach the tools. This arrangement gives good results when making screws when the form and cut-off tools operate after the die, as no time is lost in reversing the spindle. The arrangement

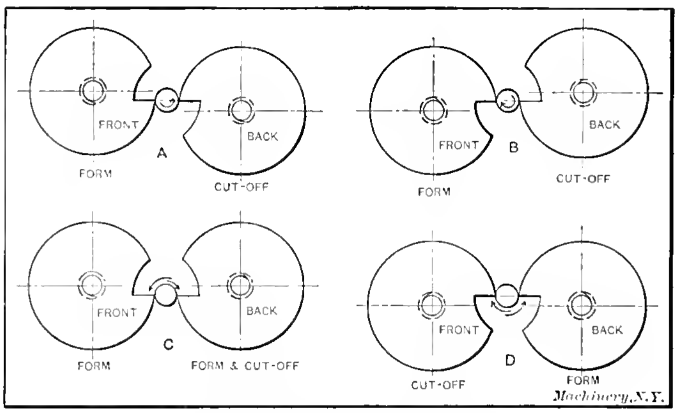

Fig. 9. Different Arrangements of Circular Tools

at C is recommended for heavy cutting on large work, when both tools are used for forming the piece; a rigid support is then necessary for both tools and a good supply of oil is also required. The arrangement at D is objectionable, and should be avoided, being used only when a left-hand thread is cut on the piece, and when the cut-off tool is used on the front slide, leaving the heavy cutting to be performed from the rear slide. In all "cross-forming" work, it is essential that the spindle should be kept in good condition, and the collet or chuck have a parallel contact upon the bar which is being formed.

Forming Spherical Work

In the making of spherical head screws or other spherical work, the circular form tool is generally used for forming part of the head, leaving the part attached to the bar to be finished by the cut-off tool. This method has become general practice on the Brown & Sharpe automatic screw machines and has proved, without a doubt, to be the most economical and efficient method of performing operations of this description. In order to produce the best results by the above method, the radius of the cut-off tool should be struck off in advance of the edge of the tool, as will be described later; otherwise a result will be produced as shown at a, Fig. 12, a ridge being formed on the head. The circular form tool should be de-

signed first, and should be made so that the circular cut-off tool will have as little as possible to form when cutting the piece from the bar. The amount that the form tool reduces the bar, as shown at b, Fig. 12, is governed by the operations following the forming cut. If heavy cuts are taken, the part b should be strong enough to resist the twisting action produced; therefore, it is not always advisable to cut a thread (especially if it be of coarse pitch) after the piece has been considerably reduced by the form tool.

In designing the form tool, there are certain dimensions which must be derived by calculation. Referring to Fig. 10.

Let r = radius of stock $= \frac{D}{2}$,

R = radius of head of screw or piece,

D_1 = distance from axis of head to point of tool.

D = diameter of head of piece,

T = thickness of head,

r_1 = radius of body of screw or piece,

O = the dimension required to be found by calculation.

Then $O = \sqrt{R^2 - D_1^2} - (R - T)$.

For example, let r = 0.175 inch, R = 0.178 inch, D_1 = 0.062 inch, T = 0.156 inch.

Then $O = \sqrt{0.178^2 - 0.062^2} - (0.178 - 0.156) = 0.145$ inch.

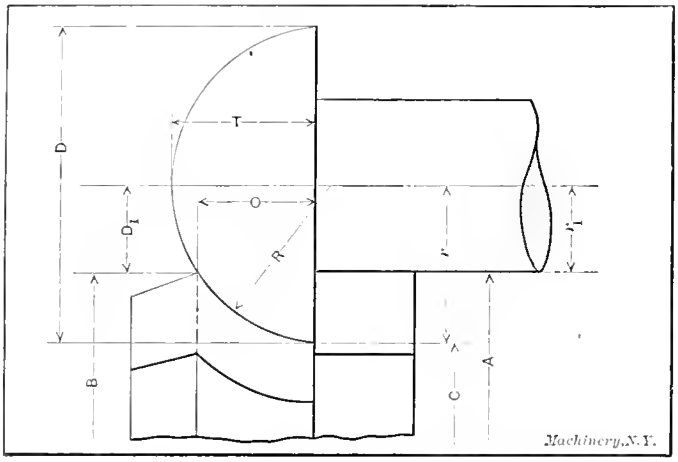

Fig. 10. Diagram for Calculating Dimensions of Circular Tools forming Spherical Screw Heads

Assume further that a form tool is to be made to form a piece as shown at Fig. 10; $r = 0.175$ inch; $r_1 = 0.043$ inch; then assume the largest diameter A to be 1.750 inch, the diameter B will be:

$A - 2(D_1 - r_1) = 1.750 - 2(0.062 - 0.043) = 1.172$ inch,

and the diameter C will be:

$A - 2(r - r_1) = 1.750 - 2(0.175 - 0.043) = 1.486$ inch.

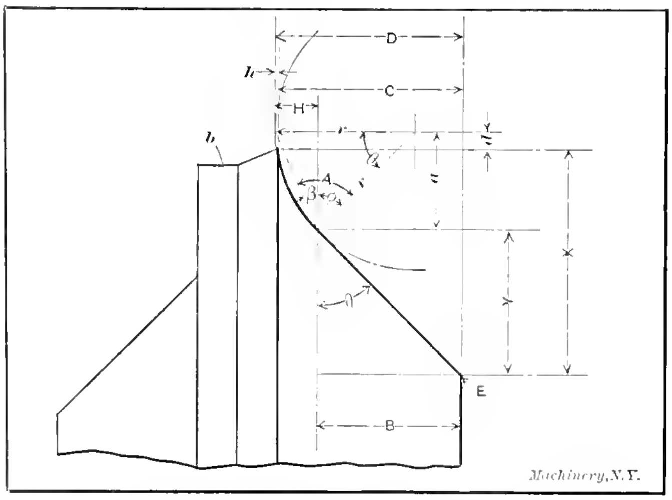

Fig. 11. Diagram for Determining Dimensions of Circular Cut-off Tool which forms Part of a Spherical Screw Head

In the above calculations the "cut-down" below the horizontal center line is not taken into consideration when finding the various diameters, but if the forms produced require to be accurate, the differences should be calculated. This question will be treated in a future issue of MACHINERY.

The feed of the circular cut-off tool should be decreased at the end of the cut, so as to leave as small a teat as possible on the work. The teat varies according to the radius formed, the size of the piece and the nature of the material. It is, therefore, impossible to specify any exact size of teat for a certain piece, but the results of a few experiments would not be out

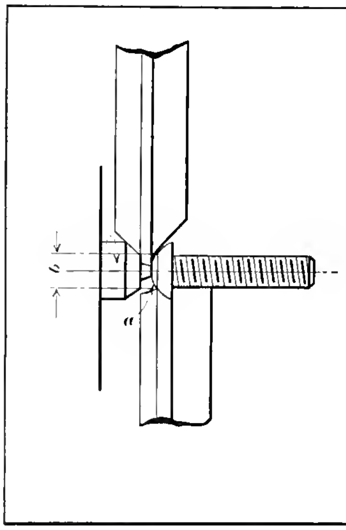

Fig. 12. Spherical Screw Head formed by Combination of Forming and Cut-off Tools

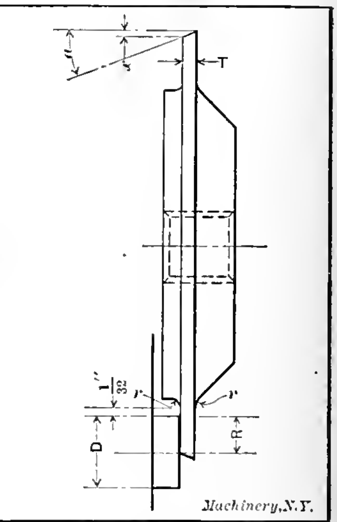

Fig. 13. Diagram showing Dimensions of Circular Cut-off Tools

of place here, as they will give a fair idea of the sizes of teats left on various classes of work. The teat left on small brass screws varies from 0.010 inch to 0.025 inch in diameter; on small screws made from gun-screw iron from 0.012 inch to 0.030 inch; on small steel screws from 0.015 inch to 0.035 inch. A good method of overcoming great variation in the size of the teat, is to make the angle of the cut-off tool similar to the enlarged view shown at b, Fig. 11, where the flat portion should be half the thickness of the cut-off tool blade. This method tends to decrease the pressure on the piece, thus preventing it from breaking off too soon.

As previously stated, the radius on the cut-off tool, if not struck off in "advance" of the edge of the tool, will give a result as shown at a, Fig. 12. There will always be a mark left on the head where the form tool finishes cutting, because the screw breaks off from the bar before the point of the tool has reached the center, and consequently the radius on the piece has not been completed. It is therefore necessary (especially for small radii) to lay off the radius in advance of the cutting edge of the tool. This method is clearly shown in Fig. 11, where d is the distance the center is in advance of the point of the tool. Then, to determine the dimensions of the tool, take any approximate dimension D as required, and also take any angle which will suit the radius of the tool, and cut away that portion of the tool which is not required for forming. In order to determine the dimension X (see Fig. 11) it will be necessary to make the following calculations:

$$A = \frac{180 \text{ deg.} - \theta}{2}$$

$$\phi = 90 \text{ deg.} - \theta$$

$$\beta = A - \phi$$

Then $a = \cos \phi \times r$; $H = \tan \beta \times a$; $B = D - H$;
$Y = B \times \cot \theta$; $X = Y + a - d$; $C = D - h$;
$h = r - \sqrt{r^2 - d^2}$.

Where h works out to less than 0.002 inch, it can be disregarded for all practical purposes.

For example, let D = 0.2343 inch; r = 0.175 inch; θ = 45 deg.; d = 0.021 inch;

Then $A = \frac{180° - 45°}{2} = 67° \; 30'$.

$\phi = 90° - \theta = 45°$.

$\beta = 67° \; 30' - 45° = 22° \; 30'$.

$a = \cos 45° \times 0.175 = 0.1237$.

$H = \tan 22° \; 30' \times a = 0.0512$.

$B = 0.2343 - 0.0512 = 0.1831$.

$Y = 0.1831 \times \cot 45 = 0.1831.$

$X = 0.1831 + 0.1237 - 0.021 = 0.2858.$

$h = r - \sqrt{r^2 - d^2} = 0.175 - 0.1737 = 0.0013.$

Therefore, in this case for all practical purposes, the dimension C would equal the dimension D. When the largest diameter of the circular tool is 2.250 inch, the diameter of the tool at point E will be $2.250 - (0.2858 \times 2) = 1.6784$ inch.

Angle on Blade for Cutting Off Various Materials

The function which the angle on the edge of the tool performs is to reduce the teat on the end of the work by minimizing the cutting pressure which becomes greater as the angle that the tool makes with the work decreases. Therefore, as the material becomes harder, the angle on the tool may decrease, since the material will stand more pressure before breaking. It is obvious, therefore, that certain angles are better suited for the various kinds of material than others. The values given in Table I have been found to give good results on the materials specified.

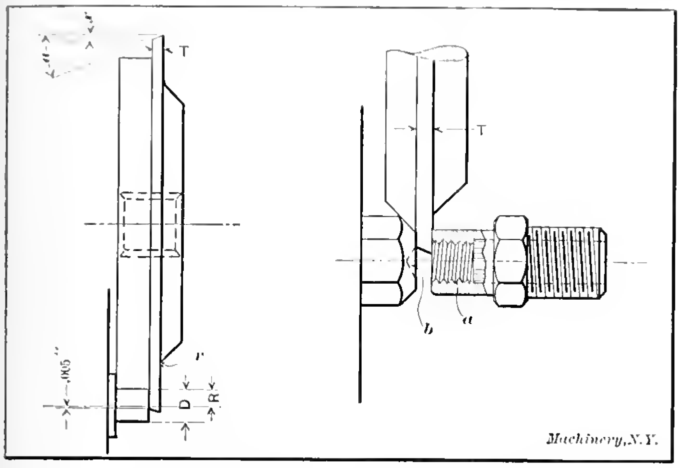

Fig. 14. Diagram showing Dimensions of Circular Cut-off Tool when it is used both for cutting off and forming part of the Work

Thickness of Blade on Cut-off Tools

The thickness of the blade is an important point in the design of circular cut-off tools. It is governed by the angle on the edge of the tool and also the diameter and hardness of the material being operated on. It is obvious that a circular tool with an acute angle (about 23 degrees) and a narrow blade would not work satisfactorily on hard material, as the blade would not stand the cutting pressure and would bend, producing a concave surface on one end of the piece and a convex surface on the other. This has been thoroughly experimented with by the writer and an empirical formula has been derived which has given good results. For standard circular cut-off tools, as shown in Fig. 13, where the tool is not required to form part of the work, the formula is as follows:

$$T = \sqrt{\frac{D \times \cot a}{3}} \times 0.14,$$

where T = thickness of blade in inches,

D = the diameter of the stock in inches,

a = the angle on the edge of cut off blade.

The value of r (the radius to obviate cracking in hardening) for standard circular cut-off tools for cutting off various diameters of stock is as follows:

From 1/8 to 3/8 inch diameter = 1/32 inch,
From 3/8 to 3/4 inch diameter = 1/16 inch,
From 3/4 to 1 inch diameter = 3/32 inch.

The actual length of the blade on cut-off tools is found by the formula:

$$L = R + x + r + 1/32,$$

where L = actual length of blade in inches,

R = radius of stock in inches,

x = dimension as shown in Fig. 13,

r = radius to obviate cracking while hardening, as shown in Fig. 13.

For example let $D = 3/8$ inch; $a = 20$ degrees.

Then $T = \sqrt{\frac{D \times \cot a}{3}} \times 0.14 = \sqrt{\frac{0.375 \times 2.747}{3}} \times 0.14 =$ 0.082 inch.

$L = R + x + r + 1/32$, where $R = 0.1875$; $x = \tan 20° \times 0.082 = 0.364 \times 0.082 = 0.0298$; $r = 1/32$ inch.

Therefore, $L = 0.1875 + 0.0298 + 0.0312 + 0.0312 = 0.2797$ inch.

The thickness of the cut-off tool blade, and the value of x and $2x$ are tabulated in Table I. The above formula is applicable where the cut-off tool does not form down the stock. It will be necessary to change the formula somewhat when calculating the thickness of blade when the tool is used for partly forming the work, as shown in Fig. 14.

When Cut-off Tool Forms Stock

When the cut-off tool is used to form down end of stock, as shown at Fig. 14, the following formula is used for finding the thickness of blade:

$$T = \sqrt{\frac{D \times \cot a}{5}} \times 0.17,$$

where T = thickness of blade on cut-off tool in inches,

D = diameter of end of piece in inches,

a = angle on edge of tool blade (see Fig. 14).

The actual length of the cut-off tool blade $= R + x + 0.005$ inch,

Where R = radius on end of piece in inches,

x = dimension as shown in Fig. 14.

The dimension 0.005 inch is the clearance to pass the center. To find the value of x multiply T by $\tan a$ as before.

For example, let $D = 0.250$ inch, $a = 20$ degrees.

$$\text{Then } T = \sqrt{\frac{0.250'' \times \cot 20}{5}} \times 0.17 = \sqrt{0.13737} \times 0.17 = 0.063$$

$L = R + x + 0.005$, where $R = 0.125$ inch; $x = 0.063 \times \tan 20^\circ = 0.023$ inch.

Then $L = 0.125 + 0.023 + 0.005 = 0.153$ iuch.

In cases where pieces are being manufactured similar to that shown in Fig. 15, where the tapped hole *a* is not bottomed but passes through the piece (it being necessary to have a chamfer on the tap to facilitate tapping), the blade on the cut-off tool would have to be of sufficient width to remove the portion taken up by the chamfer on the tap. Otherwise, if the blade is too narrow, the hole *b* will extend part way into the next piece to be made. Then, if the drill had a tendency to run eccentric, the centering tool would not remove the eccentric hole thus formed by the drill, which would result in the drill running out and finally in the breaking of the tap before many pieces would be completed.

The amount of chamfer required on taps for various pitches is as follows:

	Lead
From 14 to 24 threads................	2½ threads.
From 26 to 32 threads................	3 threads.
From 36 to 48 threads................	4 threads.
From 56 to 80 threads................	5 threads.

When the thickness of the blade as derived by the formulas is not equal to the amount required for the lead on the tap, the thickness of the blade must be increased to at least the amount specified as lead on tap.

COST OF POWER FOR VARIOUS INDUSTRIES

In a paper entitled "Cost of Power for Various Industries Under Ordinary Conditions," which was presented before the Boston Society of Civil Engineers, by Messrs. Charles T. Main and F. M. Gunby, the following general summary of the cost of electrical power for various purposes and under varying conditions, was given. The prices quoted are approximately those found in the vicinity of Boston.

Power in small amounts and with a varying demand, can be purchased for from about 10 cents per kilowatt hour, in five kilowatt lots, down to about 6 cents a kilowatt for 100 kilowatt lots, where the power is used for about 50 hours a month.

The rate for a permanent or steady power of 100 kilowatts for 300 hours a month would be about $2.68 per kilowatt hour, and for 500 hours a month about $1.84 per kilowatt hour. The two conditions mentioned are only used as illustrations to show normal cases as in a city like Boston.

Assuming a plant of 2,000 kilowatts capacity, the approximate costs and prices for power are given in the following table:

Kind of Plant and General Use	Hours per Year	Cost per Year			Cost per K.W. Hour
		K. W.	E. H. P.	I. H. P.	
Textile (engine)....	3,000	$32.00	$23.80	$20.80	1.065c.
Textile (turbine)...	3,000	29.00	21.60		0.965c.
Paper mill (engine).	7,200	57.00	42.50	37.00	0.792c.
Paper mill (turbine)	7,200	52.00	38.80		0.734c.

The above figures are for cases where uo waste products are used for manufacturing.

For electric lighting or railway work with a load factor of 30 per cent the cost would be about $1.55 per kilowatt hour, or $40 per kilowatt year. This is $29.80 per engine horsepower year or an equivalent of $26.00 per indicated horsepower year.

For paper mill work, 24 hours a day, 6 days a week, power only, $57.00 per kilowatt year, or 0.792 cents per kilowatt hour for engine plant, or about 8 per cent less for a turbine plant. If the waste products were used for manufacturing, these costs might be reduced by about one-third.

For industrial plants, 10 hours a day, 300 days a year, straight power would cost $32.00 per kilowatt year. If heating is done, by exhaust steam, these figures may be reduced by about $1.20 per kilowatt or to say, $30.60 per kilowatt year. This would be about $23.00 per engine horsepower and $20.00 per indicated horsepower year.

For colored textile mills, making use of exhaust steam and water of condensation, the original cost of straight power would be the same as that given in the preceding paragraph. This may be reduced by using the exhaust steam and waste products by from $2.00 to $12.00 per kilowatt year, depending upon the amount of steam and waste products used.

The common price for hydro-electric power, 24 hours a day, 6 days a week, is from $30.00 to $40.00 per electrical horsepower or $40.00 to $53.50 per kilowatt.

The common price for hydro-electric power, 10 hours a day, 3,000 hours a year, is from $20.00 to $25 per electrical horsepower, or from $27.00 to $33.50 per kilowatt.

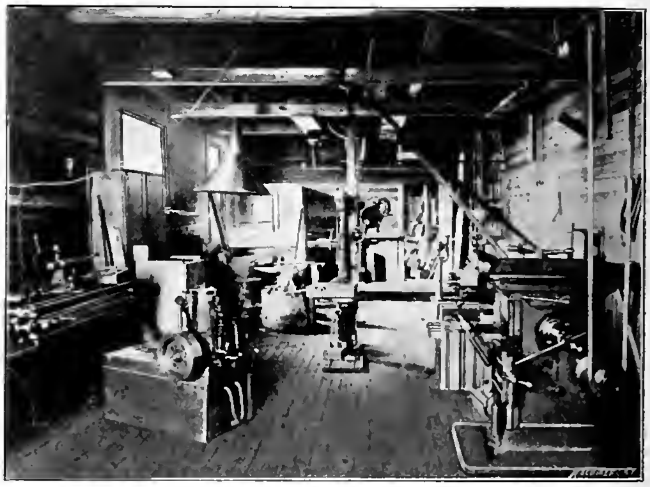
A MACHINE SHOP IN ALASKA

By C. S. BROWN*

The readers of MACHINERY may be somewhat interested in a thriving little machine shop in the far north near Valdez, Alaska. The proprietor is Mr. Charles Crawford, who is considered one of the best all-around machinists on the Pacific coast, having left behind in Seattle a reputation for mechanical skill of which any man might well be proud. The various shops cover about three acres of ground and employ a dozen men most all the time. The machine shop is equipped with milling machines, lathes, drills, etc., and stands ready to build anything from a stove to a ship. For example, it has built two wharves, and an 80-foot launch which was sold to the United States government for $21,000. While doing a general machine business, its principal work is the manufacturing and installation of mining machinery such as hoisting machinery, pumps, drills, etc. One of its most important branches of work is the building and repairing of motor boats,



View of a Machine Shop at Valdez, Alaska

of which there are a few hundred in Valdez Bay. Beside wharf building, the manufacture of freight sleds is work that tends to make up a lucrative business. In connection with the machine business there is a tin shop which is always kept busy. Notwithstanding the fair wages paid to machinists—62½ cents per hour—Mr. Crawford experiences considerable difficulty in obtaining men, as most machinists, like the majority of workmen in Alaska, feel strongly the call of the north and go into the hills to seek the illusive pot of gold that is so well secreted in the frozen earth. A few are successful, but the most return with empty pockets. One machinist who has been smiled upon by Dame Fortune is Jack Carroll, who was one of Dr. Cook's guides on the Mt. McKinley trip.

Valdez is situated near the head of a beautiful land-locked bay on Prince William sound in the Gulf of Alaska. It is open to navigation the year round, and has water deep enough to float the world's navies. Six Seattle steamers call monthly with mail and merchandise, and the trip between the two ports is often made in four days. It takes nine days for a letter to reach Boston from there. Valdez is the farthest north open-all-the-year port in America.

* Address: 206 Clark Place, Elizabethport, N. J.

HANDLING AND STORING COMMERCIAL IRON AND STEEL PRODUCTS

By ETHAN VIALL*

There is a vast difference between the handling and storing of pig iron and that of the product that comes from the mills. The former may be loaded into cars with magnets—or just dumped in—and it may be unloaded on the same plan; but for handling sheets of metal, bars, tubes or beams, dumping is out of the question and magnets are impracticable and dangerous; that being the verdict of the firm of Joseph T. Ryerson & Son, Chicago, who probably handle more structural iron, sheet metal, bars and material of that sort than any other firm in the world.

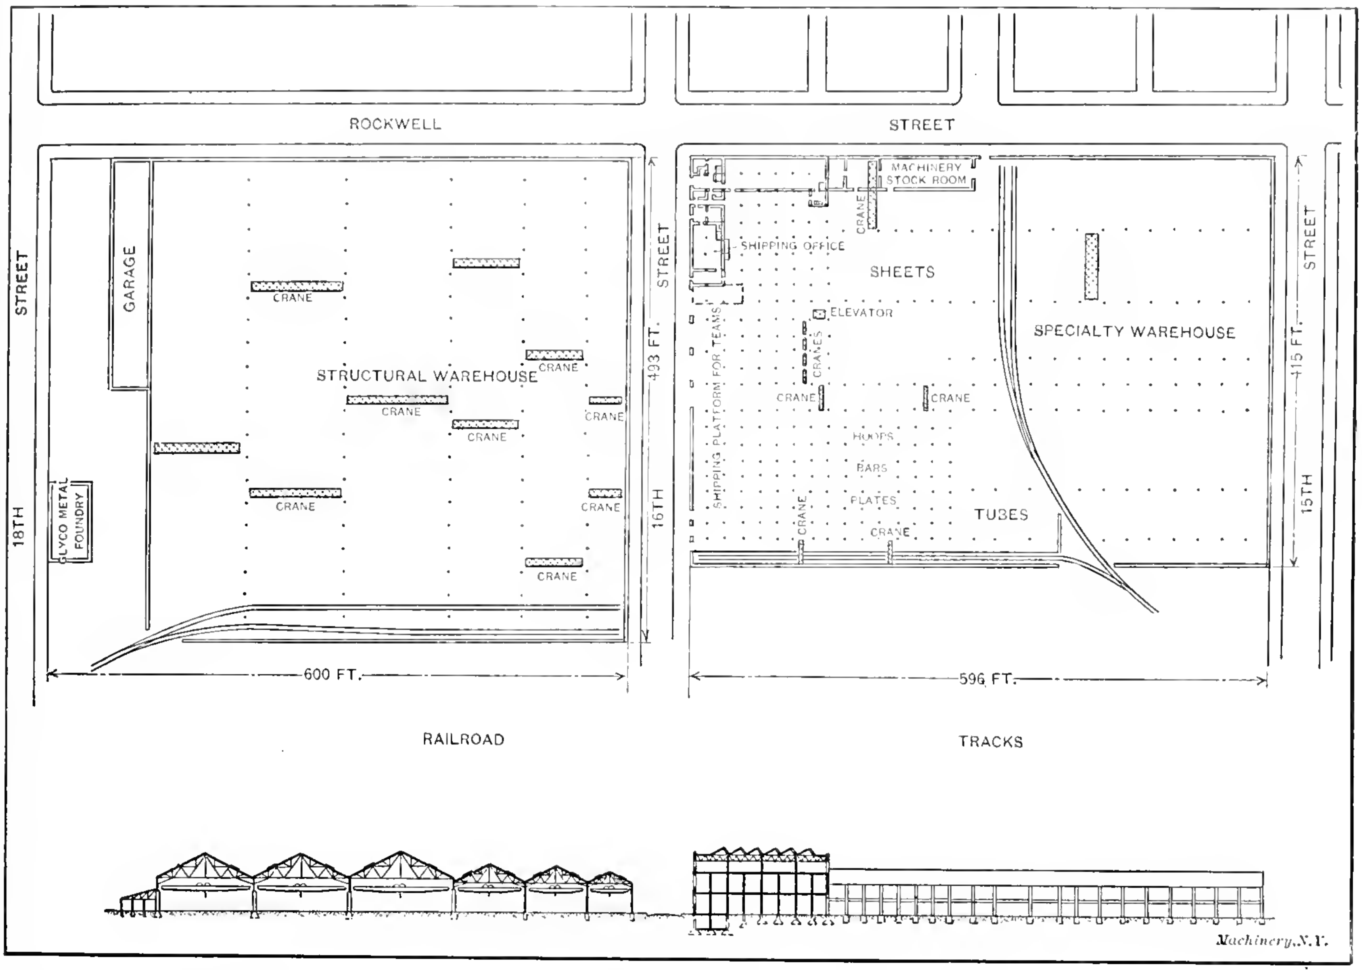


Fig. 1. Ground Plan of the Warehouse of Joseph T. Ryerson & Son, Chicago, Ill.

Fig. 2. View in the Structural Warehouse showing Cranes and Method of Storing Stock

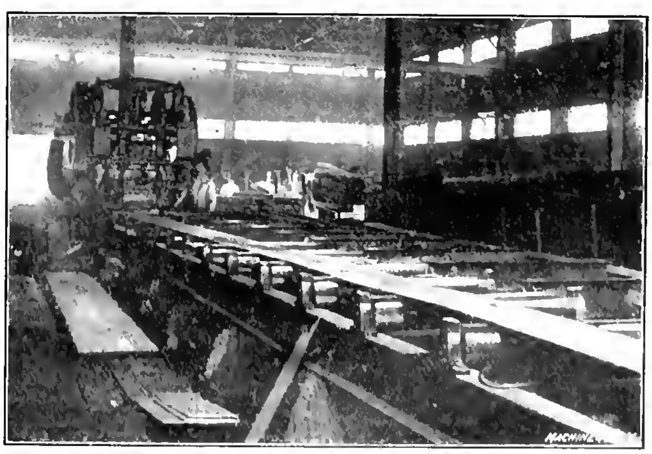

Fig. 3. Roller Table used to feed Stock to Big Shears

The general layout of the great Ryerson system of warehouses, the floor plan of which is shown in Fig. 1, is the best for the purpose that modern engineering skill could plan. These warehouses have 750,000 square feet of floor space, affording storage and handling facilities for 150,000 tons of material. The structural warehouse alone covers over eight acres. It is divided into bays, each being about five hundred feet long and varying in width from forty-five to one hundred and ten feet. All buildings are of steel construction throughout, with roofs of corrugated iron and glass. Three railroad switch tracks enter the structural buildings and extend along the entire east end, furnishing, under roof, accommodations for forty-nine cars at one time. The crane service operating in each bay over and at right angles to the railroad tracks, affords loading and unloading facilities which cannot be excelled. These shipping facilities of the structural warehouse, are supplemented by two wide wagon driveways, one entering the northeast portion of the plant and the other the southwest. These driveways are wide enough for a number of wagons, and like the switch tracks, are accessible to the entire warehouse crane service. The crane equipment is exceptionally extensive and complete, being composed of eight high-speed traveling bridge-cranes and two radial wall jib cranes in addition to the roller-tables and hoist systems used in connection with the various machines. Of the cranes just men-

* Associate Editor of MACHINERY.

tioned [illegible] are of one hundred foot span and ten tons capacity and each is equipped with two trolleys and is operated from a stationary cage. These big cranes have a bridge traveling speed of 350 feet, and a trolley travel of 175 feet per minute.

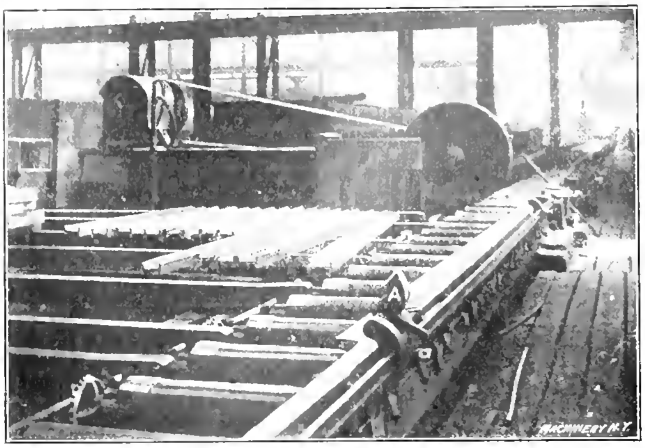

Fig 4 Roller Table for the Friction Disk-saw

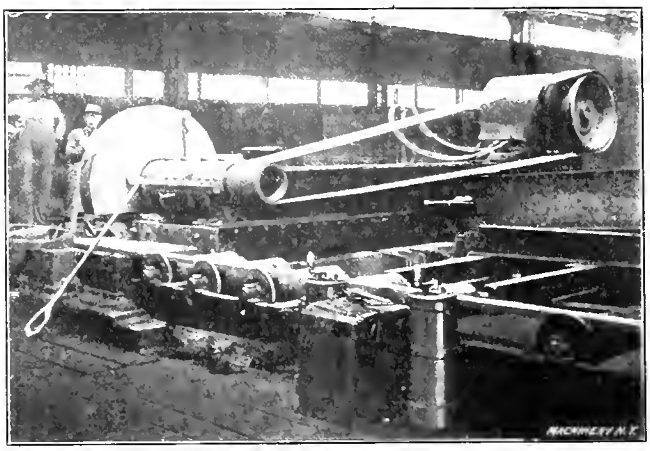

Fig. 5. Another View of the Friction Disk-saw showing Controller

A view of one of the structural warehouse bays and two of the cranes, is shown in Fig. 2. This view also shows the method of laying I-beams, etc., on structural iron "horses" so that they may be more easily picked up.

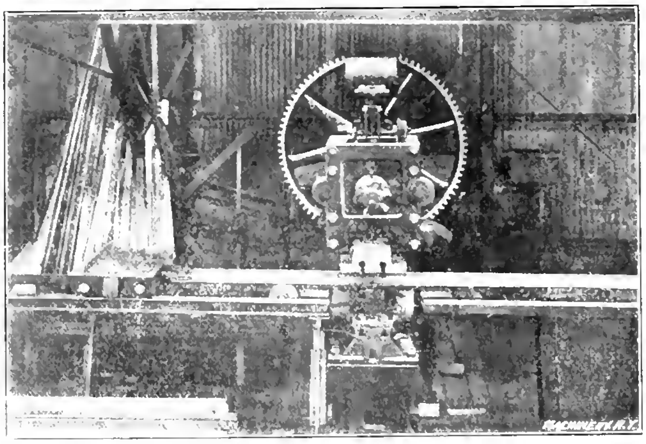

Fig 6 Punch Press and Device used to space Holes in Angle Irons

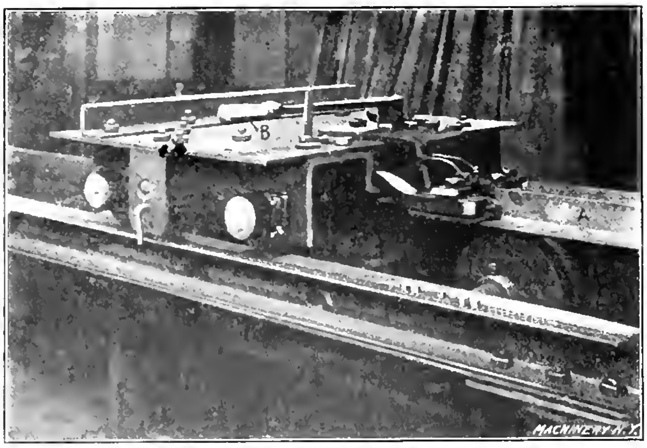

Fig 7 Detailed View of the Punch-press Spacing Mechanism

As just mentioned, the crane system is supplemented by an elaborate and carefully designed motor-driven, roller-table system, parts of which extend in three trains across the entire building and feed the high-speed friction saws and heavy shearing machinery. Fig. 3 shows one of these roller-tables that is used to carry material to one of the big shears, and in Fig. 4 is shown the roller-table of one of the big friction disk saws. The adjustable stop by which the length of the piece to be cut is gaged is shown at *A* and at the left of the rolls, may be seen the shaft and bevel gears by which the rolls are driven. Fig. 5 is a closer view of the saw from the other side, and shows the operator's seat and controlling levers in the foreground. Fig. 8 shows a view of another table with the saw in the act of tearing through an I-beam. These

Fig 8 One of the Friction Disk-saws cutting a 10-inch I-Beam

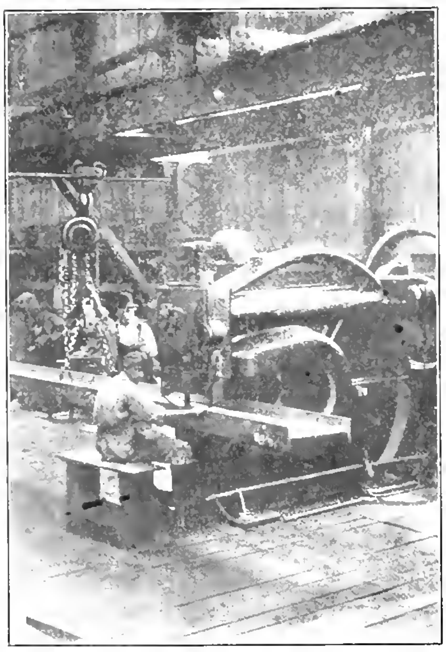

Fig 9 Traveling Hoist used to feed I-Beam under the Punch

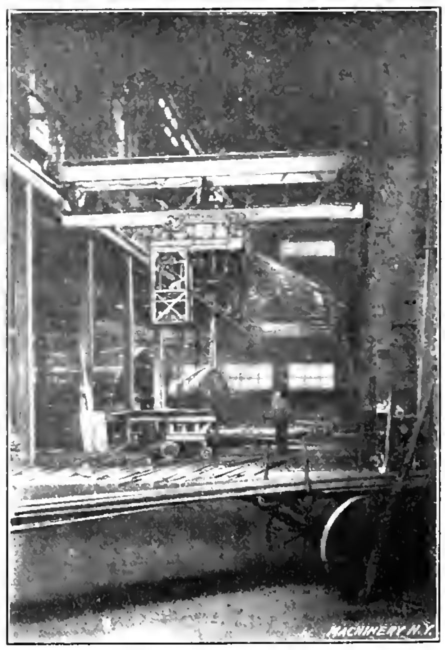

Fig 10. Cranes carrying Strap Iron to the Scales

friction disk saws have been previously described in detail in several technical journals, so only a very brief description will be given here. Each machine consists of a steel sliding

carriage, hydraulically driven forward and backward in V grooves, on a structural steel and cement foundation or bed. The saws are 52 inches in diameter, made of $\frac{5}{8}$ inch flanged steel, and run, driven by a 100 H. P. motor through a three-ply 16-inch belt, at a peripheral speed of 27,000 feet a minute.

Fig. 11. Closer View of the Portable Scales

There are no teeth on the saw, but the edge is hacked closely by using a fishtail chisel and a hammer, and instead of cutting, the disk literally melts its way through. The entire machine is 22 feet long, 5 feet 6 inches wide, and weighs

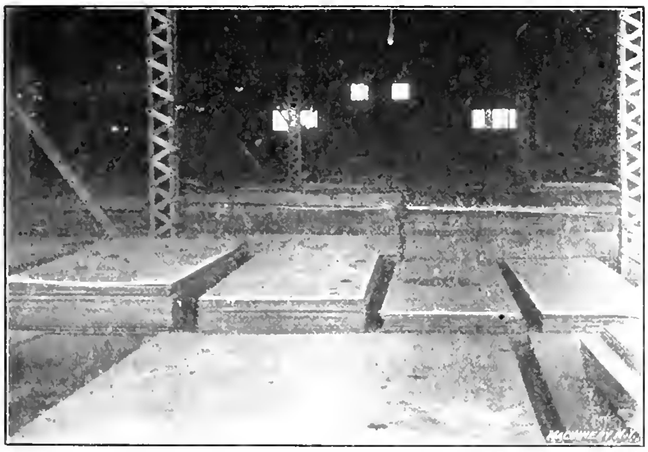

Fig. 13. The Way Flat Plates are stored

about 35,000 pounds. Some idea of the cutting capacity of these machines can be had from the fact that a 24-inch, 100-pound I-beam is cut in less than twenty seconds.

In Fig. 6 is shown a very unusual spacing device that is

Fig. 15. Grappling Claws for Plates, and Push Truck

attached to a punch press. It is designed to feed two angle irons (right and left) at once under the punches, so that the holes wanted may be punched quickly and accurately, and any number of pairs may be spaced and punched exactly alike. The device itself is shown on a larger scale in Fig. 7. It consists of a carriage mounted on wheels which run on a channel-iron track, one rail of which is drilled with three rows of holes so spaced that a stop-pin may be set every eighth of an inch; by filing a pin half away, a stop can be made within 1/16 inch of any distance, or number of distances, wanted within the length of the rail, which has been made ample for all needs. The angle irons *A* are clamped by means of the lever *B*. A dog back of the piece *C*, does the spacing

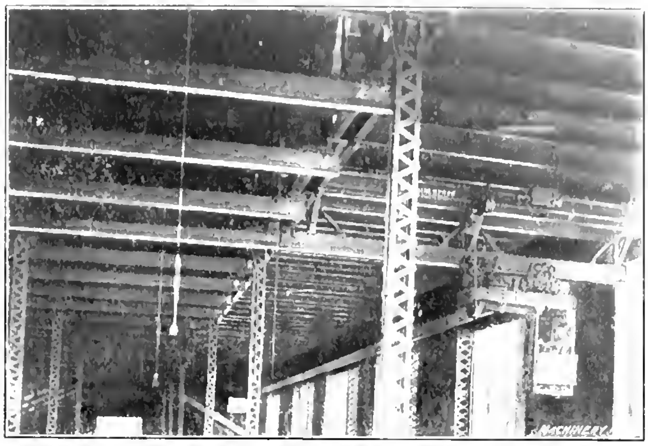

Fig. 12. System of I-Beams for Crane Trolley

for the carriage, as it drops over and is held against each pin in turn. The dog may also be lifted out of the way of the stop-pins, by using the handle just under the letter *C*, when it is desired to run the carriage out or in for any purpose.

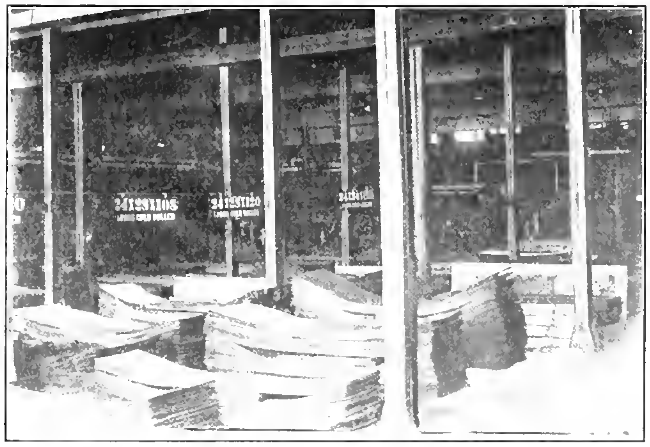

Fig 14. The Way Bundles of Sheet Metal are stored

In Fig. 9 is shown a small traveling hoist that is used to handle I-beams while punching rivet holes in them.

Fig. 10 shows a crane in the plate and bar warehouse, carrying band iron to one of the portable scales. A closer view of

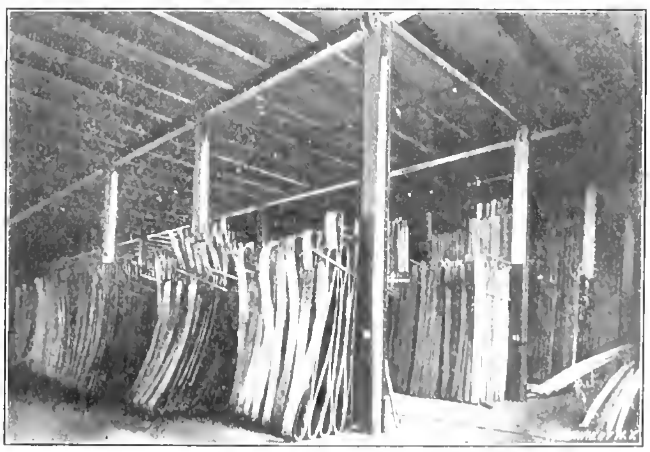

Fig 16 The Way Strap, Band or Hoop Iron is stored

the scale is given in Fig. 11. These scales are easily taken anywhere that is most convenient.

The crane system of the plate and bar warehouse, just referred to, is unusual. This building is of heavy steel, two story construction and provides 140,000 square feet of storage space. It has double crane runways, which extend the entire length of the structure, one on each side. The cranes are of ten tons capacity, and are so designed that the carriages can

be run off of the crane bridges proper onto the I-beam trolley system, illustrated in Fig. 12, which serves the entire storage floors. Beneath one of the crane runways, there is a switch track, and beneath the other, a wagon driveway, both of which extend the entire length of the building, so it will be seen that any material, such as the plates shown in Fig. 13, for example, may be taken off of a car or wagon and carried by the crane directly to and deposited on the pile designated, with but one handling. As the illustration just referred to indicates, all plate stock is laid on the floor in flat piles for convenience and to prevent distortion, each size being located in a separate pile and arranged in bays according to grade and thickness. The light sheet iron in bundles, is also stored in this way as shown in Fig. 14.

At the beginning of this article, it was stated that magnets are not used at all here as they are unsatisfactory and too dangerous for this kind of work. All crane grappling is done by means of chains or single beam-hooks or claws, two claws for plates being shown at *A*, Fig. 15, while at *B* is a short

Fig. 17. A View in the Bar Stock Storage

I-beam with an eye in the middle for the crane-hook and chains at each end, which is used for handling limber band iron, wide plates and other stock.

A rather surprising thing to most people when visiting these warehouses for the first time, is that all band and bar stock, of which there are 740 sizes carried, is stood up on end as shown in Figs. 16 and 17.

Located on the main floor of the north warehouse, and between the plate and sheet storage sections, are three heavy motor-driven, guillotine plate-shears, the largest one of which has the power and capacity to shear 12 feet of 2-inch steel plate at one stroke, and it weighs 260,000 pounds and stands 28 feet above the floor.

Boiler flues are brought in on cars as shown in Fig. 18,

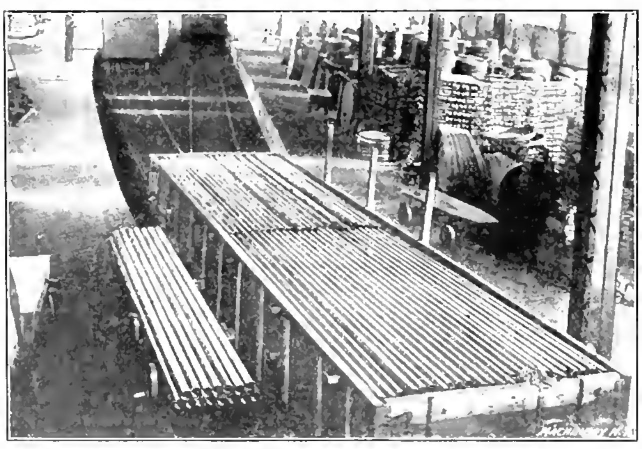

Fig. 18. Boiler Tubes loaded for Shipment

loaded onto small push trucks and then stored in structural steel racks as in Fig. 19. The various qualities of tubes such as seamless steel, lap weld steel, charcoal iron, etc., are each given different sections of the floor, while each size and length is given a separate compartment.

It must not be imagined by those not familiar with this firm, that the brief description here given covers even a small part of the immense variety of material handled and stored by the concern, for the variety of the structural and special steel and iron material, machines and specialties, is almost endless and only enough has been mentioned to give something of an

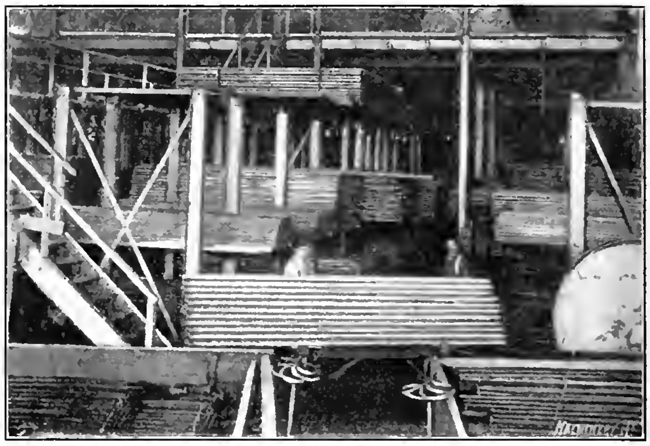

Fig. 19. Structural Iron Racks in which Boiler Tubes are stored

idea, in a general way, as to the methods used in the handling and storing of this material, in the greatest iron and steel "department store" in the world.

THE STRENGTH OF CHANNELS AND OTHER STRUCTURAL SHAPES

Experiments on standard channels carried out by Mr. C. Bach and reported in detail in the *Zeitschrift des Vereines deutscher Ingenieure*, issue of October 30, 1909, show that the regular bending formula for beams freely supported at their ends and loaded in the center gives too high a value for the strength of structural channels. The experiments show that the amount by which the value obtained from the formula is greater than that obtained by experiments, is, for channels

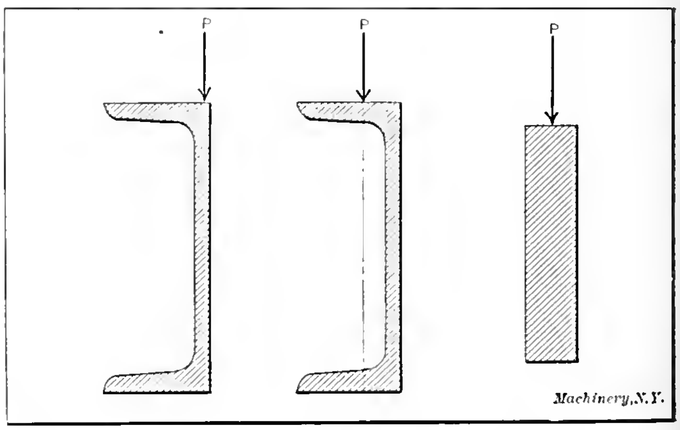

Fig. 1 Fig. 2 Fig. 3

twelve centimeters (4¾ inches) high, 7 per cent; for channels 22 centimeters (8¾ inches) high, 18 per cent; and for channels 30 centimeters (11¾ inches) high, 26 per cent. These values are those found when the load is assumed to be applied in the center line of the web of the channel as shown in Fig. 1. If the load is placed along the line of the vertical neutral axis of the channel as shown in Fig. 2, the permissible load according to the beam formula is 10, 25.5 and 34 per cent greater than that shown by the experiments. These experiments, therefore, indicate that when the usual formulas are employed in calculations, for channels or other structural shapes, a liberal factor of safety should be allowed in order to compensate for the difference of the results given by the formula and those of actual experiments. It should be noted, that apparently the formula for bending is fully correct whenever the section of the member is such that the load is fully distributed over the whole sectional area, as in a rectangular section, Fig. 3; but in the case of channels as well as many other structural shapes, the load is not, as a rule, properly distributed over the whole section, but stresses certain portions of the section in a higher degree than others.

MAKING A PRECISION DIVIDING WHEEL

There are various methods employed for making accurate indexing wheels for a definite number of divisions. One of these methods, suitable particularly for small numbers of divisions, employs a split wheel with a series of taper holes reamed through the two divisions. By shifting the two divisions from point to point and reaming and re-reaming the taper holes at each shifting, they may finally be brought very accurately into position. Another method that has been employed consists in clamping about the rim of the dividing wheel a number of precisely similar blocks, fitting close to each other and to the wheel itself. These blocks are then used for locating the wheel in each of its several positions in actual work. A third and simpler method (a modification of the one last described) consists in grinding a series of disks and clamping them around a rim of such diameter that the disks all touch each other and the rim simultaneously. The wheel we are to describe is made in this way. It is shown in Fig. 1.

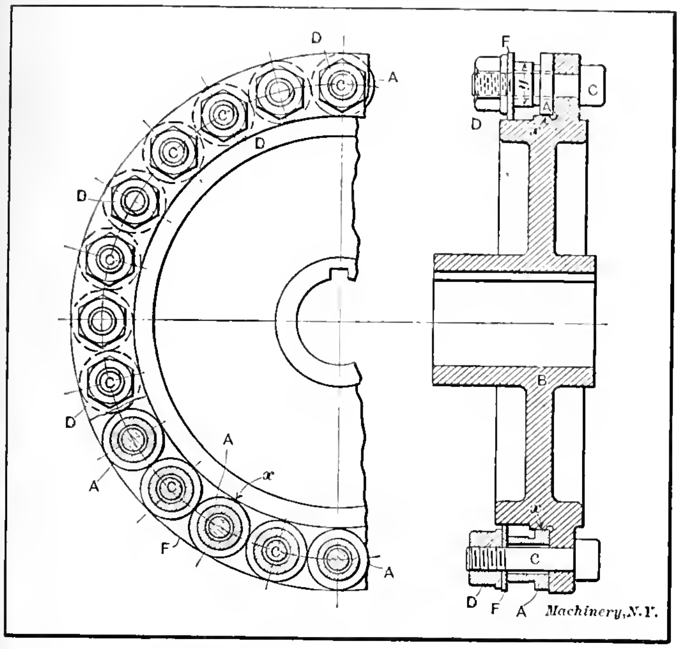

Fig. 1. An Improved Construction for Dividing Wheels of the Disk Type

In this, wheel disks *A* are clamped against an accurately ground face of the wheel *B* and are supposed to just touch each other all around, and to be each of them in contact with the ground cylindrical surface at *x*. They are held in proper position by bolts *C* and nuts *D*. The bolt fits loosely in the hole of the disk or bushing *A* so that the latter is free to be located as may be desired with reference to the bolt.

One or two improvements in the construction of this type of dividing wheel may be noted before proceeding to a description of the way in which it is made. For one thing, instead of having an indexing bolt enter the V-space between two adjoining disks, a smaller diameter *y* is ground on each of them, over which locking finger *E* (see Fig. 2) passes, holding the wheel firmly from movement in either direction. This construction has the advantage of a probable lessening of error by locating on each bushing instead of between two bushings; it gives a better holding surface and better holding angles, as well, than would be the case if this smaller diameter were not provided.

A second improvement refers to the method of clamping the bushing *A* in place. Instead of providing each bolt with a separate washer, a ring *F* is used. This ring fits closely on a seat turned to receive it on the dividing wheel *B*. When one bushing *A* has been clamped in place, the disk is locked from movement so that there is no possibility, in clamping the remaining bushings, of having their location disturbed in the slightest degree by the turning of the nuts in fastening them in place.

The bushings *A*, of which there were in this case 24, were first all ground exactly to the required diameters on their locating and locking surfaces. The important things in this operation are, first, that the large or locating diameter of the bushing should be exactly to size; and second, that this surface should be in exact alignment with the diameter in which the locking is done; and, finally, that the face of the bushing should be squared with the cylindrical surfaces. A refined exactness for the diameter of the locking surfaces is not so important, as the form of locking device provided allows slight variations at this point without impairment of accuracy. This dimension was kept within very close limits, however. The truth of the two cylindrical surfaces and the face of the bushing was assured by finishing all these surfaces in one operation on the grinding machine.

The sizing of the outer diameter of the bushing, which was 1.158 inch, must be done so accurately that it was not thought wise to trust to the ordinary micrometer caliper. An indexing device was therefore made with a calipering lever, whose long end, in the ratio of 10 to 1, actuated the plunger of a dial test indicator of the well-known type made by the Waltham Watch Tool Co. The thousandth graduations on the dial of this indicator would then read in ten-thousandths, permitting readings to be taken to one-half or one-quarter of this amount. The final measurements with this device were all taken after dipping the bushings in water of a certain temperature, long enough to give assurance that this temperature was universal in all the parts measured. It will be understood, of course, in this connection, that getting the diameter of these bushings absolutely to 1.158 inch was not so important as getting them all exactly alike, whether slightly over or slightly under this dimension; hence, the precaution taken in measurement.

Wheel *B* was next ground down nearly to size, great care being taken that it should run exactly concentric with the axis on which it is mounted for use. As soon as the diameter of the surface *x* was brought nearly to the required dimension as obtained by calculation, the disks were tried in place. The first one was put in position with its loose hole central on the bolt and clamped in place under ring *F*. The next bushing was then pressed up against it and against the surface *x* of the wheel and clamped in place. The third one was similarly clamped in contact with its neighboring bushing and the wheel, and so on, until the whole circle was completed. It was then, of course, found that the last disk would not fill the remaining space. This required the grinding off of some stock from surface *x*, and a repetition of the fitting of the bushings *A* until they exactly filled the space provided for them.

This operation required, of course, considerably more skill than a simple description of the job would indicate. One of the points that had to be carefully looked out for was the cleaning of all the surfaces in contact. A bit of dust or lint on one of the surfaces would throw the fitting entirely out. The temperature of the parts was another important consideration. As an evidence of the accuracy with which the work was done, it might be mentioned that it was found impossible to do this fitting on a bench on the southern or sunny side of the shop, the variations of temperature between morning and noon, and between bright sunshine and passing clouds, being such that the disks would not fit uniformly. The variation from these minute temperature changes resulted from the different coefficients of expansion of the iron wheel and the steel bushings. The obvious thing to do would be to build a room for this work kept at a constant temperature (preferably that of the body), so that the animal heat of the operator would make no difference in the results. It was found sufficient in this case, however, to do the work on the northern side of the shop where the temperature was more nearly constant, not being affected by variations in sunshine.

The dividing wheel, whose construction has just been described, was made by the Fellows Gear Shaper Co., of Springfield, Vt. It is used for indexing the Fellows gear cutters in the machine in which the teeth are ground. The indexing mechanism of this machine is shown in Fig. 2. The handle *G*, by which it is operated, is pinned to rock-shaft *H*, to which is keyed arm *J*. Pivoted to *J* is a pawl *K* engaging the teeth of ratchet *L*, which revolves loosely on shaft *H*. This ratchet *L* controls the movement of locking finger *E*. The

parts are shown in their normal or locked position in the engraving.

As the handle G at the right of the engraving is pulled toward the observer, arm J at the left of the engraving is raised, carrying the ratchet wheel around in the direction of the arrow shown. This allows flat spring M to drop over the ratchet tooth, permitting helical spring O to raise latch E and thus leave the wheel free. The continued movement of the hand-lever and of rock-shaft H, by means of gear N, intermediate pinion P and gear Q, causes the indexing pawl R, pivoted to the latter and acting on the head of the bolt C, to index the wheel one step. Just before reaching its new location the new tooth of ratchet wheel L coming up, bears down on the top of spring M, pressing latch E into place against the tension of coil spring O. By this means the wheel is locked in position.

When the operator pushes the handle G back again to its position of rest, the pawl R is retracted into position to act on the next bolt head for the next indexing. Star-wheel L remains stationary on this backward movement, being prevented from revolving by the notch on the top of the tooth into which spring M fits. Pawl K on its return engages with the next tooth of this wheel, ready for the next indexing operation.

A slight rotary adjustment of dividing wheel B, independent of this indexing mechanism, is required for the feeding of the machine. This is accomplished by the end movement of latch E, which is pivoted in slide S. This latter is pressed to the right by spring plunger T, and is adjusted positively in the other direction by feed-screw U, which is finely graduated to permit accurate adjustment. The accuracy in indexing obtained by the use of a wheel thus made was required to bring the finished cutters within the very narrow limits allowed for them in the final inspection.

R. E. F.

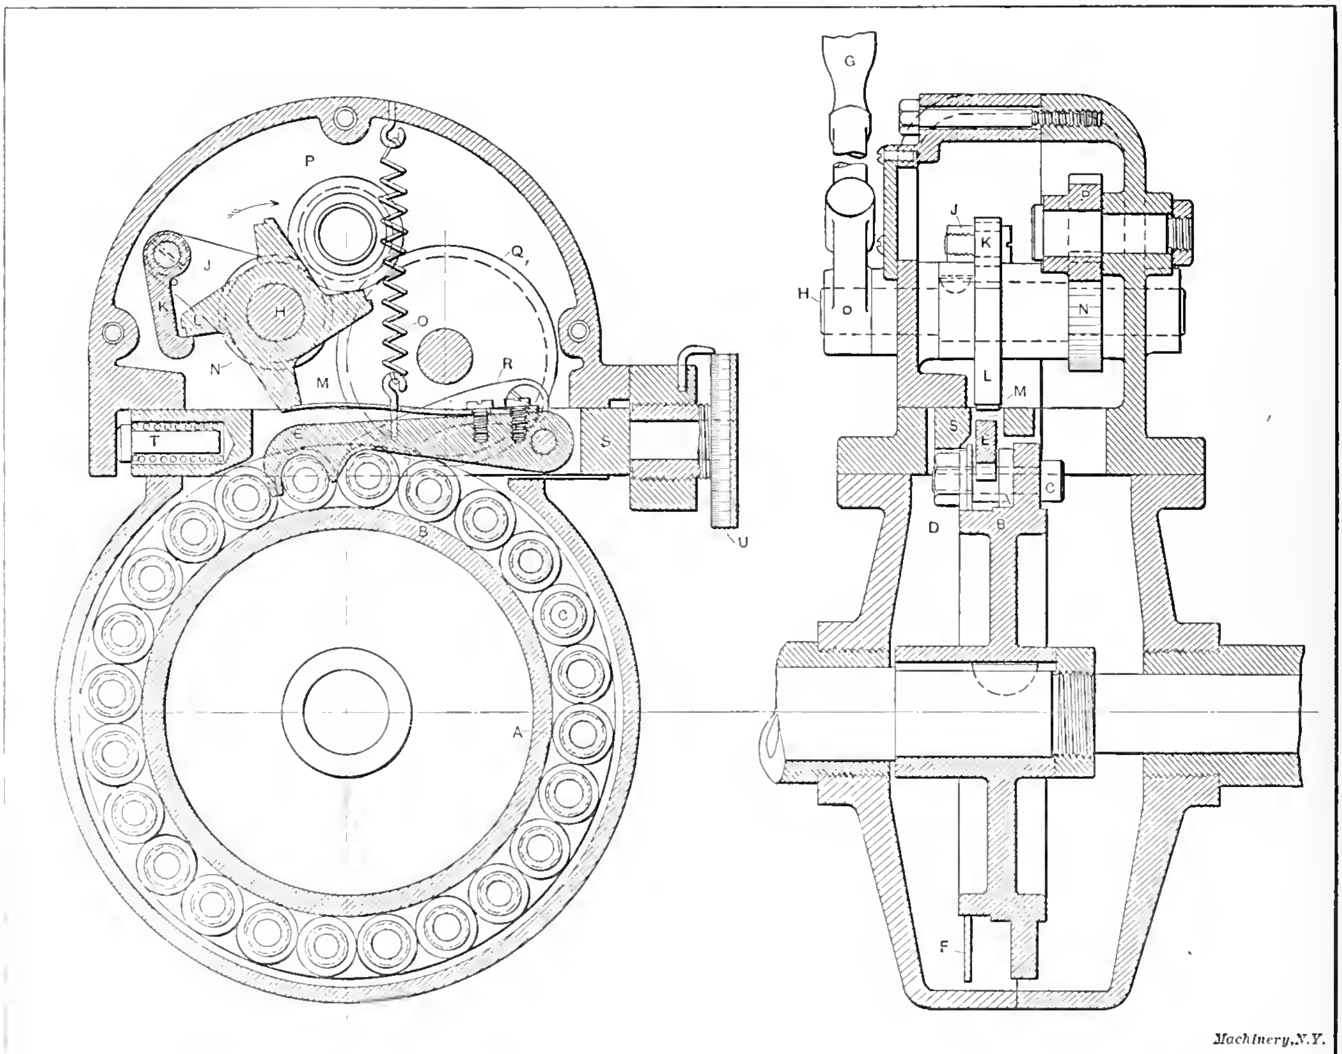

Fig. 2. The Indexing and Feeding Mechanism of the Fellows Gear Cutter Grinding Machine, in which the Dividing Wheel is used

EXPLOSION GAS TURBINES

In the March, 1907, and July, 1908, issues of MACHINERY, engineering edition, articles were published on practical results obtained with actual operative gas turbines in France. These articles consisted of abstracts from accounts published in *Cassier's Magazine*. The same magazine some time ago published additional information relating to recent developments in this field.

During the past year there has been built in Paris, by Mr. Karavodine, an explosion gas turbine developing about two horsepower; the machine has been operating with regularity, and recent tests have been undertaken from which the following data are obtained. In the Karavodine explosion gas turbine there are four explosion chambers, the products of the explosions being directed through four nozzles upon a single turbine wheel. The wheel is of the De Laval type, about six inches in diameter. This wheel makes 10,000 revolutions per minute, corresponding to a peripheral velocity of about 260 feet per second. The gasoline consumed per horsepower-hour amounted to 4.93 pounds. The machine gave 1.6 brake-horsepower, and the frictional losses were determined by the experiments to be 0.5 horsepower, so that the actual indicated horsepower was 2.1. In considering the availability of a machine of this type, there are some considerations other than fuel consumption. The continuous turning effort is often desirable, and considering the small size of the machine, the results were not unfavorable. The absence of a compressor and the corresponding reduction in weight and size are some of the advantages of the machine over previous types. Of course, the gas turbine is not yet a practical machine, but it is interesting to note the progress being made.

Don't dry freshly applied blue vitrol by brushing the piece of work against your overalls or apron; it destroys the fabric.

CUTTING SMALL SPUR GEARS IN SPECIAL SEMI-AUTOMATIC MACHINE

By E. H. WEISS*

When it is necessary to cut a large quantity of small gears of say 80 millimeters (3 5/32 inch) diameter, it is a job of some delicacy if it is necessary to do the work accurately and economically. This condition is met with periodically in our factory, particularly in the manufacture of small gears for the magnetic calls for telephone service. These gears are first turned on the outside in gangs while they are held between two clamping plates, thus making the periphery true with the bore which is sometimes slightly eccentric. As we possessed but one small and unsuitable sawing machine, it was decided to cut the gears and pinions (the latter also being of brass but only about 20 millimeters in diameter) by mounting them in gangs of eight or ten between the dividing heads of an old milling machine.

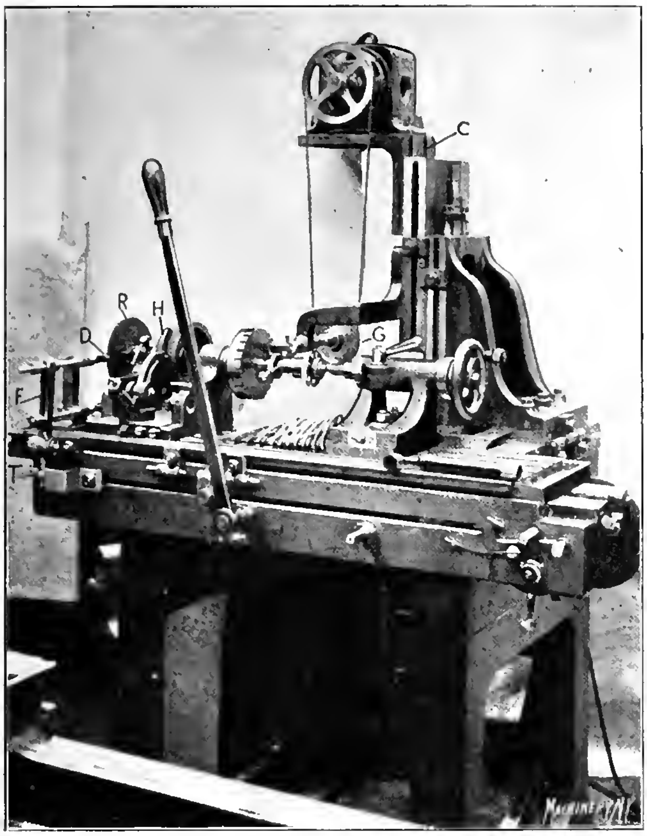

Fig. 1. Machine for Cutting Small Spur Gears, with Automatic Indexing Mechanism and Hand Lever Feed

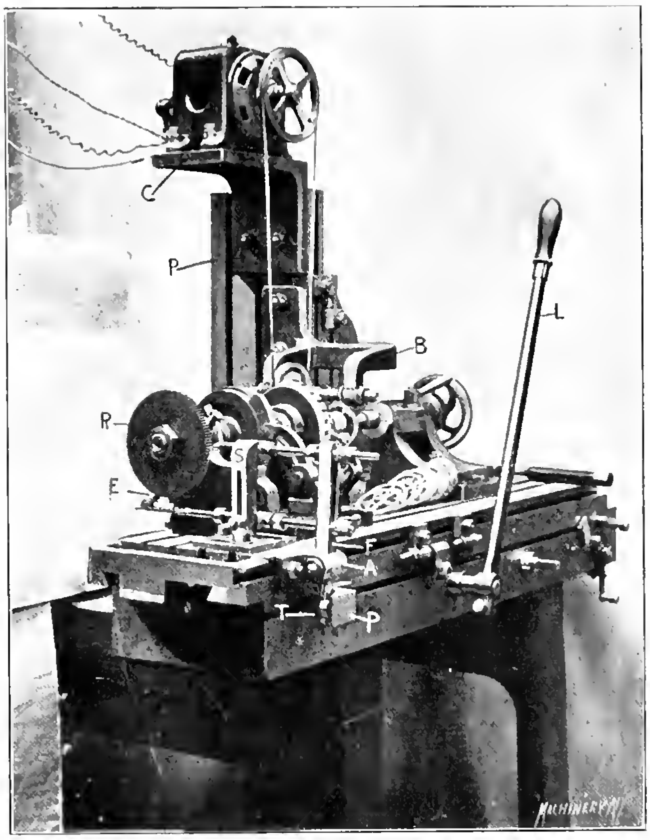

Fig 2. Another View of the Spur Gear Cutting Machine

Two difficulties presented themselves: First, the maximum speed of the cutters was 1,800 revolutions per minute, which was not sufficient to finish the surface of the teeth properly without reducing the feed of the table, which would have increased the cost of the work; furthermore, as the platen was fed by hand, naturally it was difficult to feed it uniformly and with the required feed reduction. Second, the pressure necessary to hold the gear blanks together produced a slight curvature at the center which, in conjunction with the distortion due to the pressure of the cutter, caused the depth of the teeth in different gears to vary. It was then decided to mount the cutter on a special arbor which could be run at the required speed, and furthermore, to render the indexing automatic (the dividing was intended to be controlled by the to-and-fro movement of the lever *L*). The cutter-head was removed and on the vertical platen *P*, as shown in the accompanying illustrations, there was bolted a bracket *B* having two arms to support the cutter arbor. The latter, which revolved between centers, could, without difficulty, be driven at a speed of 3,500 revolutions per minute. Besides the cutter, this arbor carried a pulley *G* having a V-shaped groove. It was out of the question to drive this pulley from the driving shaft of the machine, for that shaft revolved only 150 revolutions per minute, therefore, it would have been necessary to have had a series of belts and pulleys which would probably have become heated on account of the high speed. It was decided then to drive the cutter arbor by means of a small motor. In order to avoid having a tightener on the driving belt, a large bracket *C* was fixed to the upper part of the slide *P*, and this bracket supported a shunt motor, on the armature shaft of which was fastened a grooved driving pulley. Since the cutter arbor is adjusted up and down with the slide *P*, the distance between the centers of the two pulleys, of course, is always the same.

The method employed to automatically effect the indexing of the dividing wheel is as follows: On the back of the dividing head a bronze wheel *R* is keyed, which is provided with either the same number of teeth, or a multiple of the number of teeth in the gear to be cut. The indexing of wheel *R* is effected by a dog *E* which has an adjustable movement, permitting the indexing of one or several teeth. After wheel *R*, and with it the work, has been indexed, the finger *D* which moves with *E*, enters a tooth space in wheel *R* thus locking it in position. The stems of parts *E* and *D* both slide in the same support *S*, and their backward movement against the pressure of coiled springs bearing against an abutment, is effected by a slotted lever *F*, which is pivoted at *A* and carries at its lower end a roller *T*. The base of the machine is provided with a wedge-shaped dog *P*, which is fixed in place. At the end of the movement of the table, that is to say, when a tooth has been finished, the roller *T* is displaced by the wedge-shaped surface on *P* thus effecting the movement of lever *F*, and through it that of stems *E* and *D*.

After experimenting, it was found that the work spindle needed to be braked more or less (depending on the number of holes being indexed) to check the table at the end of its movement. To effect this, a fiber brake *H* was provided, which supplied more or less pressure on a disk keyed to the spindle by means of an arm held down by spring pressure.

After the wheels are once placed on the arbor, the workman, who under the circumstances may be a common laborer, has only to move lever *L* back and forth and he does not need to occupy himself with the details of the cutting action. The work is finished when it has made a complete revolution. The movement of lever *L* can be very rapid, as the cutter, because of its speed, does not rough up the work.

As previously stated, this gear cutting operation is only re-

---

quired periodically, though several thousand gears are cut at a time. When the milling machine is not required for this work it is only necessary to remove the two heads, the bracket C and the arm B, when the machine may be used as an ordinary milling machine after the vertical or horizontal head has been replaced on the platen P.

* * *

"COST OF POWER" DEFINED

"Twenty-five years ago, the expression 'cost of power' was fairly well defined as meaning the yearly cost per indicated horsepower, if produced by steam; or power on the wheel shaft, if produced by water, for ten hours a day and about 308 days a year, or for 24 hours for the same number of days. This was fairly well understood by those who had to deal with these matters and who gave the matter any thought." This was the statement made by Charles T. Main and F. M. Gunby in their paper entitled "Cost of Power for Various Industries Under Ordinary Conditions." Continuing, this paper, which was recently read before the Boston Society of Civil Engineers, the authors go on to say:

"Since that time when mechanical transmission of power by shafting, belting, ropes, etc., were about the only methods in use, there has been developed the electrical transmission of power now so commonly in use, with new units of power as electrical horsepower, and the kilowatt, which is equal to 1.34 electrical horsepower. There also has now come into common use the steam turbine, for which there is no indicated horsepower, the measurements of power being either in brake horsepower, electrical horsepower, or kilowatts. There is the power produced by water wheels, which is gross horsepower, net horsepower at the wheel shaft, and when changed into electrical power, electrical horsepower and kilowatts.

"To-day the statement, 'cost of power,' unless clearly defined, may mean one of many things, and the men who are used to thinking in indicated horsepower are sometimes at a loss to know what is meant when the cost is stated as so much per kilowatt, delivered. It must be translated back into indicated horsepower or its equivalent, before there is any definite impression made on their minds.

"There is another source of great confusion because, during this period of time, there have been developed industries like electric lighting and street railway plants, in which the load is extremely fluctuating, in which, therefore, the cost per horsepower of unit of product is more and cost of plant more than for steady loads. Now that electrical transmission has been developed so that the current can be transmitted and used at a distance, it must be sold as electric current, delivered, and if a price is quoted to a mill manager at 32 dollars per kilowatt, delivered, he says: 'How much is this a horsepower?' and you answer, '24 dollars.' He then says: 'I can beat that in my engine,' and when he says it he is thinking of indicated horsepower at about 20 dollars a year per horsepower, with no allowance for friction loss in the engine or transmission to the same point where the electric current is delivered.

"If lighting current is offered to him at 3 dollars and 20 cents per kilowatt hour he says: 'How much is that a year?' 'For 3,000 hours it is 96 dollars a kilowatt, or 72 dollars a horsepower.' 'Well,' he says, 'that is outrageous when we produce at 20 dollars a year per horsepower.'

"It may be possible that he can beat the figures presented to him, but there is a reason for the discrepancy between his conception of what prices ought to be, and what they are.

"The cost of power and the value of steam and water power to the various industries varies between very wide ranges. Steam power costs the most per unit of power when produced in small amounts, and the cost is increased for fluctuating loads and when used for purposes where the load factor is small. By 'load factor' we mean, in this particular instance, at least, the average output in per cent to the full load capacity of the plant. Loads with a small load factor are obtained in electric lighting and street railway plants, in which cases there is generally no use for the 'by-products of power.'

"Steam power costs the least per unit of power for comparatively steady loads, and the cost is still further reduced where there is use for exhaust steam or the overflow water from the condenser. Such conditions as these are found in colored textile mills. Another example of the low net cost of power is in steel mills where the waste gases of the furnaces are used, either for the production of steam or directly in gas engines. Between these extremes there are various industries for which the cost of power will vary greatly."

* * *

ROOTS BLOWER PISTON PROFILES*

The design of the profile of the pistons of a Roots blower presents great difficulties to the novice who attempts to arrive at a correct form by the process of "trial and error," or the complicated method of making tracings of the pistons in twenty or thirty different positions on one piece of paper. The matter is very simple, however, when analyzed, and the writer believes the method of drawing the profiles, given herewith, to be original. It was at any rate discovered by him recently, when the design of some Root's blowers came into his hands, and the results appear to be excellent. A favorable point is that all the curves are parts of circles, which greatly facilitates the machining of the faces by making it possible to rotate the work on centers when planing.

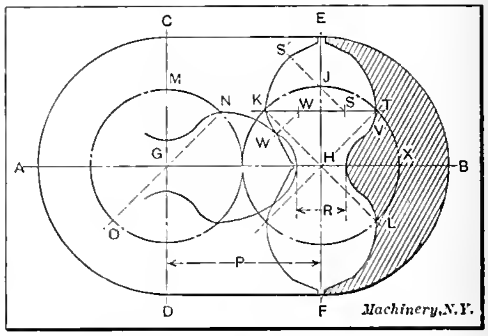

Diagram Illustrating Method of Laying out Root Blower Pistons

In a blower of this design the air space available is about 60 per cent of the area swept out in one revolution of the pistons; *i. e.*, the area X, Fig. 1, equals 60 per cent of the area of the half circle EF. In calculating the output, an efficiency of 70 per cent can be allowed, so that $L = 4 \times A \times R \times 0.7$, when L = length of piston in feet, A = area of one air space X in square feet, R = revolutions per minute. The diameter of the pistons is, of course, made sufficient to give a proportionate length of, say, 2 diameters. The distance P between the centers (see illustration), equals 0.6 times the diameter of the piston plus 1/8 to 1/4 inch for clearance. This makes the width at the narrowest part R = 1/5 of the diameter EF, and it may not be less.

To lay out the profiles, set down the horizontal and vertical center lines AB, CD and EF; and from the centers G and H strike the pitch circles JKL and MNO with radius $= \frac{1}{2} P$.

It will be seen that at the points K and N the profiles of pistons cut the pitch circles. These points are found by drawing a line at 45 degrees from the centers H and G. Through the point K draw a line KT parallel to AB. From center S with radius SK = radius of pitch circle, describe the arc KS', placing center S on the line KT. From center W with the same radius describe the arc TE. From center S describe arc TV, and from the center W describe the arc KW'.

This produces one pair of faces, and the opposite pair is produced in a similar way. A radius must now be found such that with the center on the line AB an arc may be struck connecting the inner part of the faces and the outside of the center boss. The useful part of the curving faces thus produced lies within the angles formed by the lines SS' and WW', and the line KT. These lines SS' and WW' are struck at 45 degrees from the centers S and W. The useful part is all of the faces that need be machined, though in practice it is as well to extend it 1/2 to 3/4 inch beyond.

The outer part of the pistons should be formed into a rib which may project 1/4 to 3/8 inch, and the base of this rib may be joined by a straight line to the point on the face at which the machining finishes. It may be stated that this construction does not produce perfect contact at all times between the faces, but the error is negligible. Allowance must, of course, be made for clearance between the pistons.

* R. Hampton, in the *Mechanical World*, December 24, 1909.

DON'TS FOR MACHINISTS*

By H. E. WOOD†

Don't run an emery wheel that is on a shaky machine.

Don't use a hand reamer for power reaming.

Don't run cutters backward in a milling machine.

Don't finish a milling machine job with dull cutters.

Don't put up pulleys unless they are properly balanced.

Don't leave set-screws sticking out of shafting collars.

Don't use one emery wheel for all kinds of grinding work.

Don't set the stroke on a shaper longer than is necessary.

Don't put on a belt with the flesh side next to the pulley.

Don't file holes oblong to let a bracket up to its place.

Don't force an emery wheel on an arbor; it should be an easy fit.

Don't let your milling machine cutters slip around on the arbor.

Don't work on any machine if the countershaft hangers are loose.

Don't believe that emery wheels are the only abrasive wheels made.

Don't put wooden wedges under the hanger feet without nailing them.

Don't make a new piece just like the old piece when making repairs.

Don't screw the clamping nut too tight against an emery wheel; it is dangerous.

Don't work under a cracked pulley; it should be patched or scrapped.

Don't leave anything loose lying overhead where machinery is running.

Don't bear on an emery wheel too hard; it will only cut so fast anyway.

Don't fail to have all oil cans marked so that the kind of oil in them is known.

Don't try to put in lag-screws without first boring pilot holes for them.

Don't put lag-screws into hardwood timber without a good heavy grease on them.

Don't forget that fast speed is better than slow speed for slotting saws.

Don't run a milling cutter against the table or vise jaws and then deny it.

Don't forget that very high speed should be used to make brass cut nicely.

Don't think that locomotive work is altogether like stationary engine work.

Don't get your shirt or frock sleeve close enough to touch a running drill.

Don't forget that sheet steel has an end grain, similar to a piece of board.

Don't make center punch marks to work to, when you can see your scratch lines.

Don't try to make a straight hole in a spongy piece of cast iron with a drill.

Don't forget that large flat castings will bend with their own weight.

Don't run an emery wheel any faster than one mile a minute at its cutting surface.

Don't forget that a taper reamer makes a good backing-off tool in punch and die work.

Don't forget that it is an impolite question to ask the new man where he worked last.

Don't fail to make allowances for the sag of your shafting when putting up a line shaft.

Don't neglect an emery wheel until the face is entirely clogged full of metal and dirt.

Don't put up a chain hoist and use it without making sure that it will hold more than the load.

Don't put up overhead shafting without making provision to catch or absorb the surplus oil.

Don't use flanges or washers on the emery-wheel arbor without a slight concave to their face.

Don't allow work to rattle loose on the lathe centers, except when filing or polishing.

Don't put lag-screws through a board, plank, or timber, without washers under the heads.

Don't set the outer support for a milling machine arbor up tight to the nut, but leave a little end play.

Don't mount an emery wheel without first tapping it lightly, to see if it is sound or cracked.

Don't start up a milling machine unless you have the arbor in tight enough so that it will not slip.

Don't forget that canvas or leviathan belt works better in some places than leather or rubber.

Don't use too much belt dressing as too much is worse than none at all; besides it is expensive.

Don't use a large emery wheel on a small machine, or a small one on a large machine; it does not pay.

Don't try to start a milling cutter into a piece of steel that has the rolling mill scale still on it.

Don't cross your belt laces on the side next to the pulley, for that makes them cut themselves in two.

Don't forget that a power-transmitting belt will almost invariably go to the tightest point it can find.

Don't let the full weight of a power hacksaw be on a square or flat piece of work when the saw is started.

Don't forget that you can cut flat, square and round pieces of stock in a power hacksaw at the same time.

Don't try to get along with only one center-punch, or scratch awl, but have two or three; you'll need them.

Don't forget that there is a difference in letting a bracket "up to its place" and "back to its place."

Don't put a large washer on one side of an emery wheel and a small one on the other side; it is dangerous.

Don't bolt a rough casting down on a milling machine table or planer bed; it is better to put brass shims between them.

Don't saw a piece of steel nearly through from one side only, and then break it the rest of the way.

Don't start to do a drilling job unless the drill is tight enough in the chuck so that it can't slip around.

Don't forget that a shaft bearing will only take so much oil; any more than that amount will be useless.

Don't fail to leave a liberal allowance for expansion and contraction (or end play) in a line, or jack shaft.

Don't screw the bolts up too tight on one side of a pulley; both sides should be tightened together.

Don't blow dust from a hole or a corner unless you expect it to float back and get into your eyes.

Don't put a countershaft overhead without first putting it together on the floor, to see that it goes all right.

Don't use machine lubricating oil on taps, drills, or any cutting tools, and lard oil to lubricate a machine with.

Don't think that it is absolutely necessary to be just as precise and neat in repair work as you should be in new work.

Don't let a cone pulley get gummed up with belt grease; in fact, it is better not to use belt grease on cone belts.

Don't believe that it is economical to save emery wheels by neglecting to keep them trimmed and sharp.

Don't fail to get a little originality into your head, and try to reason out the why and wherefore.

Don't spit on the floor, because there is not a sufficient amount of iron on the floor to kill the tuberculosis germ.

Don't be reluctant to use the emery wheel dresser, as it has much the same effect as a file has to a carpenter's hand saw.

Don't mount an emery wheel carelessly, because ninety per cent of the emery wheel accidents come from this carelessness.

Don't think that a shaft must be absolutely level to run correctly, for the alignment of the centers is the most important.

Don't hesitate about asking your foreman questions; it is better to make him mad that way than by spoiling a piece of work.

Don't place pulleys so close together that there is not room enough for the full width of their belts to go down between them.

Don't forget that you may resort to many tricks in repair work that would not be tolerated for a minute in manufacturing work.

---

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

MARCH, 1910

PAID CIRCULATION FOR FEBRUARY, 1910, 25,687 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition $2.00 per year—coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 300 pages additional reading matter, and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

A POWERFUL COMBINATION

Considerable space has recently been used by some trade journal publishers to deny the existence of a trust or combination of their properties. This was followed by a statement signed by Messrs. Charles G. Phillips, I. A. Mekeel, John A. Hill, James H. McGraw, W. H. Taylor, E. A. Simmons and Robert Tinsman, as owners and managers of eighteen important trade journals in the iron, steel, hardware, metal, machinery, mining, power, steam and street railway, electrical, boot and shoe, and dry goods industries, explaining the purpose of a combination of the above interests "to conduct complete campaigns for advertisers in every important line in the trade or technical press or the general publications. . . . The power of this organization for the general improvement of advertising effort is immense in its possibilities."

The power of this organization is beyond question. It is a combination of five powerful organizations in the trade paper field, comprising most of the leading journals in the industries represented; and it is idle to deny that the power referred to will be exercised to secure advantages for the publications in the combination to the exclusion of their competitors. That is what the organization is for.

Without seeking to make capital out of this situation or to exaggerate its importance, we may say that such a combination is a menace to trade journalism, because its object is to weaken if not to kill the independent journals in those fields. Aggressive competition is fully as desirable between trade journals as in any other line of business.

* * *

THE FUTURE OF THE AUTOMOBILE INDUSTRY

A good many manufacturers of machine tools and supplies who are selling from fifty per cent to one hundred per cent of their product to the automobile trade are asking themselves how long the demand will continue, and if it will drop off as suddenly as the bicycle trade did. We think not.

Bicycle riding was a craze that went through a family like the measles. There were five members of the writer's family and we had five wheels. That was ten years ago, and since then a new generation of children has grown up, but they don't ride wheels. The industry is now reduced to a commercial basis, and not one rider in a hundred uses his wheel for pleasure.

Bicycling as a fad began to expire when it became commercialized, and all sorts of people took to wheeling. The future of the automobile industry, as we all agree, lies in the adaptation or development of cars to commercial uses—not accomplished yet because manufacturers so far have been unable to supply the demand for pleasure cars, and also doubtless because of the smaller margin of profit between a luxury and a strictly commercial proposition.

After the existing and projected automobile works are equipped, we shall have some let-up in the demand for machine tools for that purpose, but the skill of our mechanics probably will develop the automobile industry gradually and conservatively until it becomes as safe and permanent as any other.

SIGNS ON FACTORIES

There are many forms of advertising a manufacturing business, and not the least valuable is by means of harmonious signs on the buildings, especially when they are located within sight of a railroad. Some large and prosperous concerns neglect signs and consequently lose an opportunity of making their business known to the traveling public. An Industrial Department circular issued by the Erie R. R. places the subject in another light which is worth considering by the public-spirited manufacturer: "Signs make business. . . . Apart from all business interests, a sign on a factory is an ethical courtesy to the traveling public."

An ethical courtesy in this respect is equivalent to the answer to a stranger's civil inquiry on the street. The railway traveler is prompted to ask what the industry is that he sees housed in some fine large buildings, and the plant should answer his question with a sign. Not only is a sign an ethical courtesy, but it often is a great time-saver. A traveling man or a customer visits a place new to him, with but little time to spare between trains, and loses many valuable minutes in locating the concern he desires to visit, which might be saved if he saw its sign from the approaching train.

Manufacturing concerns should display their name and business, when practicable, prominently on their factory buildings for the reasons just given; and, finally, a plain but artistic sign is not only a good advertisement, but it gives an air of prosperity to a plant, especially if the buildings and grounds are well-kept.

THE VALUE OF THE TECHNICAL WRITER

If it were possible to follow in detail the evolution of our highly-developed mechanism and to trace to their origin the superior methods employed in the modern shop, the credit given to the technical writer, and his status in the industrial world would probably be much greater than is apparent on the surface. In the advancement which is constantly taking place throughout the entire realm of mechanics, there is reflected to a considerable extent the work of men who have given publicity, through the printed page, to valuable knowledge they have acquired in the school of experience. And while all that is published is not valuable, it should be remembered that a large part of the technical matter which appears in the columns of this and other publications, as well as that which is presented in book form, has a value often far in excess of its apparent merit. The description, for instance, of a certain method or mechanism may suggest an idea which results in the adaptation of the same principle in other ways for other purposes; and if it were possible to trace some of the most valuable pieces of mechanism or inventions back to their origin in many instances we should find that the technical writer was largely responsible for their development. If all technical literature were to be suddenly blotted out of existence and no more contributions were made to it, say, in a generation, the resulting retrogression would reveal, as nothing else could, the value of the technical writer. So the man who records the knowledge that he gathers through the years and transmits it by publication to thousands of readers should be treated as a member of that class to which is largely due the advancement of industrial knowledge.

HOPE AS A NATIONAL ASSET

It has been a matter of perennial comment that the American workman has characteristics which are all his own. He stands preeminent among all the great industrial peoples in alertness, originality, conscientiousness and ambition; and in consequence he leads the world in value of product per individual. This does not mean that he is molded of finer clay than his European brother, for every incoming ship-load of immigrants shows that the contrary is true. A few months in this country, or a few years at the most, often work wonders in the stolid, unimaginative foreigner; and the ability to thus inspire the stranger within our gates is due to our industrial development in the past, and the hope that it maintains for the future.

One basis of the efficiency of the American workman is *hope*, and that hope springs from the opportunity the individual is offered in this country. So long as he sees that faithfulness and intelligence command living wages—that exceptional ability is appropriately rewarded, and so long as he feels that no congenital social barriers exist between himself and his employer—so long is our industrial position secure.

There are, unfortunately, evidences of danger ahead in this direction. Successful employers have sometimes forgotten that they or their fathers were themselves workmen but a few years ago. The growth of monopoly and privilege has often robbed master and man alike of the just rewards of their labor; and sometimes this growth has borne its evil fruit of suspicion, recrimination and deadly warfare. Fortunately, these conditions are still sporadic. It is the duty and privilege of employer and employe alike to join hands in rooting them from the soil of our national life. It is, in fact, more than a duty and privilege—it is a necessity.

FORMULAS FOR COMBINED BENDING AND TORSION

Several formulas have been given by various authorities to be used for obtaining what is called the ideal moment of combined bending and twisting moments. Some of these formulas vary widely, and there does not appear to have been any sound practical basis for the adoption of many of them. Rankine gives a formula:

$$M_I = \frac{1}{2} M_B + \frac{1}{2} \sqrt{M_B^2 + M_T^2}$$

in which M_I = ideal or combined moment,
M_B = bending moment,
M_T = twisting moment.

St. Venant gives the following formula:

$$M_I = \frac{3}{8} M_B + \frac{5}{8} \sqrt{M_B^2 + M_T^2}$$

This formula is also given in a slightly modified form in Hütte's "Des Ingenieurs Taschenbuch." In 1900 Mr. J. J. Guest published the results of some experiments made by him, on the strength of which he gave the following formula as expressing the relation of combined twisting and bending:

$$M_I = \sqrt{M_B^2 + M_T^2}$$

It will be seen that this formula differs very considerably from that of Rankine and St. Venant, especially for increasing twisting moments. For bending moments alone, the three formulas give equal results, but as the twisting moment increases, the Rankine formula allows a steadily increasing twist to take place, so that at the point where the stress is entirely a twisting stress the permissible torque by the Rankine formula becomes twice as great as that obtained by the Guest formula. It seems evident that the Rankine formula gives too high values for very large twisting moments. The St. Venant formula is a mean between the Guest and the Rankine formulas.

Experiments have recently been carried out by Mr. C. A. M. Smith and also by Mr. W. Mason, reports of which have been read before the Institution of Mechanical Engineers, Great Britain. The experiments made by Mr. Smith confirm the soundness of the Guest formula so far as mild steel is concerned and this formula may, therefore, be assumed to agree with practical experience. Mr. Smith also undertook experiments on self-hardening steels and nickel steels, but these experiments were unsatisfactory and no definite conclusions could be drawn from them because the material gave exceedingly variable results. Specimens cut from the same bar, even, did not give the same results in two consecutive tests. The formula is applicable to machine steel, however, with which material the machine designer is almost exclusively concerned when questions of combined bending and twisting stresses demand his attention, and the fact that the other materials mentioned do not give uniform results when tested indicates that it is not possible to obtain a universal formula for them.

* * *

IMITATION OF MACHINE TOOLS

American machine tool builders frequently complain of the imitation of their machines by European manufacturers. In a few instances it appears that American machine tools have been copied outright, but in most cases the copying consists of using the principal ideas embodied in the American design, adapting them in minor details to European requirements, and introducing such improvements as appeal particularly to European users. It is evident, however, that even in such cases, where the imitation embodies certain changes and improvements, the American manufacturer who has spent a great deal of time and thought in developing the original design cannot look with equanimity upon the practice of the European builders who thus make use of his ideas; but whenever no patent rights are involved, it is not possible for the American manufacturer to interfere.

A most interesting point in this situation is that while American manufacturers often complain about their machines being copied by European manufacturers, there is but comparatively little complaint against exactly the same practice in this country, although the cases in which American manufacturers copy the designs of their competitors are far more numerous than those in which European manufacturers are the imitators. A study of representative machine tools will show that of each class there are but a few original types differing radically from other machines of their kind, these types having been developed by a dozen or so progressive American machine tool builders. Improvements on such machines have been then introduced by various other manufacturers in adapting them to special conditions, exactly as has been done in many cases by the European manufacturers who are stigmatized as imitators.

While we are not undertaking a defense of imitators, the practice of incorporating the principal points of advantage in another design and adding to them a manufacturer's individual ideas, does not necessarily deserve unqualified condemnation, for without this custom the progress of civilization would have been impeded. The whole progress of the world is based upon the imitation and adaptation of the best in previous developments, and in adding to it new features of increased utility. In the manufacture of machines, this feature has been highly important in the evolution of the art of machine construction, and it is necessary to consider these points, not from the narrow standpoint of the individual, but from the larger one of general progress.

If we prefer, however, to look upon this question from a more limited point of view, we must still recognize that the superiority of one machine over another does not lie solely in the embodied features of design; it depends also largely upon the workmanship, material and processes of manufacture. The machine builder who can make the best machine at the lowest price, due to superior organization and management, will always take the lead of his competitors, no matter if they do imitate his designs. The fact that his machines are being imitated is one of the surest indications of his success. Fear of imitation is often an indication that there are defects in the organization and management which would make successful competition possible unless a trade secret, patent, or other partial monopoly were involved. The man who can afford to let others imitate him has built his organization on the firmest foundation. He may regret to see competitors take advantage of his inventive ability, but their competition will only prompt him to still greater effort—to prove that he has not yet reached his limitations.

LAYING-OUT AND ALIGNING OPERATIONS ON MACHINE TOOLS—2

By ALFRED SPANGENBERG*

In the previous installment of this article a number of special tools and devices used in the laying out and aligning of work were illustrated and described. The use of templets and gages in this class of work was indicated by several examples. In the present installment operations of this kind performed without special tools will be dealt with.

Laying-out and Aligning Operations without the Use of Special Tools and Appliances

In the absence of special tools and appliances for laying-out and aligning operations, the principal points to be observed are the selection of a proper starting point from which to lay out all dimensions, the employment of efficient means to compensate for the deflection in horizontal aligning arbors when the bracket seats lie in a vertical plane, *i. e.*, when it is impracticable to place the bed of a machine in such a position that the bracket seats will lie in a horizonal plane and thus carry the bracket members unsupported; and the avoidance of assembling all the correlated members together for the laying-out operations.

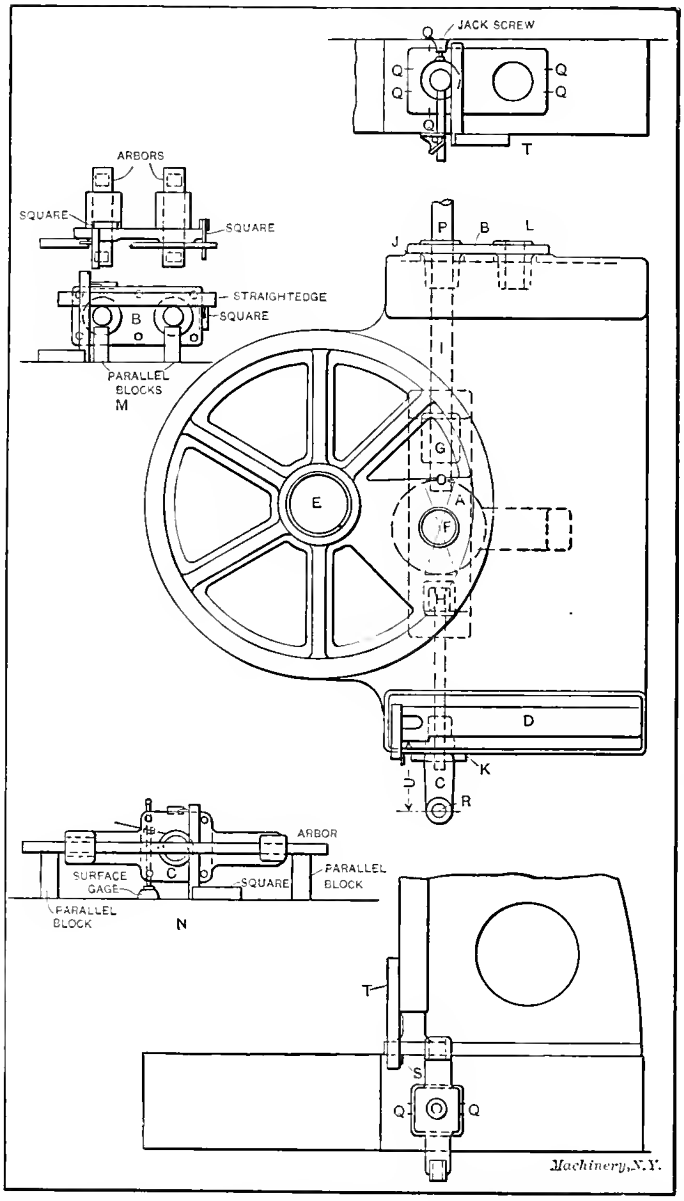

Fig. 8. Laying-out and Aligning Operations on a Vertical Boring Mill of the Spur Gear Driven Type. By the Methods shown, no Special Gages or Tools are required

The first two points brought out above are exemplified in the aligning operations on a vertical boring mill of the spur pinion driven type, which is illustrated in Fig. 8. The operations involved are the alignment of the driving pinion bracket *A*, the driving shaft bracket *B*, the feed shaft bracket *C*, and the housings; only one housing *D* is shown. The hubs on the brackets have clearance in cored holes in the bed. It is the general practice to bore out the table spindle hole *E*, and table gear pinion hole *F*, by means of a boring jig, previous to aligning the brackets; hole *F* in the bed is then used as a starting point for the aligning operations.

For convenience in setting bracket *A*, which forms the lower bearing for the table driving pinion, and also carries inner bearings *G* and *H* for the driving and feed shafts, the bed casting is turned bottom side up, the process being as follows: The table pinion is placed in position in its hole *F* for the purpose of centering the bracket; next the driving shaft *I* is put in place in its bearing *G*, and then the bracket is squared with seat *J* by means of a square held against the seat and the shaft. This setting is for marking off the bolt holes in the bed, and after the drilling and tapping is accomplished, the bracket is reset in the same manner as before and clamped by its bolts; then the dowel pin holes are drilled, reamed, and the pins fitted.

The next logical step is to turn the bed right side up and place reference lines on seats *J* and *K* respectively. A separate operation involves placing reference lines on the bracket members *B* and *C*. The reference lines represent, on each separate member, the outside diameter of the shaft used in aligning; then, in assembling the bracket members on the bed for the aligning operations, it is simply necessary to match the lines on the brackets with those corresponding on the bed. During this operation the brackets are supported on screw-jacks. This method of setting brackets illustrates the second point stated above, the employment of efficient means to compensate for the deflection in aligning arbors when the bracket seats lie in a vertical plane; another point of advantage, however, is that this method insures proper alignment of the shafts, any inaccuracy in the machining of the seats being immediately apparent when the members are assembled. For instance, another method of setting the driving shaft bracket would simply be to place the bracket in position on its shaft, support it on screw-jacks, and then shift the bracket around until a feeler indicated that all sides of the bracket were tight against its seat on the bed, attention being paid, of course, to the location of back-gear hole *L* with reference to the top of the bed. With this method it would be possible to have all sides of the bracket tight against the bed as just explained, but in the event of the bracket seat not being perfectly square with the hole, the shaft would be thrown out of proper alignment with reference to the planing on the bed and also to hole *G*.

Turning back now to the question of reference lines, the method of placing these lines on the driving shaft bracket is clearly illustrated at *M* in Fig. 8, while at *N* is shown the same operation on the feed shaft bracket; both cases are essentially the same. To place lines on the bed seat *J*, a surface gage is first set to the driving shaft at *O*; next the gage is moved to position *P* and the shaft jacked up until the surface gage indicates parallelism with the top of the bed; and then, after testing the shaft with a square on seat *J* to insure that the screw-jack is not holding the shaft out of alignment sideways, a combination square and an ordinary square are used as shown at *T*. Similar operations are involved on seat *K*. Permanence is given all reference lines by driving a thin chisel into the casting directly on the line. These lines are indicated in the engraving by the letter *Q*.

The housings are located on the bed with reference to hole *R* for the vertical feed shaft. Previous to placing the housings on the bed, however, lines are drawn at *S* on each housing and on the bed casting, which lines are in the same plane as the front face of the housings. This is accomplished in the former case by means of a straight-edge *T*, and in the latter case by laying off on the bed the correct distance from the center line of brackets *A* and *C*. In placing the housings on the bed the corresponding lines on each member are matched, and then the housings are moved so that measurement *U* is correct; this measurement is taken with a straight-edge and combination square. The housings are set for the pinning operations in the same manner. It may be of interest to state that the housings are first set on a large surface plate for the purpose

* Address: 951 W. 5th St., Plainfield, N. J.

of bolting on the arch casting and fitting the top-works, thus enabling the accomplishment of several operations simultaneously, as the cross-rail gibs also can be laid out at this time.

By observing the third principle laid down above, the avoidance of assembling all the correlated members for the laying-out operations, it is often possible to advance work that otherwise could not be accomplished. This point is illustrated in Fig. 9, which shows an oil pumping arrangement attached to an engine lathe carriage and driven by a shaft carried in bearings on the back of the bed. This outfit is special in its nature and is furnished as an attachment; considering this fact it will be apparent that the bed member is likely to reach the assemblers last, and therefore the work can be greatly advanced by laying out and fitting up the carriage members independently of the bed.

After bolting the oil tank *A* to carriage *B*, its bolts fitting T-slots in the carriage, the oil tank is set and then dowel-pinned, the operations being so simple as to need no explanation. As bracket *C* is already bored out on a boring mill, the first laying-out operation involves the location of stud hole *D* in the oil tank. Since this hole must be laid out with reference to surfaces *E* and *F* on the bed (surface *G* on the carriage is merely planed for clearance) very effective use can be made of a jig consisting of a short bed section; but if this is not available, a gage block *H* similar to that used in planing the carriage, can be substituted. A graduated try square is used first on surface *E* and then on surface *F*; the measurements are read directly from the graduations. Next, the hole is drilled and tapped using a pneumatic drill, and then bracket *C* is clamped in place by the intermediate gear *I*.

The next operation involves the alignment of hole *J* with reference to surface *E*, the object being to provide standardization for the planing of shaft bearing *K* and its seat on the bed. This is accomplished by swiveling bracket *C* around, using stud *I* as a pivot, until a combination square and scale indicate that the measurement is correct. The slide of the combination square rests against surface *E*, while its base is held in contact with surface *F*; the scale is then used to measure from the combination square slide to the center in the hole. After the bolt holes *L* and *M* are located, drilled and tapped, bolts are entered and the bracket is reset for pinning; the clearance in the bolt holes permits of adjustment.

To set the oil pump *N* it is merely necessary to bring gears *O* and *P* into proper mesh. The driving shaft brackets on the bed, one of which is shown at *K*, are located as follows: A short arbor representing the driving shaft is inserted in the bearing hole, and then the measurement is taken from surface *F* on the bed. These brackets are located and drilled on the bed while it is under a radial drill for other drilling operations, and the bed is turned over on its side at this time for convenience. The dowel pin holes in the driving shaft brackets are not drilled until all the parts are assembled on the bed; then the final alignment is accomplished by moving the carriage close to each bracket alternately and slackening off the bolts, thus allowing the adjacent bracket to be self-aligned, after which the bolts are tightened for the pinning operations.

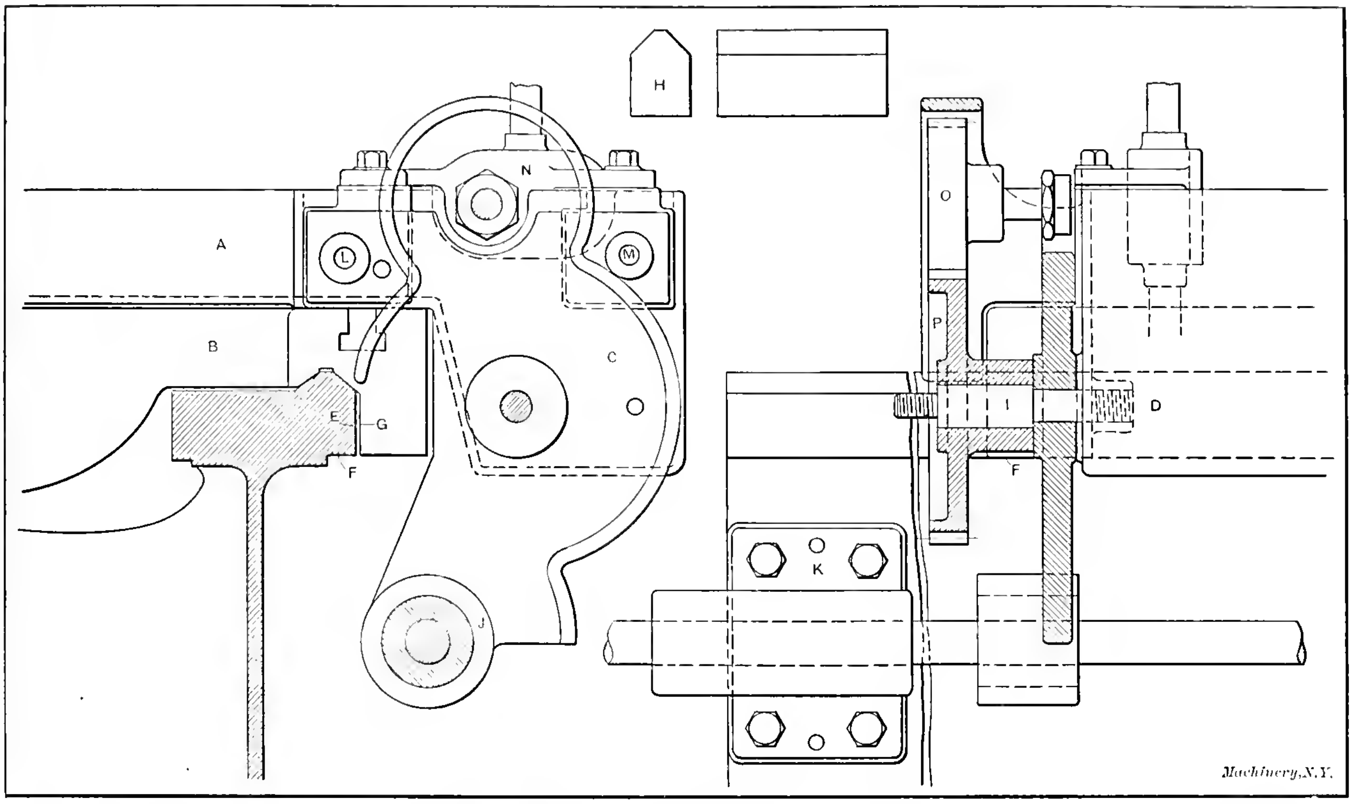

Fig. 9. Method of Laying Out and Aligning an Oil Pump Attachment on an Engine Lathe. Illustrating the Principle of Avoidance of Assembling all the Members together for the Laying out Operations

Laying Out Angles

In machine tool work it frequently becomes necessary to lay out angles, and as a general rule it may be stated that a much greater degree of accuracy can be obtained by the following methods than is possible by laying off angles with the ordinary bevel protractor made for machine shop work. The correctness with which an angle can thus be produced, however, naturally depends on the skill of the workman in working to the scribed lines and on the accuracy with which

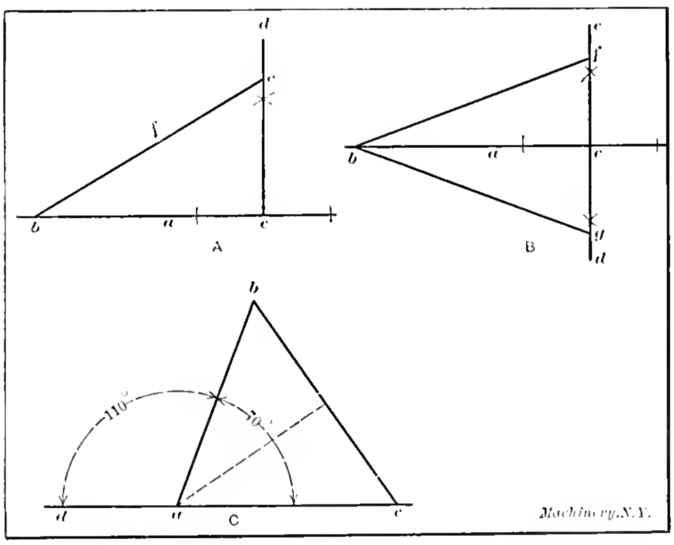

Fig. 10. Graphical Method of Laying Out Angles

they have been located. If it is not convenient to lay off the lines directly on the work, the given angle or taper may be laid off on a piece of sheet steel, which is then carefully filed to the lines scribed thereon.

Scribe a straight line *a*, as at *A* in Fig. 10; then make two very fine center punch marks, as *b* and *c*, on this line, as far apart as circumstances will permit. At *c* erect a perpendicular, as *cd*. The distance *bc* being laid off to some convenient dimension, take the tangent of the required angle and multiply the distance *bc* by this tangent, using a table of natural tangents. Then, on *cd* lay off as accurately as possible the product of *bc* and the tangent, marking it by a fine center punch mark as at *e* on the line *cd*. Scribe a line through *b* and *e*; the angle *ebc* will then be the required angle.

When the required angle is greater than 45 degrees, it is more convenient to use the method shown at *B*. Scribe the line *a* and on it lay off *bc* as long as convenient. At *c* erect the perpendicular line *de*. From a table of natural tangents, take the tangent corresponding to one-half the required angle; multiply the distance *bc* by this tangent and lay off the distance thus found on both sides of *c*, marking it at *f* and *g*. Join *f* and *g* to *b* by straight lines. The angle *fbg* is the required angle.

When the required angle is greater than 90 degrees, instead of laying off that angle, its supplement is laid off. Subtract the required angle from 180 degrees and lay off the angle thus formed. Thus, if the required angle is 110 degrees, lay off the angle *bac*, as at *C*, Fig. 10, equal to 180 degrees — 110 degrees = 70 degrees by the method illustrated at *B*. The angle *dab* is then 110 degrees. All other factors remaining as before, the accuracy attainable will be greater as the base line, as *bc*, at *A* and *B*, or *ac*, at *C*, is made longer.

The laying-out and aligning operations on machine tools require, as we have seen, a thorough understanding of the purpose of the various parts making up the machine, and the accuracy required in their alignment. Besides this, a general knowledge of elementary geometry is not only helpful but in many cases almost indispensable. The examples of aligning operations given in the present articles are, of course, intended to be primarily of suggestive value. Individual judgment will have to be used in each particular case, and definite rules cannot be laid down that would be applicable under all conditions. The general outlines presented above, however, and the simple methods given for the laying out of angles will be found useful in operations of this kind not only on machine tools but on all classes of machinery where the accuracy of the alignment of interdependent parts is necessary for the successful working of the machines.

* * *

At the meeting of the New York Electrical Society at the Engineering Societies Building, 29 West 39th Street, January 27, Prof. W. S. Franklin of Lehigh University lectured on "The Practical Applications of the Gyrostat." The lecture was made exceptionally clear by means of lantern slides and was illustrated by experiments. A working model of the Brennan monorail car was also exhibited in action. The points discussed by Prof. Franklin were, in particular, the physical action of the gyroscope exemplified by illustrations of the gyrostatic action of the fly-wheel of automobiles; gyrostatic action on board ship, and the Schlick device for preventing the rolling of ships at sea; and, finally, the application of the gyroscope to the Brennan monorail car. Prof. Franklin explained in a very clear and concise manner the principle of the gyrostat and showed how by simple means the action may be exhibited; for example, by simply rotating at a reasonably high speed a bicycle wheel having its rubber tire replaced by a lead rim and suitably mounted in a frame on a platform, it is possible for a person sitting on the platform to balance himself on but two supports or legs.

After the lecture a description of the Scherl gyroscope monorail car was read and also a communication from Mr. Frank J. Sprague relating to his own early ideas for the utilization of gyroscopic action. The general discussion was then opened by Mr. E. A. Sperry, who explained, in particular, the design and action of gyroscopic devices installed on board ship for preventing rolling.

ELECTRIC WELDING OF COPPER, BRASS AND ALUMINUM*

By A. E. BUCHENBERG†

The welding of brass, bronze and other alloys of copper is almost impossible as a forging operation. The fusing points of the several alloy metals are considerably below that of copper, and it becomes a very difficult matter to prevent the oxidization of these metals before the copper component has reached a welding temperature. While it is possible to weld copper and aluminum in the same manner as iron or steel by the forging method, the work is more or less difficult and requires a careful and skilled operator. Some of the difficulties are as follows: The welding temperature of copper is much higher than that of iron or steel; while the metal is at or near the welding heat and exposed to the air, a very rapid surface oxidization takes place, and the oxide or scale formed is extremely difficult to treat with any flux. The range of temperature between the heated plastic or welding condition and the fusing point of the material is very small. To add to the difficulties the metal becomes brittle as the temperature approaches the welding heat.

While aluminum reaches a welding heat at a temperature considerably below that of copper, it is also subject to a serious surface oxidization when exposed to the air at high temperatures. The range of temperature between the welding and fusing points of aluminum is only about 180 degrees F. If overheated it will simply spatter away under the hammer when attempt to make a weld is made.

The fundamental principle in the electric welding of metals is the same as in the forging operation, *viz.*, forcing the two welding surfaces into intimate contact while each is in a heated plastic condition. With the electric method the surfaces to be welded are butted together endwise instead of being "scarfed" and lapped. The repeated blows of a hammer are replaced by a mechanical pressure exerted in a direction forcing together the abutting ends of the work. The welding temperature is created by the heating effect of a current of large volume flowing through an electrical circuit in which nearly all the resistance is located at a single point. The abutting ends of the stock to be welded form this point of highest resistance in the electrical circuit of the welding machine, and practically all the heating effect is concentrated at this one point. A very rapid rise in temperature takes place until a welding heat has been reached. The electric current is simply the heating medium, and in itself has no effect upon the physical or chemical properties of the metal. The actual welding is due to the mechanical end pressure exerted while the material is in a plastic condition.

The electric butt-welding of wires, bars, rods, rings, etc., of the metals mentioned above requires a machine into which are incorporated the following essential parts in their proper relation to each other: 1. An alternating current transformer whose primary coils are made up of a large number of turns of insulated copper wire. The number of turns will depend upon the voltage of the supply circuit and the transformer secondary voltage required to make the weld. The size of the conductor will depend upon the kilowatt transformer capacity required to weld the largest stock the machine is designed to handle. The secondary winding of the transformer, on account of the very low voltage required, reduces to the equivalent of a single turn. This may be either in the form of a solid cast copper bar or a laminated copper structure whose cross-section is very large as compared to that of the primary conductors. The secondary voltage of the transformer will depend upon the cross-section and electrical conductivity of the stock at the point of the weld and varies from 1½ to 5 volts. The volume of current flowing in the primary and secondary conductors of the transformer will, of course, be in inverse ratio to the primary and secondary voltages. As an example, assume current at 220 volts primary voltage and that the current flowing in the primary coils of

* For additional information on the subject of electric welding, see the following articles previously published in MACHINERY: Some examples of Electric Welding, April, 1908; Electric Welding of Dissimilar Metals, July, 1908; Electric Welding of Tools, October, 1908; Electrical Welding, February, 1909.

† Electrical and Mechanical Engineer, The Toledo Electric Welder Co., Cincinnati, Ohio.

the transformer is 45.5 amperes. Assuming the secondary or welding voltage to be 2½, the secondary current will be (220 ÷ 2.5) × 45.5 amperes = 4,000 amperes, about.

2. A pair of copper dies or work holders in each of which is securely clamped one of the two pieces to be welded together. These dies serve to convey the secondary or heating current of the transformer through the stock to the point of weld, and are attached to the secondary terminals of the transformer in such a manner as to allow a small movement of the dies toward and away from each other. In practice one of the dies is fixed and the other movable.

3. A break-switch or circuit breaker mounted on the machine in a convenient operating position and so arranged as to be automatically opened and the primary current of the transformer broken at a certain predetermined point in the converging movement of the dies.

4. Arrangement for obtaining pressure. The pressure required to compress the stock while at the proper temperature and plasticity to make a weld is obtained by means of a compression lever, and a weight or springs acting upon the dies to force together the abutting ends of the pieces to be welded. This pressure follows up the compression of the stock to a point where it is no longer sufficient to displace the cooler metal, and the weld is made. The surplus heated metal is forced outward all around the stock in the form of a thin upset or fin which can, when necessary, be easily removed by grinding. The pressure required varies with the material and size of stock to be welded and must be adjusted to a point where compression takes place the instant the stock has reached the proper welding temperature. This adjustment, when once made, remains the same for all welds of the same material and cross-sectional area.

The time required to electrically weld copper, aluminum and copper alloys depends to a very great extent upon the cross-section of the stock, and varies from one second or less on very small stock to a minute or more on the larger sizes. The time limits between which stock of any given cross-section can be successfully welded are comparatively wide and governed in both directions by the volume of the heating current through the point of weld. If the current is low, the temperature rises more slowly at the point of the weld, and the heat travels back a considerable distance on each piece by conduction before the surfaces to be welded reach the required temperature. Under these conditions the fin or upset becomes quite large and entails too much expense in grinding to remove it. In the extreme case of insufficient current the heat is carried away from the point of the weld by conduction to the copper dies and by direct radiation to the air so rapidly that a welding temperature cannot be attained. If the volume of current is too great a very rapid heating of the stock takes place and trouble is experienced due to the fusing and oxidization at the point of weld which occurs more rapidly than the pressure can follow up the softening of the metal, and the excessively heated stock "spatters." Although the heating current is automatically cut off at the instant the forward motion of the die begins, the oxide coating on the end surfaces prevents a molecular union and a perfect weld. In other words, the stock is burned.

The heating current must be adjusted between the two extremes given above to a point where it is intense enough to bring the stock to a welding temperature, yet not so great as to cause an excessive heating and a "blowing out" of the weld. The correct adjustment is not a difficult matter, and is attained by varying the voltage impressed upon the primary coils of the transformer in one of two ways.

If the electric welder is operated by an alternator carrying this machine only, the voltage of the alternator (which in this case is the same as the primary voltage of the transformer) can be varied by a manipulation of the alternator rheostats.

When the electric welder is being operated from a circuit whose voltage must be maintained at a constant value, such as a power circuit from which other welders or motors are being operated, an inductive regulator is used as an auxiliary apparatus to the welding machine. The action of such a regulator is simply that of a variable choke coil, and any desired voltage can be obtained across the primary terminals of each welding transformer by a proper adjustment of the regulator.

A skilled or experienced man is not required for operating an electric welding machine as the only duties of the operator consist in clamping the work in the dies of the machine and closing the switch. For this reason it is customary to use boys on this work. Many machines for light work are now made automatic in their operation, requiring no attention beyond feeding in the stock to be welded.

Uniform and perfect molecular union is obtained with this process, since the heating of the stock is from within outward and the entire areas of the welding surfaces are at the same temperature. The strength of the weld is practically equivalent to the strength of any other section of the stock of equal area and will withstand any subsequent bending, rolling, hammering, or drawing process to which it may be subjected.

The difficulties encountered in the forging process due to the oxide surface films formed at high temperatures are not present in the electric process. During the extremely short heating period the welding surfaces are in contact and practically excluded from the air. Furthermore, the heating action ceases the instant the welding temperature has been reached, and the heat extends to but a very small distance on each side of the weld. It is obvious that with a continuously applied pressure which instantly compresses the stock to form a weld when the proper temperature has been reached, the difficulty experienced in other processes due to the small range of temperature from the plastic to the fused state of the metals is overcome.

The electric welding of copper, brass and aluminum is a very rapid operation and entirely free from noise, dirt and smoke. The machine can be located in any convenient position in the shop and is free from danger of electrical shocks to the operator. The motion of the movable die can be adjusted for both the forward and backward travel so that all welds are to gage. This is an important consideration when, for example, many thousands of rings must each be welded to an exact diameter.

The cost of electric welding is low as compared to other methods. Below is given a table for copper showing the kilowatts and time required to make a weld from the time of closing the switch. Also the cost per 1,000 welds at a unit basis of current cost of one cent per kilowatt-hour. To arrive at the actual cost of the current per 1,000 welds it is only necessary to multiply the cost given in the table by the price for current per kilowatt-hour in any given locality.

TIME, CURRENT CONSUMPTION AND UNIT PRICE FOR ELECTRIC WELDING OF COPPER

Area in sq. inch	Approx. Equiv. diameter, inch	Kilowatts	Time in Seconds to make Weld	Cost per 1000 Welds at 1 cent per K. W. hour Dollars

It has been found during the Zeppelin aerial tours that it is difficult for the crew to determine the exact location when sailing over the earth in a dirigible balloon. It has, therefore, been proposed to place wireless signal stations in a number of leading cities and towns from which signals can be sent which would keep the aerial navigators constantly informed of their location. The sphere of influence of each station would be small enough so as not to interfere with that of the next. In this way it would be possible to always determine within certain limits the location of the airship. It is likely, however, that except for military purposes, such expensive arrangements to aid aerial navigators will not be necessary for some years to come. Should, however, some day aerial navigation become commercially possible, it is likely that wireless stations will act as the "light houses" of the aerial sailor.

CASTING PIPE FITTINGS IN PERMANENT MOLDS

In the September, 1908, issue of MACHINERY, engineering edition, an article was published on "Casting Pipes in Permanent Molds," which described the methods in use at the Tacony Iron Co., Philadelphia, Pa. The molds used for the casting of pipes were made of cast iron, but the cores used were of the regular type, made of sand. Improvements have now been made with this process. The casting of fittings in permanent molds was experimented with, after success had followed the use of these molds in casting pipes, but sand cores were found

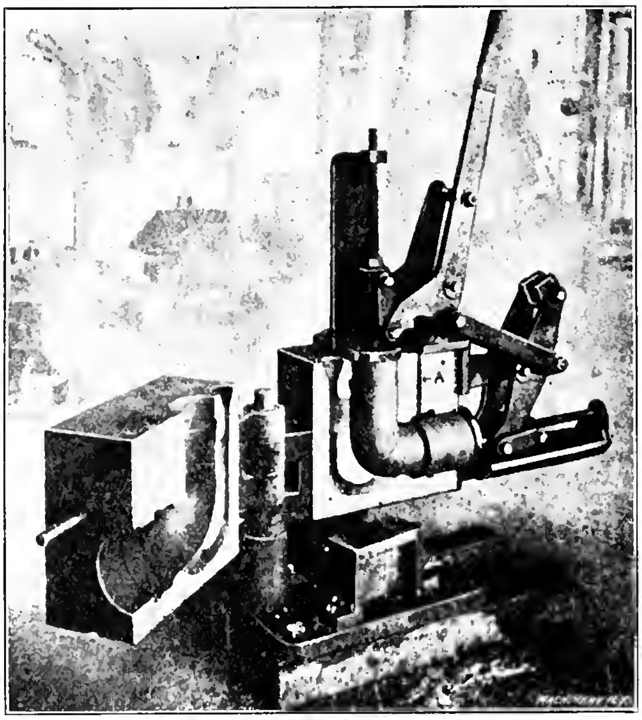

Fig. 1. Permanent Mold for 5-inch Quarter Bend showing the Cores in Position for Casting

impossible to use successfully, owing to their irregularity of form, and it was practically decided to discontinue further experiments along this line when, as a last resort, cast iron cores were suggested and tried. These experiments proved successful from the start.

This departure upsets one of the fundamental traditions in the art of founding, and may prove to have tremendous possibilities. In an article in a recent issue of *The Foundry*, the

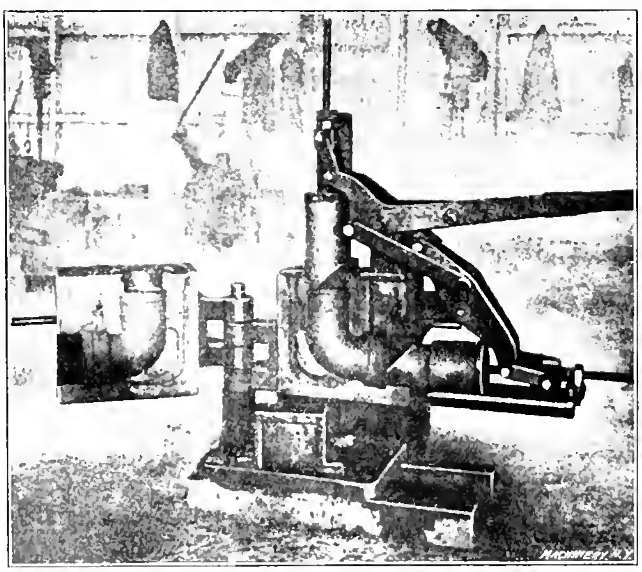

Fig. 2. Casting poured, Cores withdrawn and Mold opened, showing the Pipe Fitting

methods used are described in detail and the accompanying illustrations are reproduced from that description. It is stated that the castings made vary from 4 to 28 pounds in weight, and the average labor cost is approximately 2 cents per casting, as compared with an average molding cost of 6 cents when the fitting is cast in sand. In addition to the saving in labor cost the expense of sand and flasks is entirely eliminated, and while against this must be charged the cost of molds and the machines, this cost amounts to only a fraction of a cent per casting.

On an average each mold has an output of 1,000 pounds of castings daily. The output per day of small fittings is greater in number than that of the heavier fittings, because they can be cast more rapidly, as they do not heat the molds so quickly. If the molds are raised to a red heat they deteriorate more rapidly than when the temperature is not high enough to color them. The success of casting in permanent molds depends on a swift chilling of the molten iron to the point at which it is set, at which time it must be immediately removed from the chilling effect and permitted to cool normally. If the cast-iron cores are not removed immediately after the iron is set, the shrinkage of the iron holds the cores so that they cannot be withdrawn. However, even in such a case the mold can be opened and the casting broken with a hammer to release the cores, and the only loss incurred is the labor required in producing the casting, because the mold and core remain uninjured.

The permanent molds in the machines used for different classes of fittings and other castings are all similar in that half of the mold is fixed while the other half swings on a hinge. A machine for molding five-inch quarter bends is shown in Fig. 1. This illustration shows the mold open with the cores in position for casting. As soon as the two halves are closed up the metal may be poured. At *A* in the illustration is shown a vent which is provided to permit the air

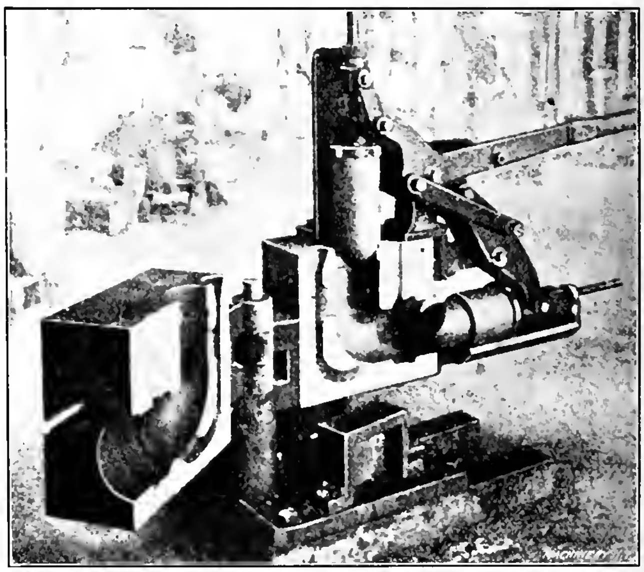

Fig. 3. Casting Removed from Mold; Cores not yet in Position for Next Casting

in the mold to escape. The cores are also drilled to permit the passage of air into the mold when the cores are removed.

In Fig. 2 the casting has just been poured and the two halves of the core have been withdrawn by depressing the operating lever. Immediately after the withdrawal of the cores the movable half of the permanent mold is swung out as shown in the illustration, permitting the removal of the casting. In Fig. 3 the casting has been removed, but the cores have not been replaced in position for casting. When this is done the appearance is as shown in Fig. 1, and the cycle of operations is repeated.

No especial care need be exercised to prevent the castings from sticking in the molds, but the mold, as well as the cores, is occasionally coated with a mixture of thin oil and graphite. The molds and the cores are cast from ordinary gray iron, such as is used for the soil pipe and fittings made, and in one mold more than 6,000 pieces have been cast without there being any signs of deterioration. Very small castings can be produced very rapidly. Plow points, for example, can be cast at the rate of four per minute, while larger fittings cannot be cast faster than one every two minutes, and in the case of pipe, it was found that but one casting could be made every eight minutes. Outside of cast-iron fittings, molds have been designed for brake shoes, sash weights and various kinds of hardware.

THE OPERATION AND CARE OF SMALL ELECTRICAL MACHINERY*

By HENRY B. BIXLER†

As the majority of users of small electrical machinery are not familiar with tho best methods employed to keep the machines in good running order and repair, tho author aims to give in this article a few practical suggestions, to be of some help in the making of necessary repairs, locating troubles, and removing the causes.

The dynamo or motor should be installed in a dry place, and under no circumstances should water be allowed to come in contact with the machine. Excessive dampness always causes trouble, and this point should be guarded against. The machine should be well ventilated, and kept free from dust as much as possible. Before starting a new machine, see that the bearings are well filled with good oil, and that the shaft turns freely in the bearings. The oil-rings should turn with the shaft, and not stick, as the lubrication of the bearings depends upon the rings working right. This is important and should be carefully watched. If the machine is belt driven, the belt should not be too tight, as this will cause undue wear on the bearing and may cause heating also. Always provide solid foundations or supports for the machine to rest on. Keep the machine cool, dry and clean, and very little trouble will result in its operation in general.

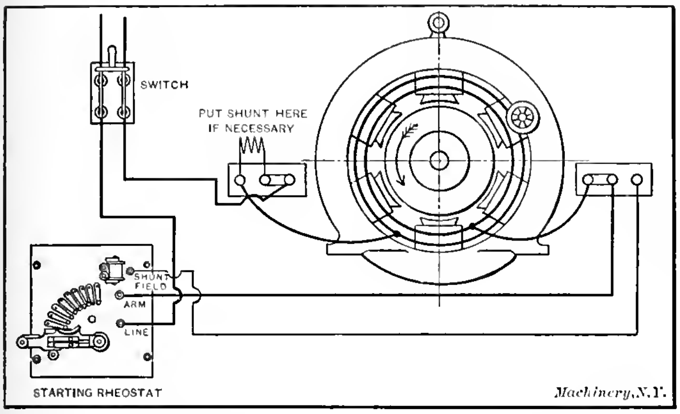

Fig. 1. Diagram showing Reduction of Over-load by means of a Shunt

When a new machine is installed and wired up, the connections should be carefully checked over, to see whether they correspond with the diagram of connections sent with the machine.‡ If this is found to be correct, and the machine refuses to act properly, the cause of the trouble should at once be located and the difficulty removed before going further.

Troubles in the Field Coils

First we will consider the troubles that may exist in the field coils, and how to proceed to correct them. If, on running a machine for some time, the field coils all become hot, the voltage may be too high and should be reduced to normal. If only a part of the coils become hot, it will usually be found that a connection exists between the coils and the frame of the machine (called "ground"), which when found should be insulated with mica or paper. Sometimes it will be found that some of the coils are cold while the remainder are excessively hot, and the cause of this is a short-circuit in the cold coils, which means that the current is not passing through the coils. Test out the coils separately with a magneto or battery, and when the defective coil is found, it should be repaired by re-insulating it.

A partial short-circuit will cause the coils to heat, and should be treated as stated above. In a compound-wound machine, *i. e.*, one having a shunt and series winding on the field coils, an over-load will cause an excessive current to flow through the series coils, causing the heat to rise above normal. The load should be reduced or a "shunt" should be connected as shown in Fig. 1. This will cause the current to divide, part of it flowing through the shunt, thereby reducing the heating of the series coils.

If a machine is run as a generator and will not generate the rated voltage, that is, if it shows too low voltage, or if the speed is too high when run as a motor, the cause may be a loose field connection, which should be carefully traced and tightened. Any extra resistance in the field will cause a motor to speed up, and the rheostat, in case one is installed, should be cut out of the circuit. The same trouble will arise from a short-circuit in one or more coils, or having the polarity reversed in one or more coils. Test this with a compass, or reverse the leads of one coil. If a generator will not hold up the normal voltage when loaded, or if the speed of a motor is too high when running under full load, the series field is either cut out of circuit or is reversed and is opposing the shunt. Disconnect the shunt coils entirely and try the machine without them. If the operation is now satisfactory, reverse the leads of the shunt field, and again connect them. If the motor refuses to start, there is no current through the shunt field, and the open-circuit should be found and repaired.

In case the motor takes an excessive starting current, the series field is opposing the shunt, and one of them should be reversed. If the motor runs the wrong way, reverse the series field or reverse the shunt field, or, in a compound-wound machine, both the series and shunt field. Never open the field circuit when the motor is running, as this would cause the machine to speed up to such an extent that the armature is liable to burst from centrifugal force. The above covers nearly everything that is due to field trouble.

Armature Troubles

When an open circuit occurs in a coil, it is shown by the broken leads, or by sparking at one or more bars of the commutator. The leads should be re-soldered into the commutator bars, or the broken wires spliced, or a new coil put in. Hot coils are caused by short-circuits at the commutator or between the separate turns of the coil, in case the winding is made up of more than one turn of wire for each coil, or from the grounding of the coil to the shaft or armature core. The leads should be separated and insulated from each other, and if this cannot be done, a new coil should be put in. Sometimes there is a short-circuit between the bars through the mica segment, or on the mica ring itself, and if this is the case, a new segment or ring should be put in, and the commutator turned off smooth in a lathe.

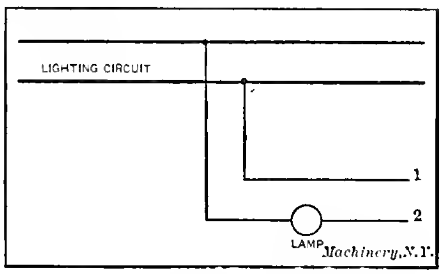

Fig. 2. Diagram of Wiring for Testing Armature Coils

When it is found that the whole armature heats up, the cause may be that the machine is pulling a greater load than it was originally designed for, in which case the load should be reduced, or else the machine exchanged for a larger one. If a machine is run at a lower rate of speed than that at which it is intended to operate, the armature often becomes quite hot, due to excessive iron losses, which will practically disappear when the speed is brought up to normal. The entire armature is sometimes heated by "cross-currents" which are set up in the windings due to the fact that the brushes are not set or spaced properly on the commutator. The only way to be sure that the brushes are spaced correctly is to count the commutator bars between each brush or set of brushes; this should be done as follows: Take for instance a commutator having 120 bars, and four sets of brushes. Set the first brush on any segment, and count thirty bars ahead of the bar on which the first brush is set, placing the next brush on this bar, and continuing thus around until all four brushes are placed in position. This will space the brushes equally apart, and when they are set properly, they can easily be kept in this position by making a gage of soft wire, just the length of the space between them.

* The following articles dealing with the care and repair of electrical machinery have previously been published in MACHINERY: Electric Repairing, December, 1904, January, 1905, and February, 1905; Winding of Direct Current Armatures, March, 1906; Tests for Faults in Armatures, May, 1906; Dynamo and Motor Troubles, September, 1906. † Address: Hower Building, Akron, Ohio.

‡ Wiring diagrams for motors of various types, will be found in the Data Sheet Supplement accompanying this issue.

To fit the brushes properly to the commutator, set them in position as nearly as possible, and place a strip of coarse sand-paper around the commutator (sand side up) and turn the armature around slowly; finish with fine sand-paper, preferably No. 00. This, of course, refers to carbon brushes only, as hardly any other kinds are now used. After the brushes have been "sanded down," the spacing should be tested again, and the brushes re-sanded if necessary. Radial type brushes should present the entire end to the commutator, and should be thus fitted. After fitting the brushes, the carbon dust should be carefully blown off the machine before starting it up. Shift the brushes to the best running position, *i. e.*, where no sparking occurs at full load, and clamp the brush holder yoke in this position, marking it in some way so that it can be set again in this position if it becomes necessary at any time to move it. Sometimes the armature becomes hot from the heat given off from a hot bearing or commutator, and as this is a purely mechanical fault, it will not be discussed here.

Heating in many cases is caused by poor ventilation, and if this is found to be the trouble, the obstruction which prevents a free circulation of air around the machine should be removed, or if this cannot be done, a small fan can be used to give artificial ventilation to the machine.

Burned-out armatures owe their destruction to one or more of the following troubles: over-load, grounded line, grounded coils, short-circuit, either on the line or in the machine itself, cross-currents in the armature as mentioned above, or from lightning discharges coming in contact with the lines leading to or from the machine, or striking the machine directly, which however is a rare thing. The only remedy for a burned-out armature is to rewind it, or to replace the defective coils.

When a break-down of insulation occurs, a "ground" is the result, owing to the fact that a part or all of the current does not complete its circuit through the coil, but passes through the armature core and frame of the machine to the earth. If the bad place in the insulation cannot be found any other way, the leads should be removed from the commutator and tested out separately. If a lighting circuit is available, an effective test can be arranged as follows: Connect up a lamp as shown in Fig. 2 and place lead No. 1 on the shaft or other bright part of the machine; then touch lead No. 2 on each coil separately. If a coil is grounded, the lamp will light up, but will remain dark on the good coils. A bell and battery may be used with the same results, the bell ringing on the defective coils only. The grounded coils should be carefully insulated with mica or good tape, and the leads soldered into position.

Bearings are sometimes allowed to wear so much that the armature rubs on the lower pole-pieces, wearing the banding wires to such an extent that they break. The bearings should be renewed, and the armature re-banded, and centered up with the pole bore. Be sure there is plenty of good insulation under the band wires, and if this insulation comes out, as is often the case in old machines, it should be renewed, and new banding wires put on the armature.

Commutator Troubles

Excessive sparking at the brushes is one of the troubles most frequently met with, and one or more of the following reasons may be assigned to its cause. In nearly every case this trouble is caused by the brushes being out of position, and care should be taken to see that they are properly spaced as mentioned above. If, after the brushes are properly spaced, sparking still occurs, look for high bars in the commutator, for if one or more of the commutator bars stands out above the others, there will be a flash every time the high bar passes under a brush. The best way to remedy this is to remove the armature from the machine and turn off the commutator smoothly in a lathe, using a sharp V-pointed tool.

A high mica segment will also cause sparking, and should be brought down with a file. If the commutator is not too rough it can easily be smoothed with sand-paper, pressing this evenly against the surface while in motion. Better results are gained by raising the brushes from the commutator while sanding it off, and this can easily be done when the machine is running as a generator, but will not be so convenient in the case of a motor, unless some other source of power is available to rotate the armature. Never use emery paper for this work, as the dust may get between the windings of the armature and cause short circuits.

Sparking often results from excessive vibration of the machine, due to poor foundations, or to the armature itself being out of balance. If this is found to be the trouble, proper steps should be taken to remedy it. A weak motor field will often cause severe sparking, and the field connections should be made secure. Test the coils for short-circuits and grounds as shown in Fig. 2. When a weak field exists in a motor, it will always be noticed that the machine takes a great deal more starting current than when operating under normal conditions. Sometimes the brushes are not of the proper material; if so, they should be exchanged for others, softer carbon being used for lower voltages—110 volts, for example—and harder carbon for higher voltages—500 volts, for example. It has often been found that a change of brushes has entirely stopped excessive sparking when all other means had been resorted to and failed.

The brushes should have just enough pressure on the commutator to make good electrical contact; if the tension of the brush-holder springs is too weak, sparking will occur, as the brushes cannot follow the inequalities of the commutator, especially when it is a little rough. Too much pressure should not be given to the brushes, as this will cause the commutator to heat more or less, and will wear the brushes and commutator away a great deal faster than necessary. Oftentimes it is found that the brushes do not cover the proper number of commutator bars, and some of different thickness should be tried. If the brushes in use are too thin, they can be made to cover more bars by beveling them at a greater angle, by tilting the brush ahead and re-fitting it to the commutator.

When sparking occurs at only one or two points on the commutator, the trouble is usually due to a short-circuited or grounded coil, and a test should be made for this as shown in Fig. 2. When the defective coil is located, it should be securely insulated with mica or other suitable material. If the sparking is allowed to continue for any length of time, it may result in "pitting" the commutator so badly that it will be necessary to turn it off in a lathe before being fit for service again.

It is often found that several commutator bars become blackened after the machine has been in service for some time, the cause arising either from grounded or partially short-circuited armature coils, defective mica ring or segments, or from cross-current in the armature, set up by the brushes not being properly spaced. Directions have already been given for the repair of these troubles. Sudden or extreme fluctuations in voltage or sudden over-load will often cause severe flashing at the brushes. As this is due entirely to operating conditions, nothing further can be said than to eliminate these conditions as much as possible.

Troubles in the machine itself which cause flashing are poor brush contact on the commutator and wrong connections of the field windings in compound-wound machines. If the series field is connected in reverse to the shunt winding, flashing at the brushes is often the result. The series leads should be reversed, or if the trouble is due to the first-mentioned cause, the tension of the brush holder springs should be increased. If it is found that the commutator heats up above normal, it may be due to an over-load on the machine. If so, the load should be reduced or a larger machine substituted. Poor brushes, rough commutator or too much brush pressure always cause excessive heating, and should be cared for.

Never allow grease or dirt to accumulate on the brushes or commutator, and be sure that the brushes are having a good contact, and are pressing evenly against the commutator surface, fitting it perfectly at every point. After running a few days, the commutator should acquire a brownish glaze on the surface and nothing further need be done except to keep it clean by wiping it with a clean cloth every day or so. Very little lubrication is necessary, and none at all is a great deal better than too much.

The prime requisite for the successful operation of electrical machinery is cleanliness, and as stated in the beginning of the article, if the machine is kept cool, dry and clean, a great many of the troubles enumerated above will be greatly reduced, if not entirely eliminated.

TESTING MANGANESE STEEL SAFES

Pretty much all steel contains manganese. Ordinarily, it is to be regarded as an impurity giving brittleness to the mass. But back in the latter part of the nineteenth century it was discovered that, if the manganese content amounted to, say, $7\frac{1}{2}$ per cent or something more, the resulting steel possessed in a high degree the valuable property of toughness. This is, it will be granted, rather a marvelous result. The ingredient which in a small percentage produces brittleness gives toughness when in fairly large proportion. The reason why this is so is not known, but the fact itself is well ascertained.

Fig. 1. Manganess Steel Safe tested by exploding Nitroglycerine in the Door Joint. Tenth Explosion—5 ounces Nitroglycerine

Some have supposed that manganese steel is very hard. It *is* hard but not excessively so. It is, no doubt, its toughness which has given it this reputation. The moderate hardness combined with the great toughness gives it such a refractory character that it is practically impossible to machine it. High carbon steel and high-speed steel are alike unable to conquer it. It is formed to shape by casting, forging, rolling and grinding. But this very character of high resistivity to tools has made it a very valuable material for burglar-proof safes. It is possible to remove the metal by a grinding wheel, and the writer lately saw a hole which had been made in the back of a manganese steel safe by grinding. But the wheel was power-driven, and it required more than a day and a half to produce its effect. It seems practically impossible, therefore, that a burglar should be able to force an entrance by means of cutting tools, whether of steel or emery. However, there is nitroglycerine. There is no material known having cohesive strength sufficient to resist this explosive. So we may expect that it will rend manganese steel, if it can be properly placed to render it effective.

Experiments along this line have lately been tried with interesting results. The manganese steel safe of the Ely-Norris Safe Co., 359 Broadway, New York City, consists essentially of two castings—the body and the door. The general form of the whole is that of a flattened orange. The door is a kind of stopper or bung fitting into its opening, with a ground joint. The inner end of the door and the corresponding part of the body are fitted with a system of interlocking lugs which are the real means of resistance to an effort to force the safe. There are bolts operated by the combination mechanism and the automatic device. But their office is mainly to prevent rotation and consequent release of the interlock of the lugs. The door, although it is a single casting, consists of a forward and rear part. These are joined by connecting lugs. There is thus left between the two parts an air space which is partly occupied by the combination mechanism. This space is the explosion chamber when subjected to attack. There are two spindles of manganese steel which occupy perforations in the forward plate. The fit is a ground one. The joint on the face of the safe between door and body is ground to make the two surfaces absolutely flush when the safe is locked. The obvious method of attack is by way of this joint or those about the spindles. In a test of a new \$1,600 safe at the company's works at Perth Amboy, N. J., January 21, a point a little to the right of the uppermost part of the joint between door and body was selected as the point of attack. Without difficulty, an indentation was made by means of sledge and cold chisel. A "cup" of putty was placed in a suitable position, and one-half ounce of nitroglycerine discharged without apparently any decided effect. A second charge of one ounce was then discharged. The explosive seemed to have

Fig. 2. Twelfth Explosion—at Night—7 ounces

Fig. 3. Condition of Safe after Nine Attacks in which Nitroglycerine was exploded within the Lock Chamber. Total Explosive used in these Nine Attacks 50 ounces

had but little effect. Applying sledge and cold chisel again, a third charge, consisting of one ounce, was exploded. It was fairly evident now that the joint was widening on each side of the wedge-like indentation of the chisel. Four more charges varying from one to two ounces were then used.

After the last or seventh discharge, it was evident that the nitroglycerine was penetrating to the explosion chamber. This was to be inferred from the fact that the front plate of the door was protruding slightly all around. Charges of three, four and five ounces were next exploded successively. The door was then observed to be protruding about 1/16 inch at the top, perhaps a little less at the right. At the bottom, the protrusion amounted to about 3/16 inch, on the left, about 5/32 inch. This displacement was to be attributed mainly, if not altogether, to a stretching of the connecting lugs, as the door itself was apparently intact. Four more charges of seven ounces each were next applied. The door was then found to be out an amount ranging from about 3/16 to about 1/2 inch. A final charge of eight ounces was then employed with no especial result.

It is to be observed that even had the outer plate of the door been forced off by stretching the lugs to the breaking point, the safe could not have been entered. There would still have been in the way a 5-inch plate or plug of manganese steel securely held in position by the interlocking lugs and the bolts of the automatic time mechanism. It does not seem apparent that a burglar would have had an advantageous opportunity for attack. No holes pierce this inner door. The only joint open to attack is the 5-inch ground taper contact between it and the body. The exterior plate may be regarded as merely the outer fortification—the main works are within.

These experiments show in a forcible way what a wonderful material manganese steel is. Hardened tool steel would probably have equal capability for resistance to machining, but this would hardly be accompanied by the great tenacity shown here. The question is how to shape it.

HARDENING SMALL BLANKING DIES

By H. J. BACHMANN*

It is manifestly an unprofitable investment to equip a manufacturing establishment with all the latest and most approved facilities for hardening, if there are only a few pieces to be treated occasionally. However, in cases of this kind, especially when blanking dies are to be hardened, it is up to the diemaker to make the best of the apparatus on hand. With this condition in mind, I will endeavor to set down specific directions which will invariably give definite and satisfactory results if followed closely.

If a blacksmith's forge is used, let the die be placed in the fire with the cutting face upward. During the period of heating, keep the fresh coal away from the die by surrounding it on all sides and on top with red hot cinder coal. When turning on the blast, be careful not to give it too much air. In fact, the more sparingly the blower is used, the better are the chances of the steel becoming evenly heated throughout. Even if the blast should be applied carelessly, the scaling and oxidizing will be more prominent on the bottom of the die where it is not so harmful. But most of all I wish to insist on an intelligent use of the blast. Turn it into the fire for about a minute, then shut it off and let the heat *soak* into the die instead of *blowing* it in. This is probably the most important point. The block of steel must be evenly saturated with heat and kept from contact with cold air until it reaches the proper hardening temperature. Remember to blow a little and then stop the air while the steel absorbs the heat. While the die is being heated, prepare a pail of clean water, taking the chill from it, that is, heating it until lukewarm. The die held in one hand with tongs, is then plunged into the water and kept moving all the time; when the die is cool enough, take hold of it with the other hand and stir the water with it until they both arrive at the same degree of heat. Now instead of taking the die out of the water and reheating it over the fire or letting it finish cooling in the air, just let the whole thing stand so that the water and steel will cool off together.

The entire method may be summed up as follows. Do not *shock* the steel by quickly heating it red hot or by plunging it suddenly into cold water. Let the change from cold steel to hot steel, and *vice versa*, be a gradual one; this will avoid all cracks and breaks due to any abrupt change in the molecular structure of the steel.

MACHINE SHOP PRACTICE*

TOOL GRINDING—1

In the grinding of tools, whether they are to be used for turning, planing or boring, there are three things of importance that need to be considered: First, the cutting edge of the tool (as viewed from the top) needs to be given a certain shape; second, there must be a sufficient amount of clearance; and third, tools, with certain exceptions, are ground with a backward slope or a side slope, or with a combination of these two slopes on that part against which the chip bears when the tool is in use.

In Fig. 1 a few of the different types of tools which are used in connection with lathe work are illustrated. This illustration also indicates the meaning of the various terms used in tool grinding. As shown, the clearance of a tool is the angular distance α; the back slope is represented by the angle β and the side slope by the angle γ. The angle δ for a tool without side slope is known as the lip angle or the angle of keenness. When, however, the tool has both back and side slopes, this lip angle would more properly be the angle between the flank f and the top of the tool, measured

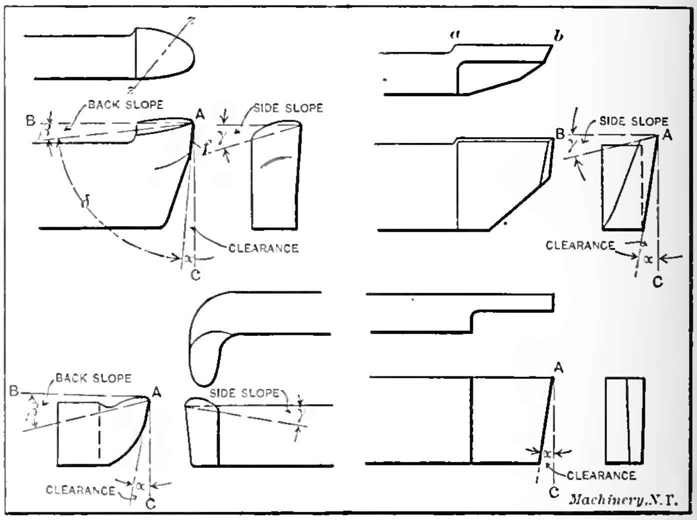

Fig. 1. Illustration showing the Meaning of Terms used in Tool Grinding, as applied to Toole of Different Types

diagonally along a line $z—z$. It will be seen that the lines $A—B$ and $A—C$ from which the angles of clearance and back slope are measured, are parallel with the top and sides of the tool shank, respectively. For lathe tools, however, these lines are not necessarily located in this way when the tool is in use, as the height of the tool point with relation to the work center determines the position of these lines so that the *effective* angles of back slope, clearance, and keenness are changed as the tool point is lowered or raised. The way the position of the tool affects these angles is illustrated on the Shop Operation Sheet accompanying this number.

Now, while tools must, of necessity, be varied considerably in shape to adapt them to various purposes, there are certain underlying principles governing their shape which apply generally; so in what follows we shall not attempt to explain in detail just what the form of each tool used in the machine shop should be, as it is more important to understand how the cutting action of the tool and its efficiency is affected when it is improperly ground. When the principle is understood, the grinding of tools of various types and shapes is comparatively easy.

In the first place we shall consider the shape or contour of the cutting edge of the tool as viewed from the top, and then take up the question of clearance and slope. Of course, when a tool is being ground it is given clearance and the required shape at the same time, but the different elements will be considered separately to avoid confusion.

The contour of the cutting edge depends primarily upon the purpose for which the tool is intended. For example, the tool A, in Fig. 2, where a plan view of a number of different lathe tools is shown, has a very different shape from that of, say, tool D, as the first tool is used for rough turning, while

* With Shop Operation Sheet Supplement.

tool D is intended for cutting grooves or severing a turned part. Similarly, tool E is V-shaped because it is used for cutting V-threads. Tools A, B and C, however, are regular turning tools, that is, they are all intended for turning plain cylindrical surfaces, but the contour of the cutting edges varies considerably, as shown. In this case it is the character of the work and of the cut that are the factors which determine the shape. To illustrate, tool A is of a shape suitable for rough turning large and rigid work, while tool B is adapted for smaller and more flexible parts. The first tool is well shaped for roughing because experiments have shown

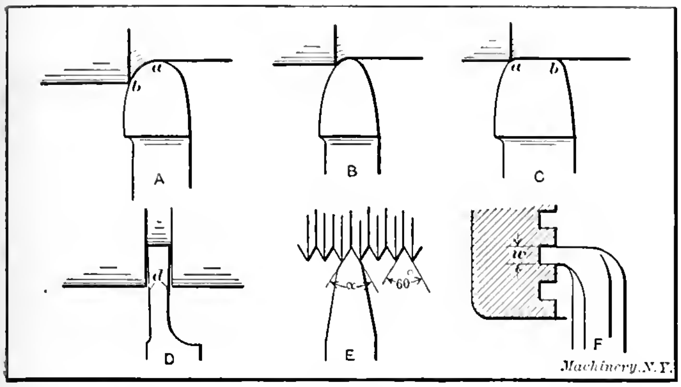

Fig. 2. Plan View of Lathe Turning and Threading Tools

that a cutting edge of a large radius is capable of higher cutting speed than could be used with a tool like B, which has a smaller point. This increase in the cutting speed is due to the fact that the tool A removes a thinner chip for a given feed than tool B. Therefore, the speed may be increased without injuring the cutting edge to the same extent. If, however, tool A were to be used for turning a long and flexible part, chattering would result. Consequently, a tool B having a point with a smaller radius would be preferable, if not absolutely necessary. The character of the work also affects the shape of finishing tools. The tool shown at C is used for taking light finishing cuts with a wide feed, and a tool similarly shaped is also used for the same purpose in connection with planer work. Obviously, if the straight or flat part of the cutting edge is in line with the travel of the

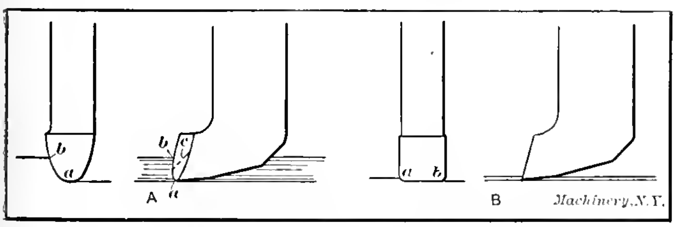

Fig. 3. Planer Tools for Roughing and Finishing Cuts

tool, the cut will be smooth and free from ridges, even though the feed is coarse. But such a tool cannot be used on work that is not rigid, as chattering would result. Therefore, a smaller cutting point and a reduced feed would have to be employed. Tools with broad flat cutting edges and coarse feeds are almost invariably used in taking finishing cuts in cast iron, as this metal offers less resistance to cutting than steel, and is less conducive to chattering.

The shape of a tool (as viewed from the top) which is intended for a more specific purpose than regular turning, can be largely determined by simply considering the tool under working conditions. This point may be illustrated by the parting tool D which, as previously stated, is used for cutting grooves, squaring corners, etc. Evidently this tool should be widest at the cutting edge; that is, the sides d should have a slight amount of clearance so that they will not bind as the tool is fed into a groove. As the tool at E is for cutting a V-thread, the angle a between its cutting edges must equal the angle between the sides of a V-thread, or 60 degrees. The tool illustrated at F is for cutting inside square threads. In this case the width w should be made equal to half the pitch of the thread, and the sides should be given a slight amount of side clearance, the same as with the parting tool D. So we see that the outline of the tool, as viewed from the top, must conform to and be governed by its use.

Aside from the question of the shape of the cutting edge as viewed from the top, there remains to be determined the amount of clearance that the tool shall have, and also the slope (and its direction) of the top of the tool. By the top is meant that surface against which the chip bears while it is being severed. It may be stated, in a general way, that the direction in which the top of the tool should slope should be away from what is to be the *working part* of the cutting edge. For example, the working edge of a roughing tool A (Fig. 2), which is used for heavy cuts, would be, practically speaking, between points a and b, or in other words, most of the work would be done by this part of the cutting edge; therefore the top should slope back from this part of the edge. Obviously, a tool ground in this way will have both a back and side slope. Similarly, the planer tool shown at A in Fig. 3, which is used for deep roughing cuts and does most of its work along the side between points a and b, should slope backward along a line c. When, however, most of the work is done on the point or nose of the tool, as for example, with the lathe finishing tool C (Fig. 2) or the planer finishing tool B (Fig. 3) which take light cuts, the slope should be back from the point or cutting edge a—b. As the side tool shown in Fig. 1 does its cutting along the edge a—b, the top is given a slope back from this edge as shown in the end view. This point should be kept in mind when grinding a tool, for when the top slopes in the right direction there is less resistance or power required for cutting. Of course, tools for certain classes of work, such as thread tools, or those for turning brass or chilled iron, are ground flat on top, that is, without either back or side slope.

The effect of too little or too much slope or clearance and some additional points of a general character on the grinding of tools, will be given in a succeeding installment.

ELECTRICAL INDUSTRIES IN GERMANY

In a paper read before the Institution of Electrical Engineers in Great Britain, the electrical industries in Germany were interestingly dealt with. The electrical manufacturing industry in Germany is at the present time almost entirely in the hands of four large companies. In the organization of these firms, we are told, an almost bureaucratic rule is in force. Each man's work is specialized in the minutest details, each branch of manufacture has an organization of its own with its own drafting-room, designing and clerical staff. Each type of motor is designed and manufactured in a separate department. Each firm has a special foreign department dealing exclusively with inquiries from abroad. All these departments are responsible only to a central authority or administration. The average technically educated employe is of high theoretical training, but salaries are kept low. As an example of the almost military rule, it may be mentioned that leave of absence of more than three days must be granted any employe by the central administration. The most striking feature of the shop system is the working day. It consists regularly of eighteen hours work in two shifts of nine hours each, with only a fifteen-minute interval during the nine hours, and half an hour between the two shifts. Thus the first shift works from 7 A. M. to 4.15 P. M., while the second works from 4.45 P. M. to 2 A. M. This system permits full advantage being taken of the machinery without working the men excessively long hours and without the necessity of paying over-time wages.

* * *

A rather peculiar safety device has recently been patented by Mr. Charles F. Pfalzgraf of Baltimore, Md., for preventing accidents to press operators. The device consists of an arrangement attached to the operator's arm, which, by means of electrical connections, makes it impossible to trip the treadle when the operator's hand is between the dies. When the device is properly adjusted, the arm must be moved back before the machine can be operated. With due esteem for all efforts that are made to prevent accidents in industrial work, it may, however, be doubted whether attachments arranged on the machine proper would not be preferable. To propose to connect up the operator directly to the machine seems like making him a part of it, even to a greater extent than he already is, and this may be neither expedient nor wise.

MILLING FIXTURES FOR AUTOMOBILE PARTS*

By E. H. PRATT†

The growth of the automobile industry has been so rapid that it has been found difficult for most factories to keep up with their orders. In order to avoid delays, a large number of companies have undertaken the manufacture of their cars complete. This necessitates the use of the most improved machinery, and also the designing and making of many special jigs and fixtures to insure the greatest possible amount of accurate work.

Among the most important fixtures are those used for the milling operations. There is a very close limit of variation allowed on most milling work, which in many cases is not more than one-half thousandth inch. This close margin is due to the introduction of the duplicate-parts system now used by the leading manufacturers. In most cases milling operations are the first ones performed; therefore the greatest difficulty is encountered in clamping the work in the fixture in such a way as to locate it properly from the uneven surface of the casting or forging without springing it.

Some of the fixtures and clamping devices used in one of the largest and best equipped automobile factories in the country, which were designed to overcome such difficulties are illustrated and described herewith. An efficient type of milling fixture for holding a number of light brass castings is shown in Fig. 1. These castings, as indicated by the dotted lines, were of a rather peculiar shape, having a heavy boss on each end and one in the center with light webs connecting them. It was necessary that the faces of the bosses *A* be milled at right angles with a hole through the central part of the casting. There was the usual difference in the shape and size of these bosses, that exists in all castings of this kind. Provision was made for machining ten at a time. The adjustable jacks *C* have swivel heads which seat themselves firmly to the uneven surfaces of the tapered end bosses. These jack heads are of machine steel and casehardened. The square bosses *D*, on one side of the fixture, each have two set-screws passing one above the other, at right angles. These screws take care of variations in the castings and securely hold the bosses in position. A hole in the center of each casting fits over a stud *E* which is provided with a slip washer *B* and a nut which aids in holding the casting securely; by using a large end mill the pieces are very quickly and accurately machined.

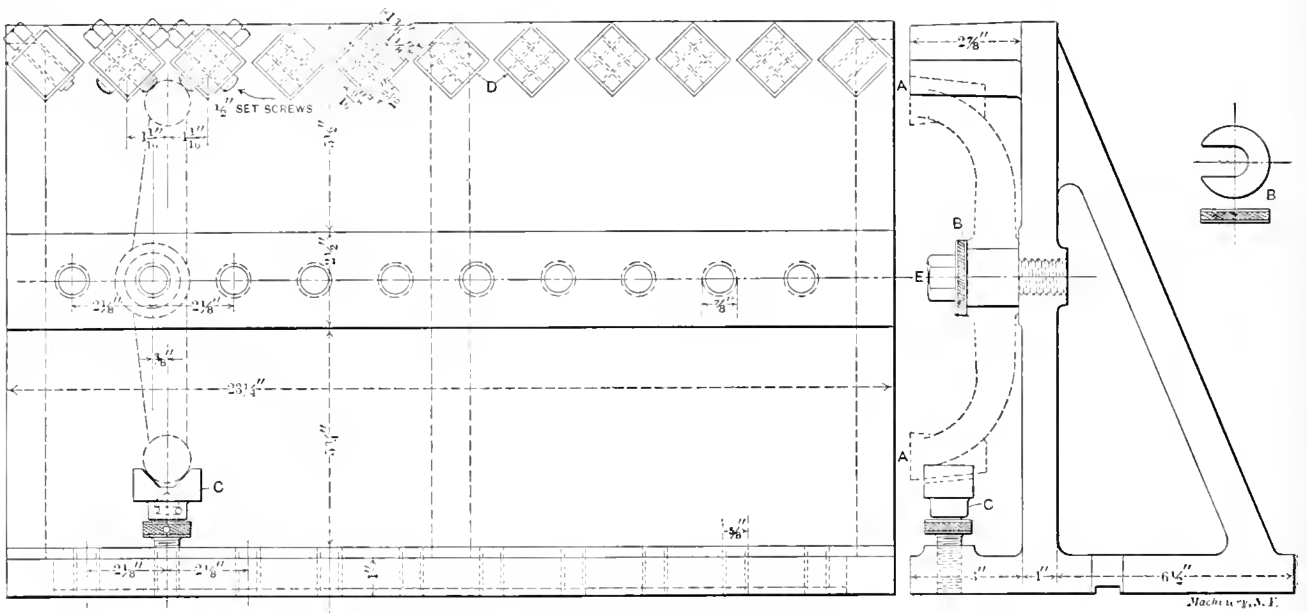

Fig. 1. Gang Milling Fixture for Castings shaped as indicated by the Dotted Outline

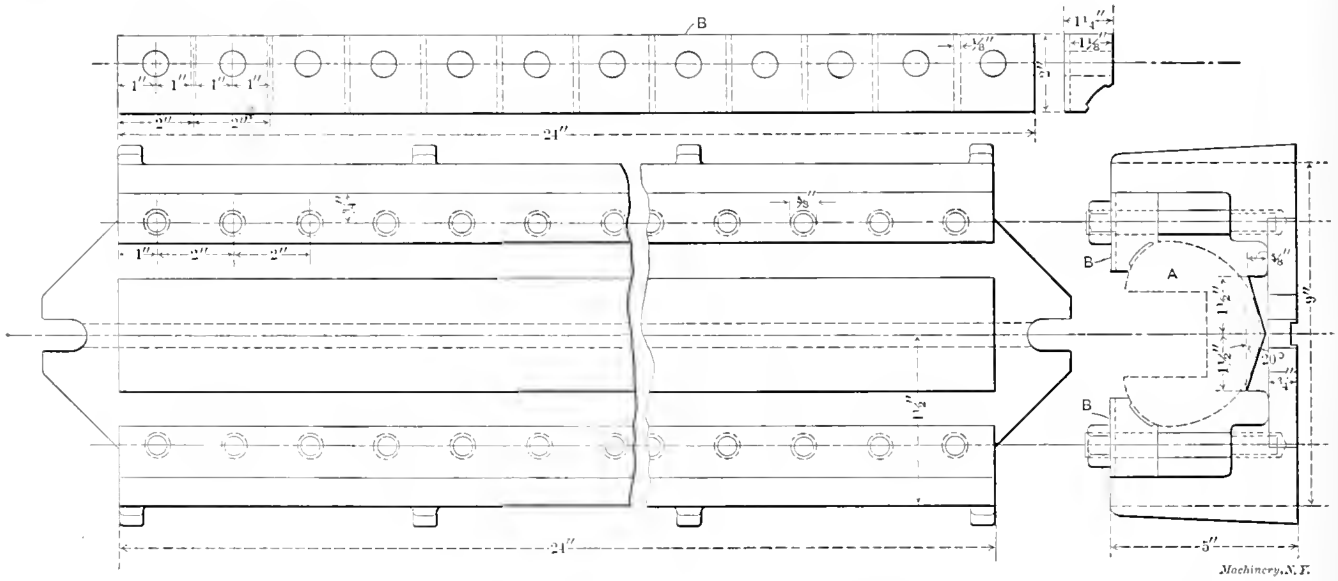

Fig. 2. Gang Milling Fixture for Engine Counterweights

A milling fixture for crankshaft counterweights and the method of clamping and locating the work in the fixture, is illustrated in Fig. 2. The counterweight *A* has circular sides and a large milled opening, as shown by the dotted lines. Twelve weights are placed in the fixture at once; these are securely held in position by one stud on either side of each counterweight, in conjunction with clamps *B*, which are machined to fit the curved surface of the counterweight. These clamps, one of which is illustrated at the top of the engraving, are machined in long strips and are sawed nearly through at

* For previous articles on this and similar subjects, see "Automobile Factory Practice" in the January, 1910, issue of MACHINERY, engineering edition, and articles there referred to.

† Address: 503 St. Joseph St., W., Lansing, Mich.

intervals equal to the width of the counterweight, thus allowing each section to act independently. The sides of the fixture are made very rigid to withstand the outward strain when clamping. The end view plainly shows the locating V in the bottom of the fixture, and also the studs and clamps in position on the counterweight. These counterweights are rough steel castings which makes it particularly difficult to keep them within the 0.0005 inch limit allowed in the milled groove. To get interlocking cutters of the dimension required, would and by using a large straddle mill both faces are finished simultaneously. After the ends have been faced, the hangers are sent to the drill department and the hole *E* is drilled. They are then returned to the milling department for the second milling operation which consists in finishing the flat surface *G* (Fig. 4) that fits the inside of the frame. As this is a slow operation, the fixture was designed to hold as many hangers as could be placed within the feed limit of the milling machine table. This fixture is shown in Fig. 4 and the

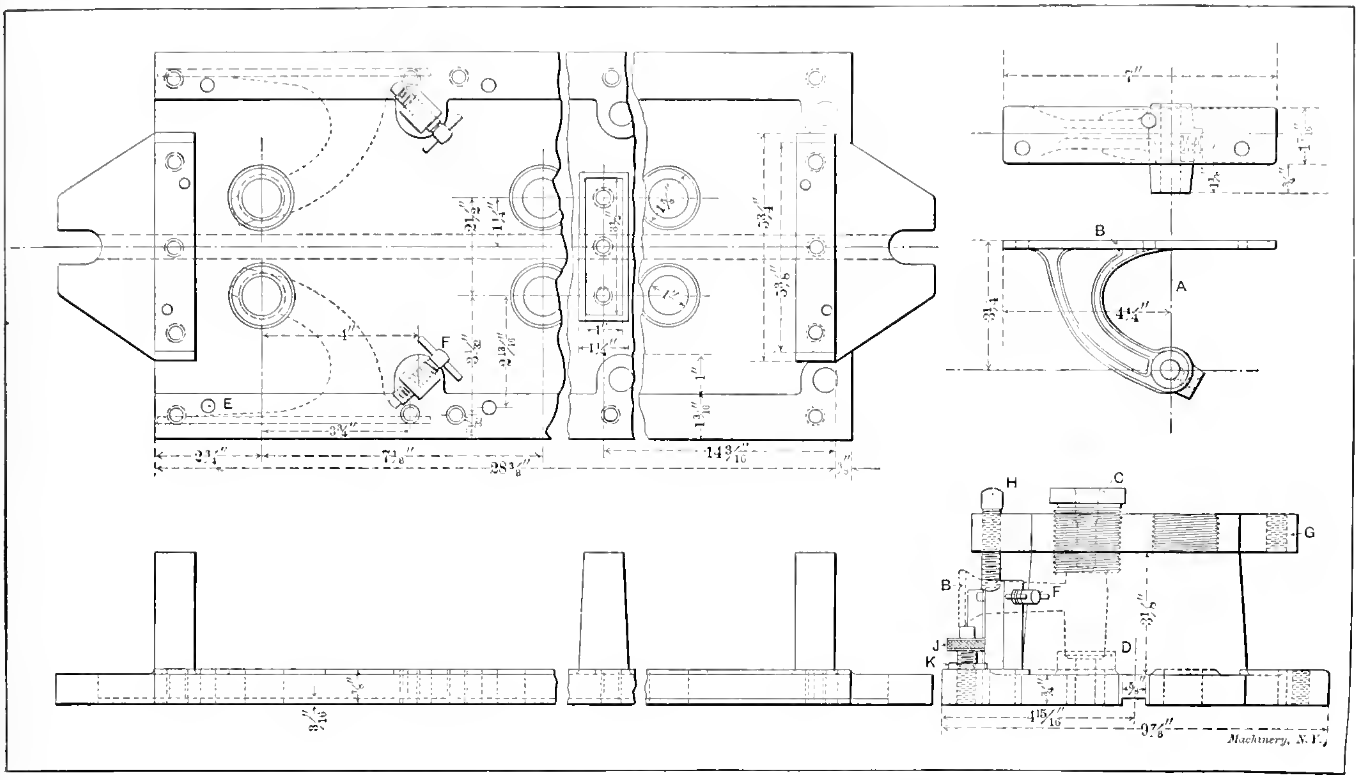

Fig. 3. Combination Milling and Drilling Fixture for Spring-hangers

take considerable time, therefore an inserted tooth cutter was made in which every alternate tooth projected ahead of the other on both sides. When the cutter becomes too narrow, it is easily adjusted by driving one tooth one way and the next one the other, and regrinding to size.

A design of spring-hanger for an automobile, and also the fixture for milling it, is illustrated in Fig. 5. This spring-hanger is a drop forging, and it is hollowed out to accommodate the width of the spring. It is not machined on the in- position of the work when set up in it is indicated by the dotted lines. The hangers are located by studs *A* that fit into the holes previously drilled, and also by the milled surface *B*. After the hangers are placed on these locating studs, they are clamped by means of the strip *C*. This strip is slotted at intervals as shown in the detail view and it is divided into as many sections as there are hangers to be clamped. As the set-screws *D* are tightened, each section acts as an independent vise jaw. The work is prevented from shifting or

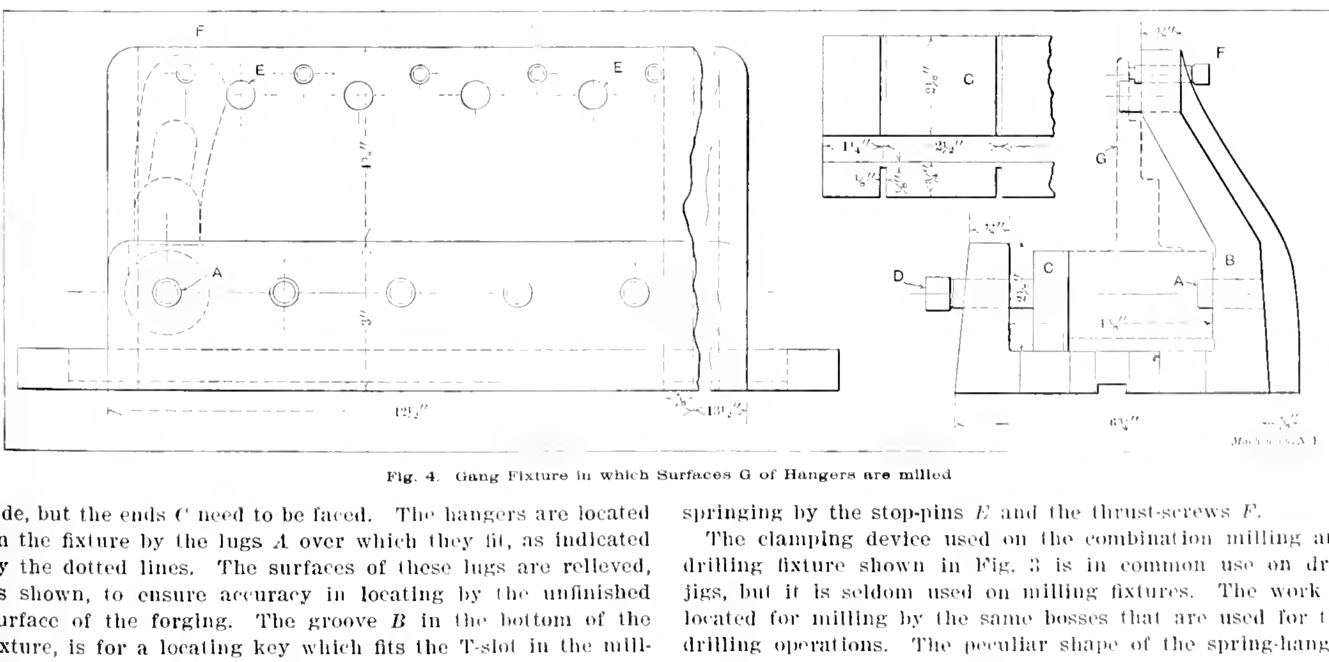

Fig. 4. Gang Fixture in which Surfaces G of Hangers are milled

side, but the ends *C* need to be faced. The hangers are located on the fixture by the lugs *A* over which they fit, as indicated by the dotted lines. The surfaces of these lugs are relieved, as shown, to ensure accuracy in locating by the unfinished surface of the forging. The groove *B* in the bottom of the fixture, is for a locating key which fits the T-slot in the milling machine table. The clamp *D*, used on this fixture, is of the type ordinarily employed on quick-acting milling devices. Both right and left hangers can be machined on this fixture, springing by the stop-pins *E* and the thrust-screws *F*.

The clamping device used on the combination milling and drilling fixture shown in Fig. 3 is in common use on drill jigs, but it is seldom used on milling fixtures. The work is located for milling by the same bosses that are used for the drilling operations. The peculiar shape of the spring-hanger forging for which this fixture is intended, is shown by the detail at *A*. This fixture is designed to mill the surfaces *B* of eight hangers at a time by using large straddle mills. Bush-

ings *C* and *D* locate the work by the hub ends as shown. The hangers are prevented from shifting by stationary stop-pins *E* against which they are forced by lock-screws *F*. The bushing plate *G* also contains clamping screws *H* which hold the hangers firmly on the adjustable studs *J*, of which two are used for each hanger. After these studs are adjusted to the work, they are held in place by lock-nuts *K*.

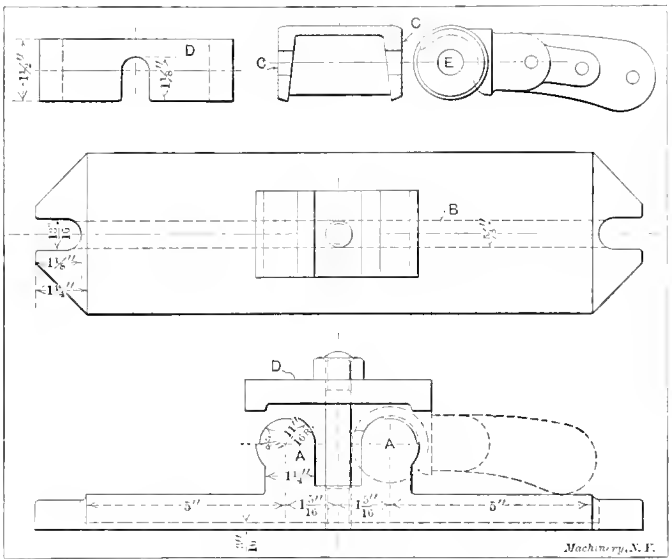

Fig. 5. Fixture for Milling Sides C of Spring-hanger

The bushings *C* and *D* are provided with holes of the same diameter as those to be drilled in the boss of the hanger, and when the fixture is not in use on the milling machine, it can be used on the multiple spindle drill press, thereby forming a combination milling and drilling fixture.

BALL POINT VERSUS ANVIL TYPE THREAD MICROMETERS

Two forms of measuring points are employed in practice for comparing the pitch diameters of threaded work. The first and oldest of these, shown in Fig. 1, is the method employed on the Brown & Sharpe thread micrometer. This may be used for positive measurements, as well as for comparisons. Figs. 2 and 3 illustrate another principle of measuring, using in the one case a ball point micrometer and in the other case wires of suitable diameter measured with the regular microm-

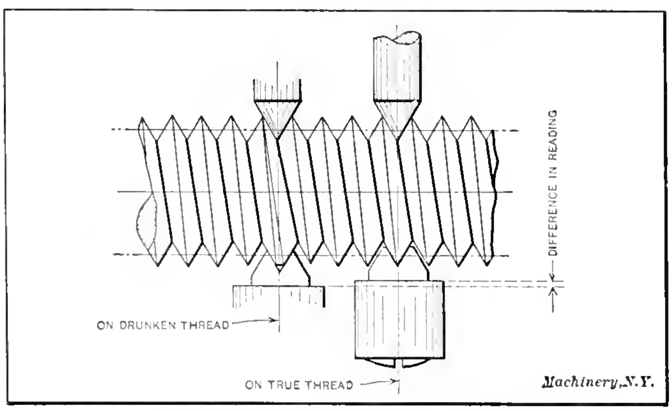

Fig. 1. The Anvil Type of Thread Micrometer gives Varying Measurements on True and Drunken Threads

eter caliper. The arrangement shown in Figs. 1 and 3 may be used for other positive measurements or comparisons with other threads. The device shown in Fig. 2, owing to the tilting of the micrometer required, should be used for comparative measurements only between two threads of supposedly the same exact form.

A recent experience of a well-known machine tool building firm shows, however, that the scheme of Fig. 2 cannot be relied on in certain cases, even for comparative measurements, and the same holds true of Fig. 3. The way in which this was discovered brings up a very interesting point in machine tool construction as well as in thread measuring.

This manufacturer bought a lathe for cutting accurate threads. It was provided with a lead-screw which proved to be satisfactory from the standpoint of the accuracy with which it was cut. A serious error developed, however, in its mounting in the machine. It was provided with a loose thrust collar between the shoulder of the lead-screw and the face of the bearing bracket which took the thrust in feeding the carriage. This thrust collar unfortunately was very poorly squared up, being some thousandths thicker on one side than on the other. Unfortunately again, the thrust surfaces on the

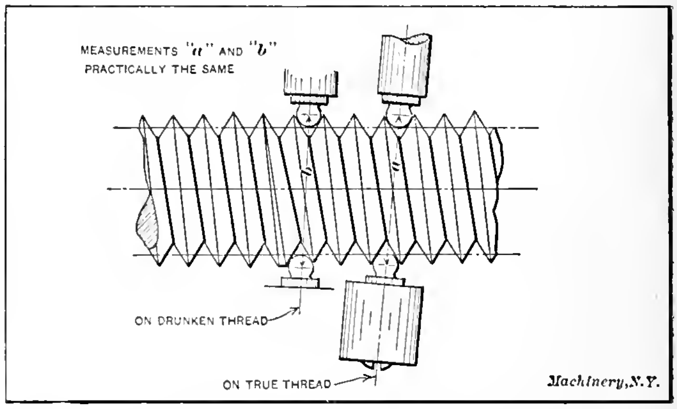

Fig. 2. The Only Difference in Measurement made by the Ball Point Micrometer is due to the very Slight Difference in Inclination—too Slight to be Appreciable

lead-screw and the bearing, between which it was placed, were also poorly faced, running out sidewise to an appreciable extent. As a result of this combination of misfortunes the lead-screw, in revolving, received an irregular endwise movement resulting from the varying position of the untrue loose washer between its untrue thrust surfaces. The machine thus cut an irregular drunken thread.

This fact was brought to the attention of the makers of the

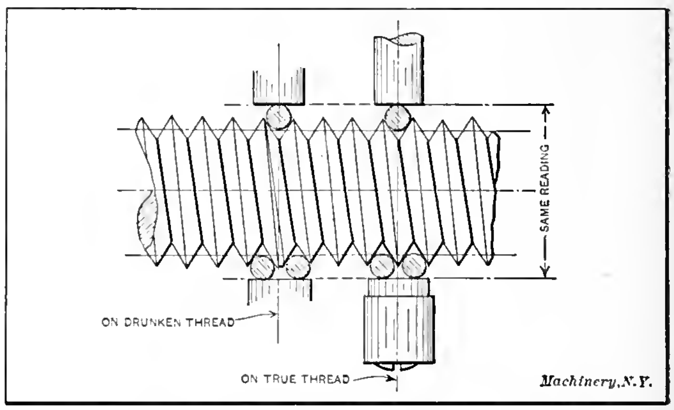

Fig. 3. The Three-wire Method of Thread Measurement makes no Distinction between True and Drunken Threads

machine, who measured with the ball point micrometers a sample screw cut by it, and pronounced it O. K. The purchaser of the machine, however, brought out a measuring tool of the type shown in Fig. 1, and this at once indicated varying diameters in different parts of the thread, giving evidence of the irregularities of which he complained.

The reason for this is evident. The ball point micrometer measures the groove cut by the thread tool, and as this is always set at the same depth and is unvarying in shape, the error was undetected. The same conditions are met with in the three-wire method, shown in Fig. 3. The lower anvil point in Fig. 1, however, since it spans the abnormal thread, instead of making contact with the sides of adjacent threads, indicates the irregularity by giving an increased reading for the pitch diameter.

This point of the accurate squaring of the thrust surfaces for precision lead-screws is a very important one; and it is one that it liable to be neglected by those who have given no thought to the matter. We have been told by a man of wide experience in accurate thread cutting, that it is fully as difficult and of fully as great importance to mount a lead-screw properly in the lathe for use, as it is to cut it accurately in the first place.

FORMULA FOR THE VOLUME OF A PART OF A SPHERICAL SEGMENT

In the December, 1908, issue a request was submitted by F. M. S. to the readers of MACHINERY for a formula for the volume of a section of a spherical segment. In the accompanying illustration the heavy lines show half of the part of the segment, the volume of which is required. The method for finding a formula for this volume involves a vast amount of mathematical work, and it is not possible to give space to the derivation, which would occupy more than four full pages in MACHINERY. The formula for the volume, however, is:

$$V = \frac{2SP\sqrt{C^2-P^2}}{3} + \frac{\pi(SC^2-4Sr^2+4r^3)}{6} - \frac{3r^2P-P^3}{3} \sin^{-1}\sqrt{\frac{C^2-P^2}{r^2-P^2}} - \frac{S(C^2-4r^2)}{3}\tan^{-1}\sqrt{\frac{C+P}{C-P}} - \frac{2r^3}{3}\left(\tan^{-1}\sqrt{\frac{(C+P)(r+C)}{(C-P)(r-C)}} + \tan^{-1}\sqrt{\frac{(C+P)(r-C)}{(C-P)(r+C)}}\right) - \frac{SC^2}{2}\sin^{-1}\frac{\sqrt{C^2-P^2}}{C}$$

in which V = the volume of the part of the spherical segment

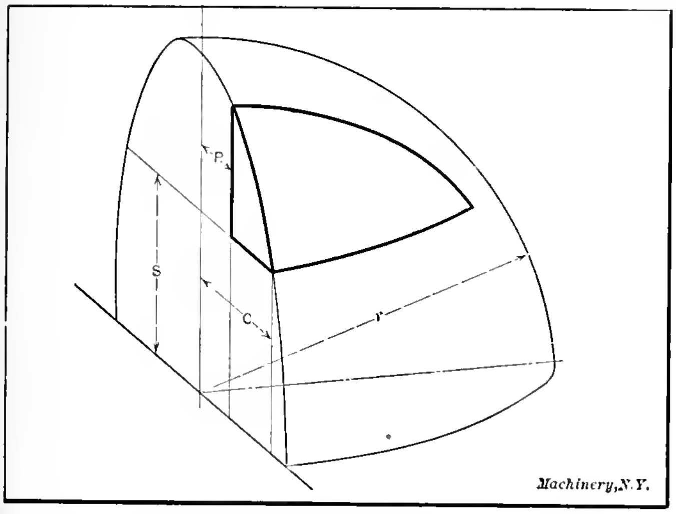

Diagram showing Notation for Formula for the Volume of a Part of a Spherical Segment

required, which is twice the volume of the section shown with heavy lines in the accompanying illustration, and S, P, C and r are dimensions as given in the illustration, r being, of course, the radius of the sphere. This formula with its derivation has been worked out by Mr. R. A. Jewett, of 35 Pinkney St., Boston, Mass., and he does not think that the formula can be simplified further. F. M. S. asked for the volume in terms of the radius of the sphere, the height of the segment, and the distance between the central plane and the plane passed through the segment, this latter distance being shown as P in the illustration. Of course, these values for the height of the segment could be substituted in the formula, but to do so would vastly complicate what is already too complicated, and the result would be an unwieldy, if not an unmanageable expression.

The formula has been checked by actual figures and been found to work out exactly. The method for checking is to assume some limiting value for certain dimensions, so that the volume can also be calculated by any of the general formulas for spherical segments. In this way, if the two values obtained by the two different formulas prove to be equal, the formula here given can be relied upon to be correct. We are reasonably sure, however, that no one will use this formula except in a case of dire necessity.

SPECIAL UNIVERSAL VISE FOR GANG PLANING

By E. H. WEISS*

When it becomes necessary to machine small, slender pieces in quantity, whether the forms are complicated or not, it is usual to use a formed cutter for milling them, the cost of which is defrayed by the economy which results from the use of such a cutter as compared with hand work. If the number of pieces is comparatively small, it is best to plane them in a gang, while they are held in the vise, by the use of a formed planer tool. This operation consists in placing a number of

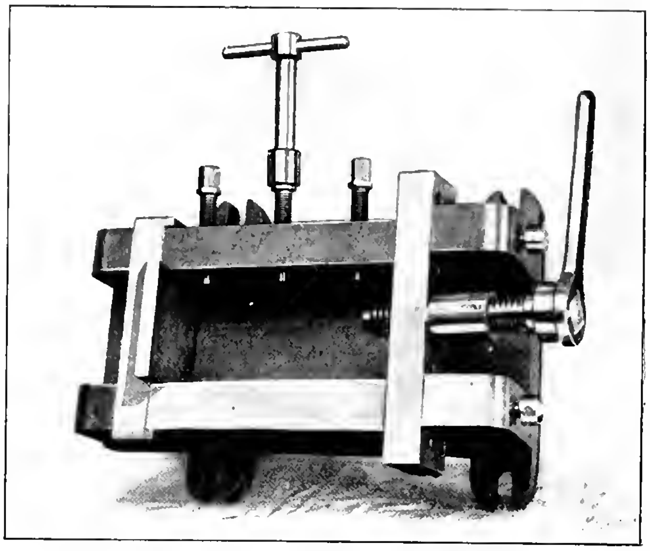

Fig. 1. Special Vise for Holding a Small Number of Duplicate Pieces on the Planer

pieces in a vise and shaping them all simultaneously. When the parts are machined by this method, it is necessary to strongly clamp them against each other, and when they are very small, it is often quite difficult to place the blocking so that it will not hinder the passage of the tool. I make use of a special chuck for this work which is of simple construction, as may be seen by referring to the accompanying illustrations, Figs. 1 and 2.

This chuck is composed of a base A of channel section, whose sides B are provided with slots in which are placed two steel rectangular cross-pieces C and D. The cross-piece D, carries a screw having a squared head which fits a wrench as shown in Fig. 1. This screw tightens the pieces together by bearing on a pad or block similar to E. It is possible to

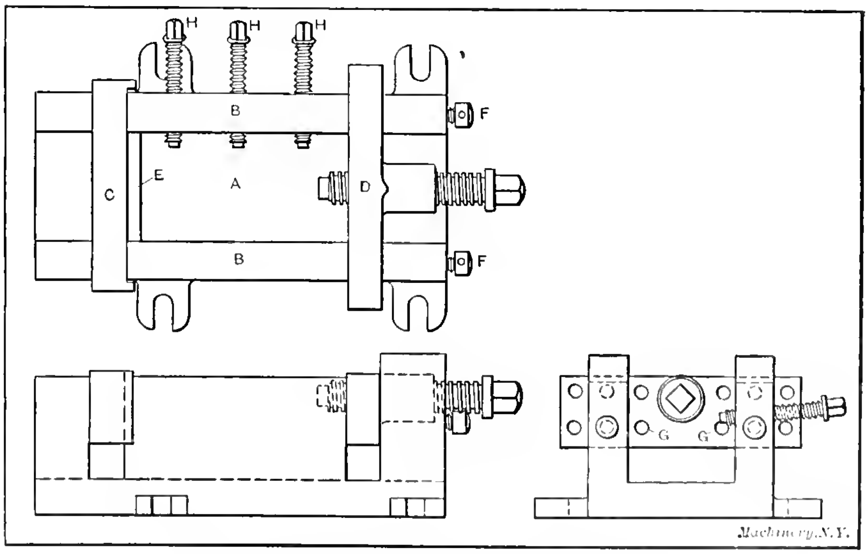

Fig. 2. Elevations and Plan of the Special Planer Vise

adjust the height of cross-piece D to agree with the height of the work, after which it may be locked in place by screws F, which fit into holes G. The location of the tightening screw can, therefore, be adjusted to any desired point on the work. To locate the row of pieces laterally, there are provided three

* Address: 2 Rue des Entrepreneurs, Paris, France.

screws H, in the side of the vise, which bear against a block similar to that shown at E. These screws are at a slight angle with the base of the vise, as shown, so that the pieces, when clamped, are forced into contact with the base or with such blocking as may be necessary to mount them on. The four slotted feet shown permit the vise to be securely clamped to the table of the machine by means of four bolts.

THE GROWTH OF CAST IRON

In an interesting paper entitled "The Growth of Cast Irons after repeated Heatings," read before the Iron and Steel Institute of Great Britain, September, 1909, the authors, Prof. H. F. Rugan and Prof. H. C. H. Carpenter, report the results of their investigations relating to the "growth" of cast iron.

The fact that certain types of cast iron grow after repeated heatings has long been familiar to engineers. Cast iron annealing ovens 8 feet in length, 3 feet in diameter, and 1½ inch in thickness, which are kept red hot for prolonged periods, between which they are permitted to cool off, sometimes grow to 9 feet in length in the course of their use. Cast iron furnace grates, range fittings, etc., subjected to alternate heating and cooling are also frequently distorted and sometimes broken from the same cause. It has been demonstrated that mild steel subjected to the same treatment does not grow, so that this quality is one peculiar to cast iron.

The principal investigator of the subject of the growth of cast iron after repeated heatings was, previous to the investigations of the authors of the paper referred to above, Mr. A. E. Outerbridge, Jr., of Philadelphia. His experiments were reported in the transactions of the American Institute of Mining Engineers, 1905, Vol. XXXV. In these experiments a cast iron bar of 1 by 1-inch section, 14 13/16 inches in length, was heated 27 times to about 1470 degrees F. for one hour. During this treatment it increased in size to 16½ inches length and 1⅛ x 1⅛-inch cross-section. This corresponds to an expansion of nearly 41 per cent. The enlarged bar had, it was stated, the same weight as the bar before the treatment. Twelve additional heatings increased the dimensions of the bar until the total expansion was 46 per cent.

The experiments of Messrs. Rugan and Carpenter were more extensive than those carried out by Mr. Outerbridge, but in the main, there is a close agreement in results. The following is a summary of the results of these investigators' experiments. The maximum growth of commercial cast iron takes place when the heating is continued for four hours at a time at a temperature of 1650 degrees F. In order that growth shall take place, both heating and cooling are required. The growths of the cast iron investigated varied between 35.2 and 37.5 per cent. It is interesting to note that the latter experimenters found that an increase in weight took place amounting to from 7.8 to 8.6 per cent. It is thus evident that the metal took up gases from the outside air, there being an oxidation of silicon and an oxidation of carbon. The ends of a cast iron bar grew more rapidly than the middle parts, which is readily explained by the fact that they expose more surface to the penetrating gases. The investigators, therefore, came to the conclusion that the influence of gases on the growth of cast iron is very important, and one test piece which grew very decidedly in a muffle furnace not only did not grow when heated in a vacuum, but it actually contracted 0.04 per cent. This would partly explain why Mr. Outerbridge's experiments did not show an increase in weight, as he enclosed his samples in an iron pipe closed at the ends with clay in order to prevent scaling; consequently there were practically no gases to be absorbed by the heated iron. On the other hand, this does not seem to explain satisfactorily the fact that his samples increased in size nevertheless.

In constructions where the growth of cast iron is objectionable, white irons should be used instead of gray; the most suitable composition appears to be an iron with about three per cent of carbon that has as few impurities as possible. As to the impurities, silicon is the most objectionable and it should not exceed 0.2 to 0.3 per cent. The only objection to using white iron for such purposes as annealing ovens, etc., would be that it might crack when heated, but this difficulty might be obviated by modifying the design.

MOMENT OF INERTIA OF BUILT-UP SECTIONS

By JAMES A. BROWN*

The usual method of calculating the moment of inertia of a built-up section involves the calculations of the moment of inertia for each element of the section about its own neutral axis, and the transferring of this moment of inertia to the previously found neutral axis of the whole built-up section. A much simpler method which can be used in the case of any section which can be divided into rectangular elements bounded by lines parallel and perpendicular to the neutral axis, is the so-called tabular method based upon the formula:

$$I = \frac{b\,(h_1^3 - h^3)}{3}$$

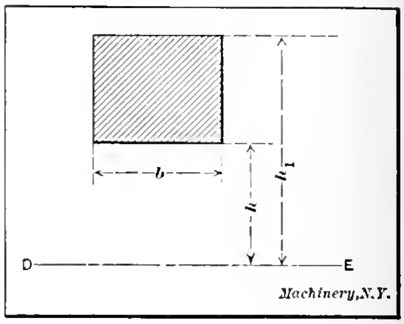

Fig. 1

in which I = the moment of inertia about axis DE, Fig. 1, and b, h and h_1 are dimensions as given in the same illustration. This method is given in Alexander and Thompson's "Elementary Applied Mechanics."

The method may be illustrated by applying it to the section shown in an article in the January issue of MACHINERY, entitled "To Calculate the Deflection of a Special Steel Section." This section is reproduced in Fig. 2, and for simplicity of calculation shown "massed" in Fig. 3.

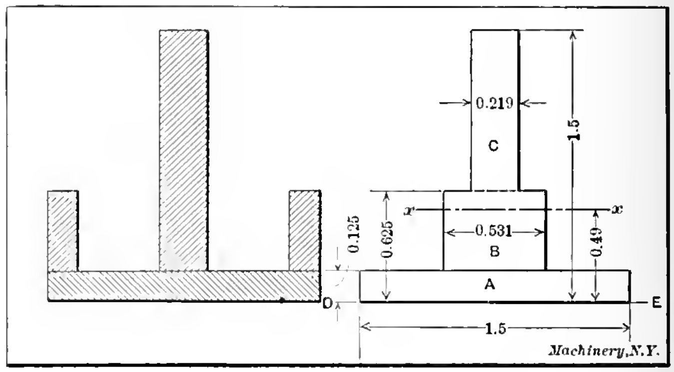

Fig. 2 Fig. 3

The calculation may then be tabulated as shown in the accompanying table. The distance from the axis DE to the neutral axis xx (which will be designated as d) is found by dividing the sum of the geometrical moments by the area. The moment of inertia about the neutral axis is then found in the usual way by subtracting the area multiplied by d^2 from the moment of inertia about the axis DE. The slight differences in the results from those given in the article in the January issue previously referred to are due to the use of a 5-inch slide rule in the present calculations.

TABULATED CALCULATION OF MOMENT OF INERTIA

Section	Breadth b	Height h	Area $b(h_1 - h)$	h^2	Moment $\frac{b(h_1^2 - h^2)}{2}$	h^3	I about axis DE $\frac{b(h_1^3 - h^3)}{3}$
A	1.500	0.125	0.187	0.016	0.012	0.002	0.001
B	0.531	0.625	0.266	0.391	0.100	0.244	0.043
C	0.219	1.500	0.191	2.250	0.203	3.375	0.228
			$A = 0.644$		$M = 0.315$		$I_{DE} = 0.272$

$$\text{Distance } d \text{ from } DE \text{ to } xx = \frac{M}{A} = \frac{0.315}{0.644} = 0.49.$$

Moment of inertia of whole section with reference to its neutral axis:

$$I_n = I_{DE} - Ad^2 = 0.272 - 0.644 \times 0.49^2 = 0.117.$$

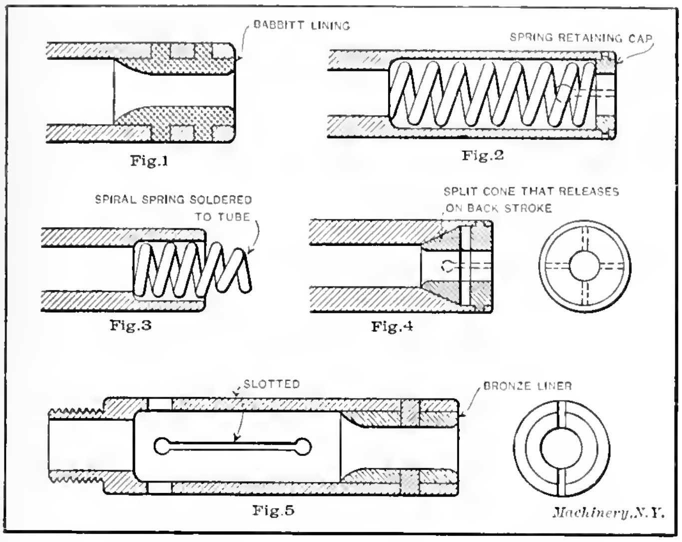
LETTERS ON PRACTICAL SUBJECTS

Articles contributed to MACHINERY, with the expectation of payment must be submitted exclusively

EXPERIMENTS WITH AUTOMATIC SCREW MACHINE FEED-FINGERS

When reading my November MACHINERY I was most interested in the "Dont's for Screw Machine Operators" by Mr. Paul W. Abbott, and the one that attracted my attention the most was "Don't let the first few pieces go by without looking to see if the feed-finger is scratching the work." Now I wonder if the writers of "Dont's" ever realize what it means to attempt to follow out their suggestions and then not altogether succeed in attaining the object in view.



Figs. 1 to 5. Various Types of Feed-fingers designed to prevent Scratching the Stock

The superintendent of a large factory once decided on the particular don't mentioned. He argued that to get closely-rolled bright stock and then mark or scratch it on the unturned parts was foolishness, so we had to get busy. To begin with, there was no thought of discarding the feed-finger and feed-tube for any other manner of feeding, as this method has many decided advantages peculiar to itself, not the least being that there is always a full chuck length of material left in the chuck when the feed-finger has parted with the last part of the bar, and there is also a minimum length of scrap.

When various makers were approached, they could suggest nothing that did not decrease the machine's capacity, such as making a 1-inch machine into a ¾-inch machine, etc., and

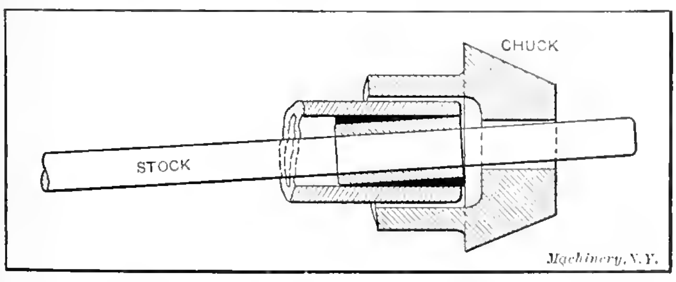


Fig. 6 Illustration showing on an Exaggerated Scale the Relative Positions of Stock and Chuck when Feed-finger Bushings are out of Line

indeed, the lack of space often cripples many of the devices which one immediately thinks of for this special operation.

We tried hardening and lapping the fingers and nicely rounding the backs of them, but while the results were better, they were far from satisfactory. The tinning of the fingers was then tried but this method was also unsatisfactory. Babbitted fingers, such as shown in Fig. 1, were then used, but these were constantly being enlarged by the new bars and relining was frequent.

Fingers such as shown in Figs. 2 and 3 were next tried, but the faults were numerous and the up-keep large, so these designs were also discarded. The design of Fig. 4 was then made and while it proved to be a useful type of finger, it had the disadvantage that when feeding up to a stop with a slight overfeed, it locked itself and caused the heating of the feed-tube; where it can be applied, however, for open feeding, it is very useful.

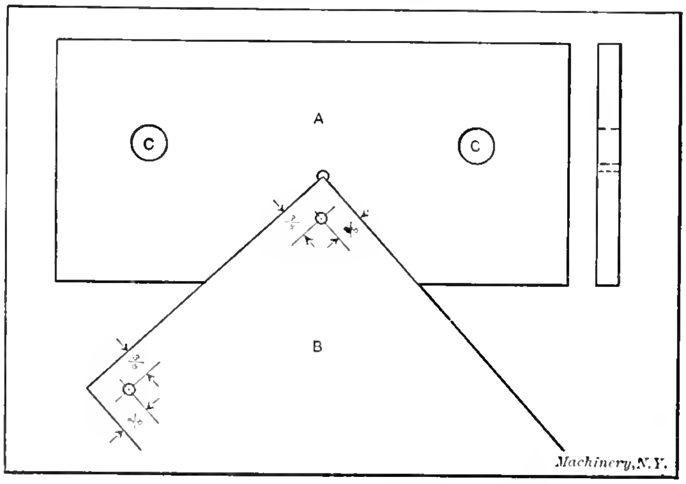
Solid bronze fingers were tried but these were rejected on the score of expense and also because they have little spring tension. Bronze bushings were next used and they, if anything, proved the best, but they left a lot to contend with. These fingers were made as shown in Fig. 5. The bushing was soldered in solid and then pinned in position so that introducing new bars would not knock it out. When the bushing was soldered in position it was placed in a little fixture and drilled to a suitable size; it was found necessary to do this as the bushings were sometimes placed in the tubes out of line, consequently the bar was fed forward out of line with the machine, as illustrated on an exaggerated scale in Fig. 6, thus putting extra work on the chuck and quickly undermining its accuracy.

As can be seen, this Don't caused considerable trouble and I should like to know if anyone else has had any particular experience with this special Don't. No doubt Mr. Abbott has some ready means of overcoming this trouble, inasmuch as he makes special refereuce to it in his interesting article.

J. S.

PLATE LOCATING FIXTURE FOR DRILL PRESS

A useful fixture for the drill press, that is used for locating steel plates, etc., that are to be drilled, is illustrated by the accompanying sketch. This fixture does away with the operation



Fixture for Locating Plates on the Drill Press

of laying out each hole preparatory to drilling. If a number of plates are to be drilled in the manner illustrated, the corner of one plate is first laid out and the hole drilled; the drill is not removed from the hole until the fixture *A*, which has been previously notched as shown, is brought against the plate *B* and is fastened to the table of the drill press by two bolts which pass through the holes *C*. The fixture is then ready for use, and it will locate the plates for the rest of the holes by simply inserting them in the locating notch.

I do not claim that this fixture will enable all the holes to be drilled with extreme accuracy as to distance, etc.; it is, however, a useful and time-saving fixture that I have often seen used with good results upon many ordinary jobs for which extreme accuracy was not essential.

C. F. EMERSON

DIAGRAM FOR GOTHIC LETTERS AND FIGURES

A diagram giving the proportions of Gothic letters and figures, is shown in the accompanying engraving. The system is so simple that the diagram is self-explanatory. By its aid Gothic letters and figures of any size may be rapidly drawn by means of ordinary instruments. In some cases,

appearance has been sacrificed to ease of construction, but the dominant consideration throughout has been absolute legibility. Many such systems of lettering have been prepared, some of which possess considerable artistic elegance, but none state with clearness the actual dimensions employed and, consequently, the construction of the letters is difficult. It was, therefore, decided to evolve a perfectly definite system of proportions. This system has been used for 5/16-inch letters on a drawing requiring unusual care, and also for painters' stencils fifty inches high. In both these extreme cases, and for many intermediate cases, the system has been found satisfactory to all concerned. CARINGTON C. CARISS

London, Ontario.

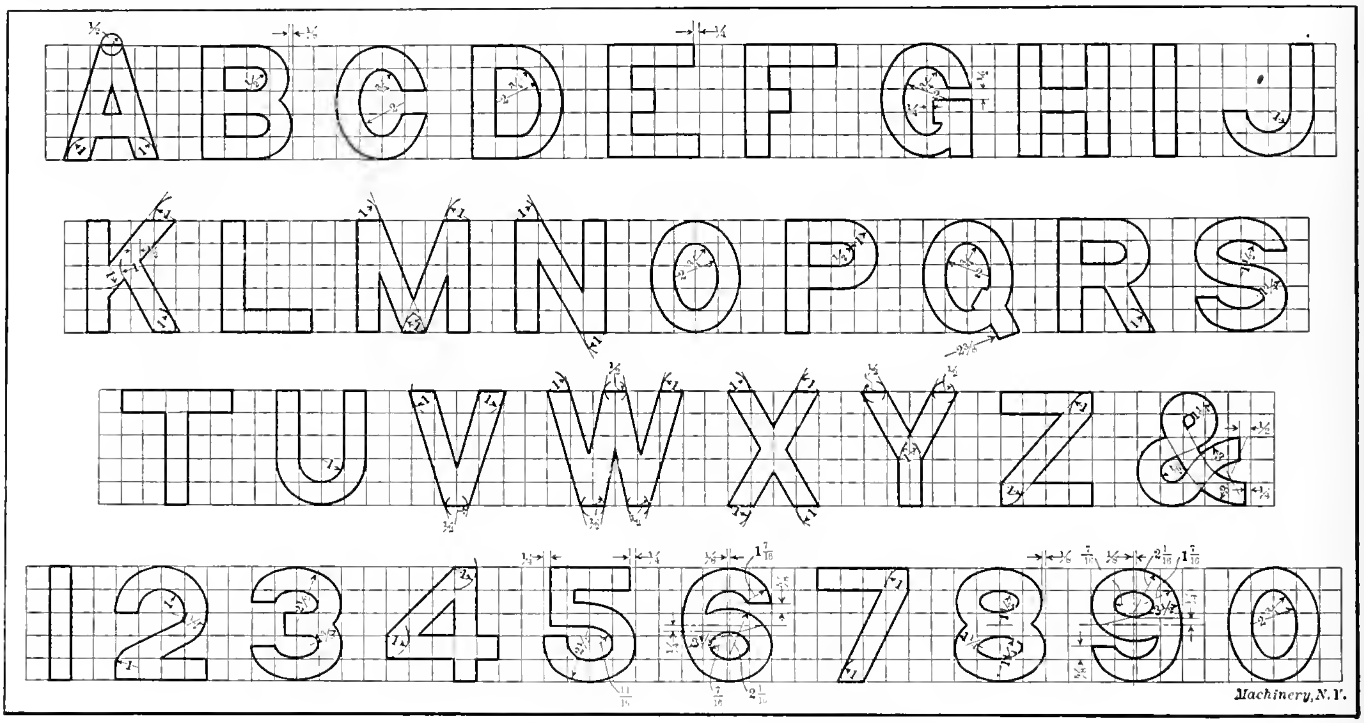


Diagram giving Proportions for Gothic Letters or Figures of Any Size

CLAMPING LONG AND SLENDER WORK

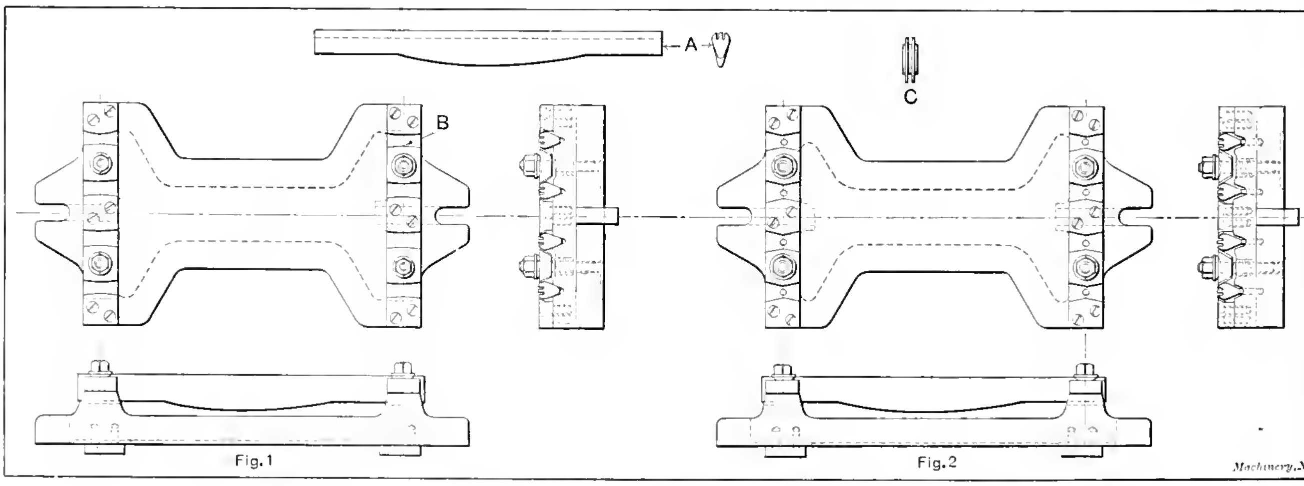
Good examples of both correct and incorrect methods of clamping a long, slender and rough casting are illustrated in the two fixture designs shown in the accompanying illustration. The piece to be milled, which is made of cast iron, is shown at *A* in the drawing. It requires a flat surface on top and two slots that must be milled straight, with only 0.0015 inch limit sideways. This is done in one cut with a gang cutter *C*. Four of the pieces are milled at the same time, but there is no reason why more than four could not be done at once, providing the milling machine table is wide enough.

In Fig. 1 is illustrated a design of fixture for holding the work that is faulty. It will be seen that the clamps are rounded at *B* and that the work rests in V's, but although the clamps are rounded, the bearing that the work has in the V's will result in bending it. In Fig. 2 an improved design is shown. The clamps are pointed instead of rounded, and the work rests on points instead of V's, and for this reason it is not distorted by clamping.

It is obvious (but often ignored), that if a rough casting is clamped onto a flat surface it will be bent.

The vital difference, therefore, in the two designs, is that one clamps on surfaces and the other on points. When the job is clamped as shown in Fig. 1, it is held at each end by four points, that is, between two clamps and the two sides of the V, while in Fig. 2 it is in contact with only three points. One other important feature is that the points are all in line with each other, making it impossible to bend the work. O. R. BARRETT

Luton, Bedfordshire, England.



Figs. 1 and 2. Two Fixture Designs Illustrating Incorrect and Correct Methods of Clamping Slender Work

DESIGN OF TOOL CHESTS AND CASES

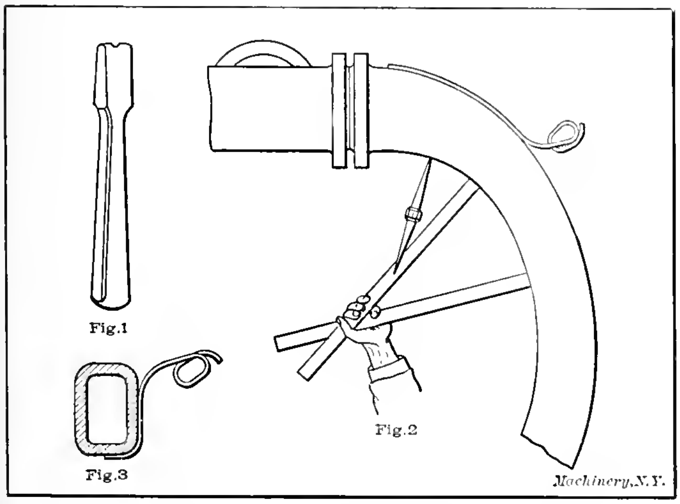
In the December number of MACHINERY there appears a suggestion by Mr. J. F. Winchester on the design of cases for small tools. As I am constantly on the road erecting textile machinery for a large English concern, I have had an excellent opportunity of finding out what is most needed in this direction. I obtained from one of your advertisers (Lyon Metallic Mfg. Co.) a steel machinist's tool-box, the weight of which is much less than that of a wooden one of the same size. When all the cases for micrometers, etc., were replaced by thin leather ones, which in my opinion answer the purpose much

better than the morocco cases that usually come with such tools, there was lots of room in the steel box and a great reduction in weight, which was important as I had continually to pay for the weight. I have been trying for some time to get a steel box for the heavier erecting tools, as wooden boxes, even when heavily banded, are constantly being split, to say nothing of the extra charges for weight. J. A. Caless

Providence, R. I.

FINDING THE RADIUS OR SHAPE OF IRREGULAR PARTS

Mechanics in the various trades often find it necessary to obtain the radius or shape of irregular parts of machinery or patterns, thus making the use of templets necessary. Making templets, even when they are made from wood or cardboard, takes a great deal of time, and in many instances it is inconvenient to get at the work. For tool, punch or die work, metal templets are, of course, necessary. When great accuracy is not required, I have a method of obtaining irregular shapes which has proved satisfactory, and which will, doubtless, be of interest to many readers of Machinery. The shape of irregular parts may be easily obtained by the use of a piece of 1/8 inch soft solder wire. This wire is bent to conform to the shape of the work, but before this is done, it should be straightened and all small kinks that may be in it from previous use, removed. The wire is then formed to the shape of the work with the end of a stick, such as shown in Fig. 1. When it is well formed and lies evenly it should be removed and laid on a flat board; then, by adjusting a pair of dividers until one point follows that part of the wire which was in contact with the work, the radius may be ascertained. Fig. 2 illustrates the application of the wire to a locomotive steam pipe which has many different radii, and irregular shapes that would be difficult to measure, especially with the pipe in place. This illustration also shows a very convenient way to get the inner radii. Two pieces of wood are held with one hand, as shown, and the dividers are held with the other, one point resting on the wooden support, while the other is adjusted to the correct radius. Fig. 3 shows the method of using the wire to get the radius on the cross-section of the steam pipe, which usually varies from end to end.



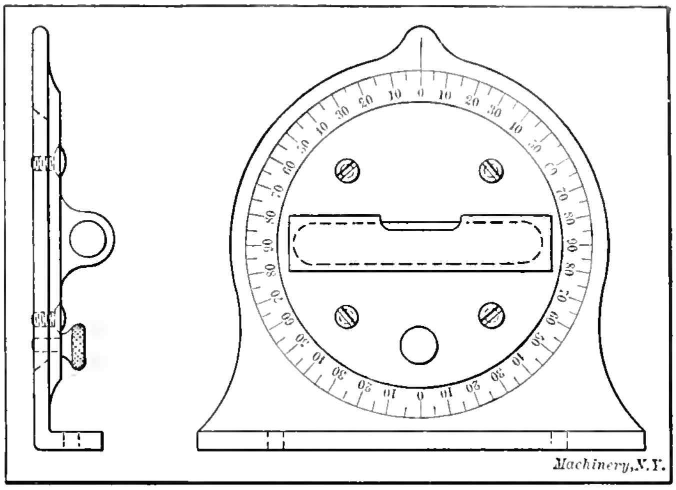
Illustrations showing the use of Soft Solder Wire for obtaining Radii on Locomotive Steam Pipe

Chicago, Ill. C. V. Frisk

NEED OF A LEVEL ON THE MOTOR DRILL

It is time that a level was applied to the motor drill; at least, one similar to the kind used on a combination square which would not cost the maker much and would be appreciated when drilling horizontal or angular holes. The level shown in the illustration would be a convenient form, and it would enable the drilling of holes to any angle by setting the protractor to the angle required and then holding the level horizontal while drilling. The hole would then be at a corresponding angle and it would not be necessary to have someone to help keep the drill straight. I have used a loose level for this work, but such a level can only be applied when drilling a horizontal hole, without special arrangements, and even when the drill is in a horizontal position, the use of such a level is often impossible as some motors do not have a surface that is parallel to the drill, for leveling. In addition, when the motor is in action, both hands are required for holding the motor and feeding the drill. Therefore the level must be dispensed with and the position of the drill guessed at.

The level should be furnished by the maker of the motor, and the latter should have a face on the body parallel to the drill center line, and two thumbscrews for holding the level so that it may be easily put on or removed.



Level and Protractor for the Motor Drill

I hope that this article will be read by both the makers and users of motor drills. It is, of course, very important to hold the motor as straight as possible when drilling, as side movements cause friction which not only requires more energy, but endangers the motor and temper of the drill, besides making the hole large or elliptical. Many broken drills are the result of this lateral movement when drilling, which could be avoided by the level attachment. A. Nielsen

Cleveland, Ohio.

REPAIR JOB ON AN ALTERNATOR

The burning of a collector ring on three-phase rotary field alternator supplying current to individual motors, forced a tie-up in a factory putting out a food product which was highly perishable. Owing to the nature of the output and the inability of the engineer to temporarily repair the alternator until a new ring could be cast, or one secured from the makers, a highly developed case of uneasiness attacked the management that was not relieved until a smart machinist made a suggestion, which he was allowed to carry out. His scheme, as simple as it was successful, is shown by the accompanying engraving.

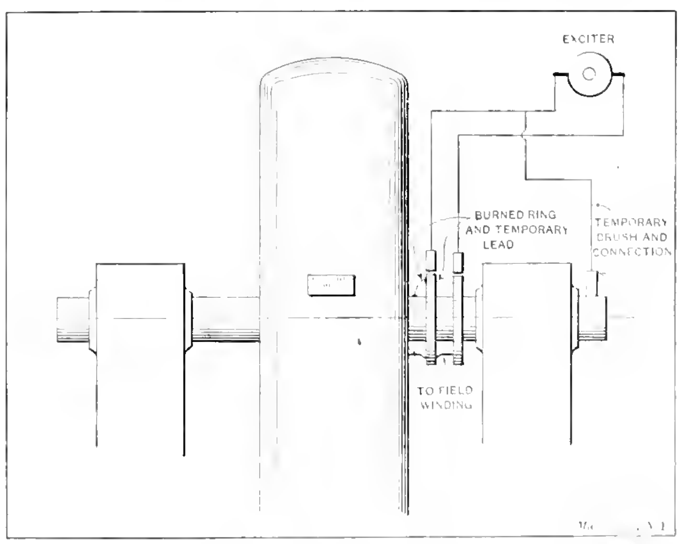


Diagram showing Temporary Repair of an Alternator with a Burned Ring

The brush was first removed from contact with the burned ring. Then by setting the brush in a temporary holder, so that it was in contact with the shaft to which a lead from the burned ring had been soldered, the exciter circuit was closed. This completed the job, and in less than two hours the machine was again running, which it continued to do until the arrival of a new ring from the factory. So, what at first seemed to be a serious breakdown and loss, resulted simply in a slight delay. DONALD A. HAMPSON

Middletown, N. Y.

ADDING, SUBTRACTING AND DIVIDING FRACTIONS

In making half-size drawings, it is often necessary to divide odd fractions by 2. I make use of the following method: Divide the whole number by 2; discard the ½; add the numerator and denominator together and double the denominator.

Example: Divide 15 7/8 by 2. The half of the whole number is 7½, and discarding the ½ we have 7; the numerator added to the denominator = 15; and the denominator doubled equals 16, giving a total of 7 15/16. By this method it is very easy to do this mentally.

Here is another method for adding and subtracting fractions:

Example: Add 9 13/16 and 6 7/16. Subtract the difference between 13/16 and 1 = 3/16; subtract the 3/16 from 7/16 which is ¼. 13/16 and 7/16 added together gives more than 1 so carry the 1 and add the units which makes 16¼. This can also be changed by subtracting 7/16 from 1 = 9/16 and then subtracting that from 13/16 = ¼.

For subtraction, this method is reversed.

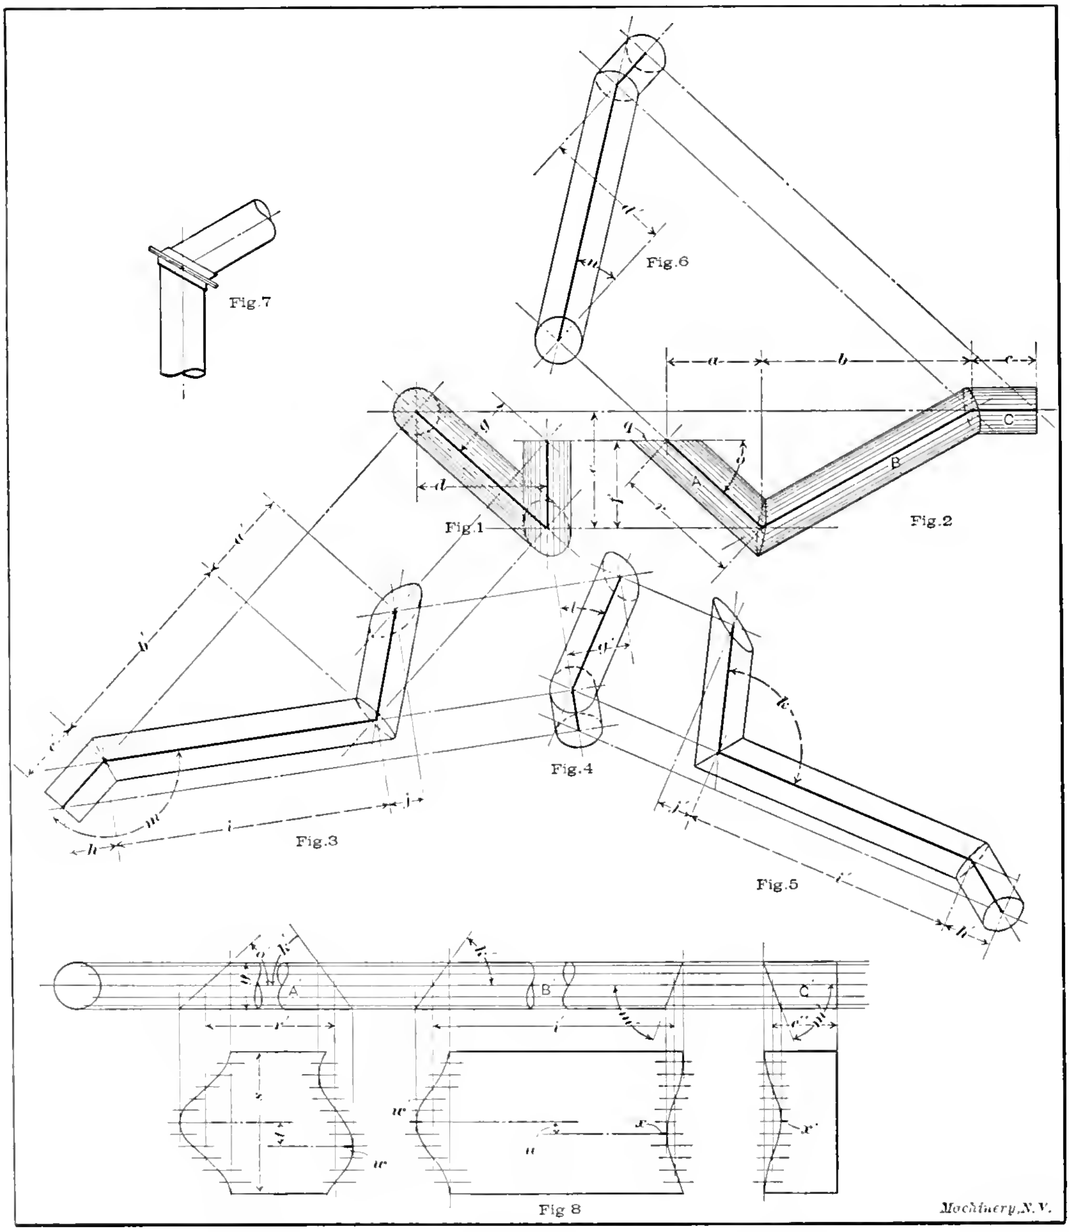
Example: Subtract 6 13/16 from 9 7/16. Add the difference between 13/16 and 1 to 7/16 = 5/8; carry the 1, and add 6 = 7; 7 from 9 = 2, and 2 plus 5/8 = the difference between the two numbers.

I have never seen the foregoing methods published; nor have I come across anyone who has used them, but I find them to be a great help to me. FRANK W. HOLCOMB

Cincinnati, Ohio.

LAYING-OUT AND DEVELOPING THE SHEETS FOR STEEL SPOUTS

It might perplex one, who had not done similar work, to lay out and develop the sheets for a steel spout such as is shown in Figs. 1 and 2 of the accompanying engraving (in which a, b, c, d, e, and f are the given dimensions)) on account of the fact that the true lengths of and the true angles between the various parts have to be obtained before the sheets can be developed. However, the task is not as complicated as it might at first appear, as it is only necessary to work with the center lines. In the illustrations, the center lines are shown heavy and the spout parts are drawn in around them merely to better illustrate the principles involved.



Method of Laying-out and Developing the Sheets of an Angular Spout

Having drawn the views shown in Figs. 1 and 2, draw Fig. 3 making $c' = c$, $b' = b$, and $a' = a$; then m will be the true angle between the pieces B and C, and i will be the true length of piece B. Next draw the view, Fig. 4, making $g' = g$; then l will be the angle made by the center lines of pieces A and C when looking directly along the center line of piece B. Draw the view Fig. 5, making $j' = j$, $i' = i$, and $h' = h$; then k will be the true angle between the pieces A and B. Draw the view Fig. 6, making $d' = d$, and n will be the angle made by the major axis of face q and the center line of piece B when looking directly along the center line of piece A.

To determine the shapes of the flat sheets at the different joints, draw A', B' and C', making $r' = r$, $i'' = i$ and $c'' = c$. Make angle $o' = o$, $k' = \frac{k}{2}$ and $m' = \frac{m}{2}$. Develop the sheets in the ordinary way, as shown, making $s = y\,\pi$, $t = s\,\frac{n}{360}$ and $u = s\,\frac{l}{360}$.

If a lap joint is to be used, allowance must, of course, be

made for it. The sheets as shown should have their edges rolled up from the plane of the paper. When assembling the spouts, points *w*, and *w'*, and *x* and *x'*, should be brought together. The connections may be made with flanges as shown in Fig. 7.

Aurora, Ill.

TEST INDICATOR

The test indicator shown in the line engravings, Figs. 1 and 2, was originally designed for very accurate bench-lathe work, but it has since proved to be a handy tool for all

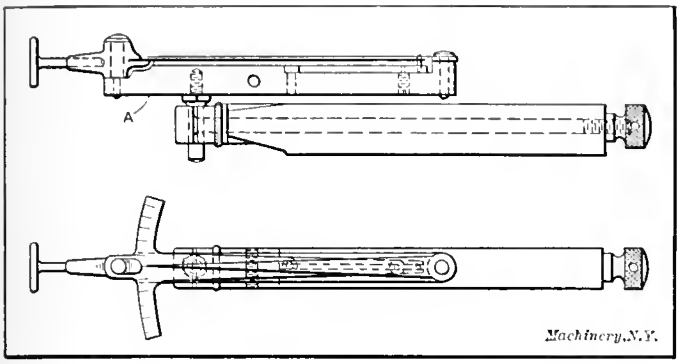

Fig. 1. Test Indicator for Accurate Work

kinds of work requiring accuracy. It is made so that it multiplies the errors in the work 120 times, or in other words, an error of 0.001 inch will show about 1/8 inch on the graduated scale. It will be noticed that the graduations extend from the zero at the center towards each side, so that both positive and negative errers are thus indicated. The design of the indicator can be easily seen by a study of Figs. 1 and 2. It consists principally of a body *A* made of tool steel and two levers and studs. The former is provided with two tapped holes, one on the under side and one on the front side. These holes are intended for studs by means of which the test indicator proper may be held to holders of different types. Examples of two kinds of holders are shown in the illustrations. The indicating device itself consists practically of only two thin levers, one of which is provided with a pointer indicating on a graduated scale as shown. The scale, of course, is graduated after the device is made, so that the graduations are exactly true. The points are made in disk form as shown in Figs. 1 and 2, but points of other shapes can, of course, be used

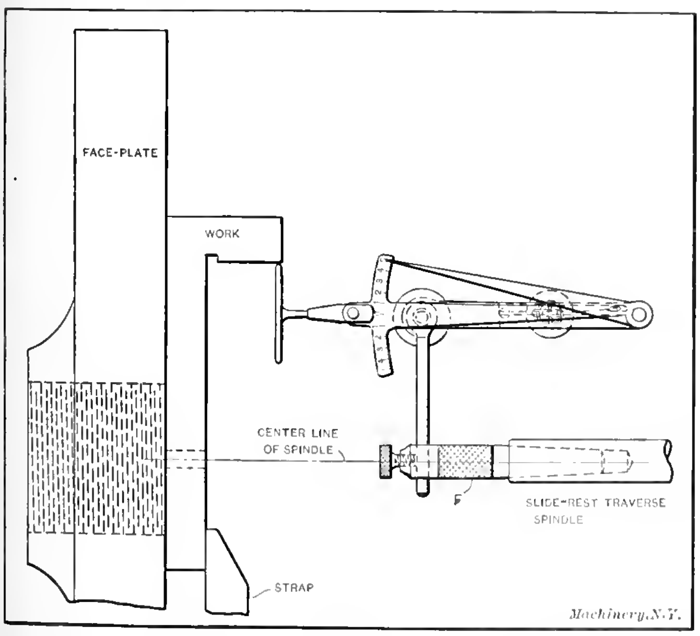

Fig. 2. Test Indicator in use for Setting up Work on the Faceplate

if preferred. Fig. 2 illustrates the use of the indicator in lining up work on the faceplate of a lathe. A number of different attachments may be made and used for special purposes, and holders of different kinds can be adopted. By means of these accessories the indicator may be used on nearly all classes of work requiring a high degree of accuracy.

The uses of the tool will easily suggest themselves. A few jobs on which the writer has used it are for testing the lead of an engine lathe lead-screw, comparing it with a master thread plug; locating buttons in making drill jigs on the milling machine; truing up work held on the faceplate of the lathe, indicating either by a hole already bored, a center, or the outside of the work.

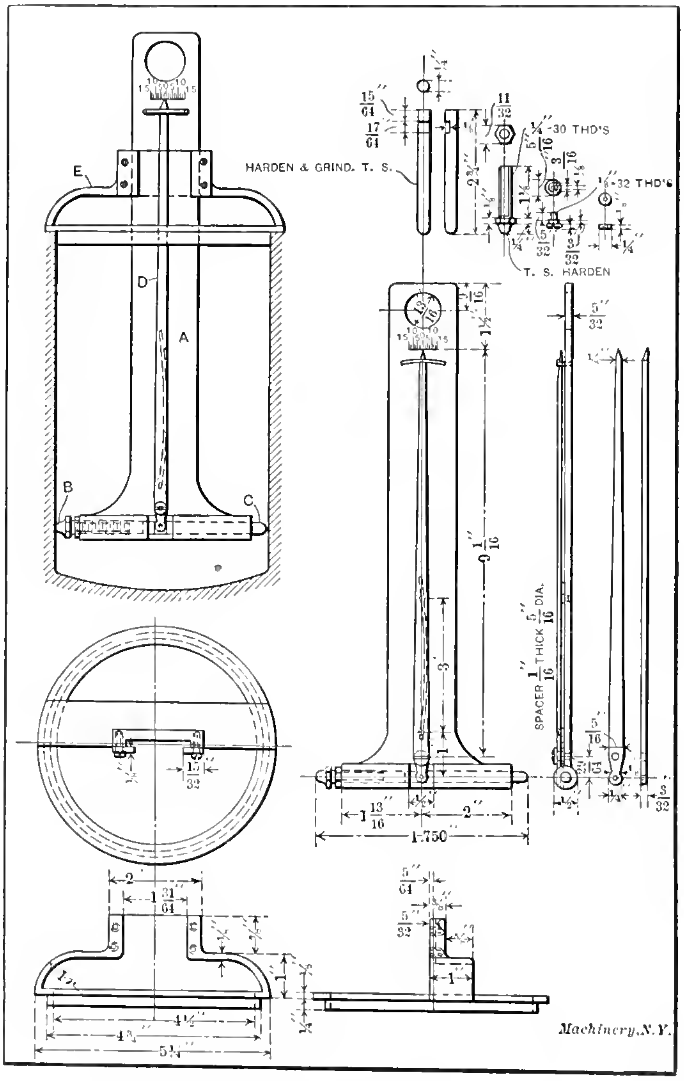
East Hartford, Conn.

DEEP HOLE CALIPERS

There has been considerable written of late on the subject of deep-hole calipers, and after studying the ones described in these columns, I have concluded that the type used at the Olds Motor Works is far more sensitive and accurate. These calipers indicate measurements within 0.001 of an inch, and



Assembled and Detailed Views of a Deep Hole Caliper for Testing Gas Engine Cylinders

they are used in our factory to test the size and alignment of the bore of gas-engine cylinders. As the variation allowed is but 0.001 it is essential that the calipers be well made to insure a long life and unimpaired accuracy. This, of course, makes the first cost considerable, but when the calipers are once finished they will last a lifetime.

These calipers consist principally of a body *A*, a fixed anvil *B*, and a movable anvil *C* which is connected with pointer *D*. The movement of this pointer along the graduated scale shown, indicates the variations in the cylinder diameters. To insure accuracy when the calipers are used by inexperienced hands, a guide *E* is used which fits the bore of the cylinder, as shown, and through which the outer end of the caliper passes. This guide so locates the calipers that the axes of the anvils intersect the axis of the cylinder and are at

right angles to it. Care is taken to have that part of the guide which enters the cylinder a very accurate fit. The ways into which the caliper body slide are carefully scraped to a perfect bearing.

The body of this caliper is a steel forging that is proportioned, of course, according to the size of the caliper. The anvil C is a sliding fit in a reamed hole in the cylindrical boss shown. The oposite anvil B is provided with a fine thread so that it may be adjusted when the calipers are being set to the size for which they were designed. A hexagon lock-nut holds this anvil securely in place after it is set in the desired position. Of course the caliper and guide are made for a specified size of hole.

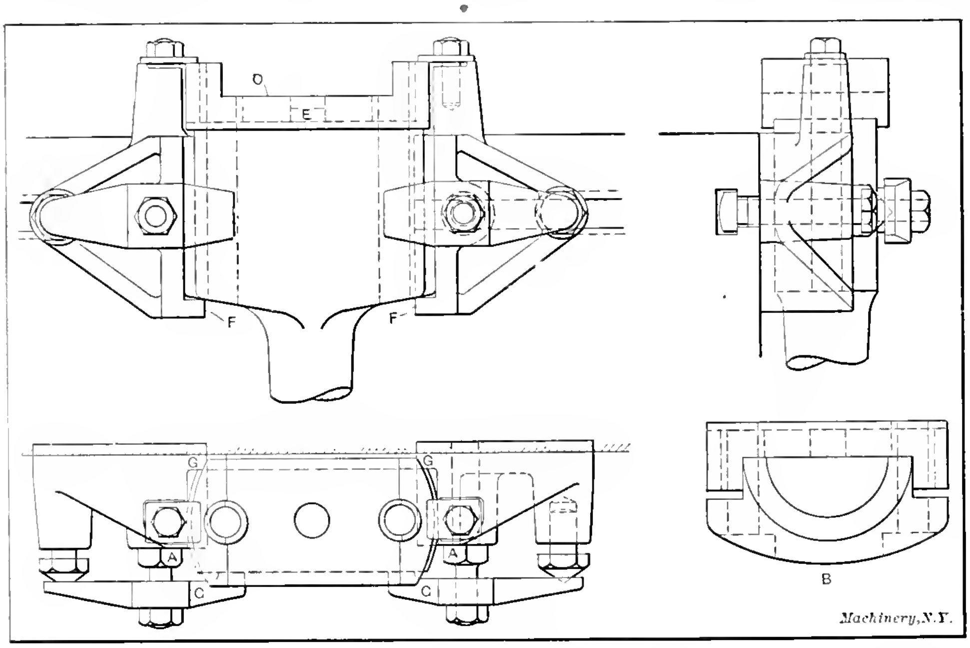
To determine the spacing of the graduation lines, an outside micrometer was set to the required dimension, and was made to bear heavily enough upon the movable anvil to bring the indicator hand to the center line. The threaded anvil was then screwed in or out until it came into proper contact with the anvil of the outside micrometer. It was then found that the point of the indicator hand had a movement of 1/50 inch, for a movement of 0.001 inch of the anvil. The caliper body was then securely fastened to an angle-plate and the graduation lines were put on with a height gage. The large hole at the upper end of the caliper body affords a hand hole that makes it more convenient to use the calipers.

This makes a very substantial tool, and it is giving perfect satisfaction in our inspection department. E. H. Pratt

Lansing, Mich.

DRILLING BOLT HOLES IN CONNECTING-ROD ENDS

A pair of special clamps for holding and aligning gas engine connecting-rods while the bolt holes are being drilled, and also the jig used for locating the drill are shown in the accompanying illustration. The end of the finished rod is held between the two clamps or special angle-plates. These clamps each have a rib or tongue on the back that fits a T-slot of the machine table. In this way they are set parallel to each other and in line with the drill spindle. By tightening the nuts A, these plates are fastened to the machine. The same bolts that hold the plates to the table are also used for tightening the clamps C. One end of these clamps rests on adjustable screws with conical casehardened heads, which may be set to different heights to correspond with work of different thicknesses. On the top of each angle-plate there is a boss in which is tapped a small stud that is used in conjunction with the clamps shown to hold the drill jig D. This jig is used for drilling the outer half of the bearing brass, as well as the connecting-rod bolt holes. A channel is planed in one side of the jig, so that it is a snug fit over the end of the rod, while on the other side it is planed out at right angles to the first side as shown. The projections thus formed on either end, fit over the bearing brass as shown at B. The jig is further located for drilling the bolt holes in the rod end, by a central hole which fits the projection E on the rod.

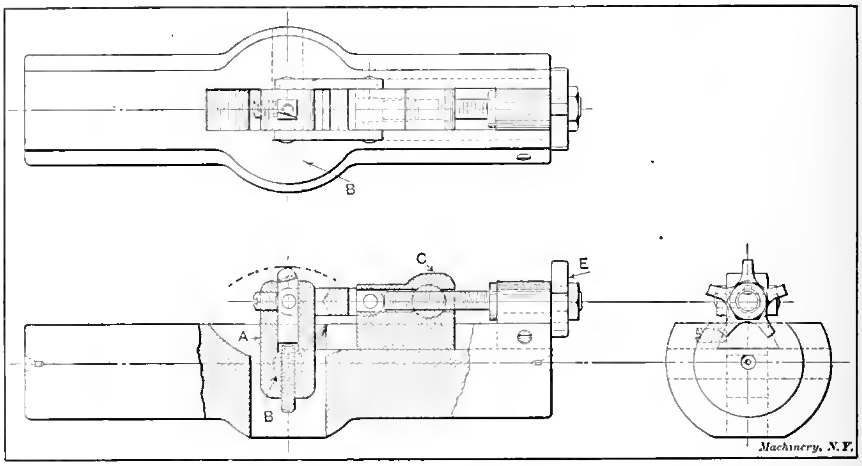


Special Clamps and Jig for Drilling Connecting-rod Ends

After the connecting-rod is turned and planed, and is ready to be drilled, it is placed between the two plates which are movable sideways. The work rests on the lugs F and the plates are fastened, as before stated, by tightening nuts A. The rod is then clamped against the faces G. The drill jig is then placed on the end of the rod and lightly clamped against it. The drilling is then done by the usual method. When drilling the holes in the outer half of the crankpin brass, with the jig in the position shown at B, the tool steel bushings not only locate the drill properly, but take the side thrust while the drill is cutting on one side only, through part of the hole.

P. A.

SPHERICAL BORING ATTACHMENT



Compact Design of Spherical Boring Attachment for the Lathe

The design of spherical boring attachment illustrated herewith, is in use in one of the largest automobile concerns in the country. This attachment is used on the lathe in connection with a fixture that is fastened to the carriage for holding the work. It is held between the lathe centers and is driven by a dog. The boring tool is clamped in a tool-holder A that is attached to a pin B, which is free to turn in the bar. The upper end of the tool-holder is connected with a slide C by two links. Through this slide the feed-screw of the tool passes. As the bar revolves, the star-wheel E is actuated by a dog which is clamped to the tailstock spindle, thus giving the tool a circular movement about the axis of the pin B, as indicated by the dotted line. This movement combined with the regular rotary movement of the tool produces the spherical surface. G. R. Richards

Brooklyn, N. Y.

TO GET THE FOURTH DIMENSION OF SPACE

Take a hecatonicocehedridgon and multiply by four,
A sexicocehedrigon plus half as many more;
Put in some polyhedrigons where gaps suggest a minus
And you will have a polyhedral-perpendodicahedrinus.

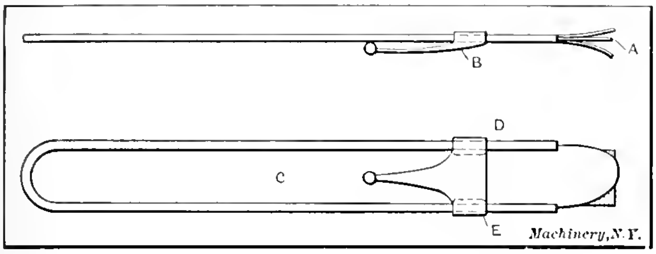
SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

TO PREVENT LOSS OF POCKET SCALE AND CASE

Nearly every man in the machine shop carries a six-inch steel scale, and often loses it because it so easily slips from his pocket. The device shown in the accompanying sketch has overcome this difficulty for the writer, and it is so simple and easily made that others may provide themselves with it

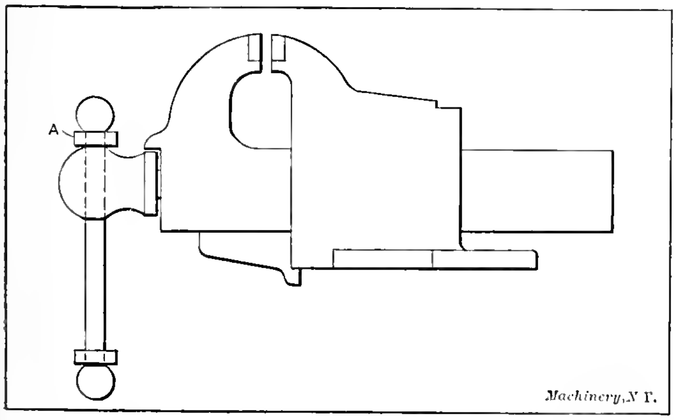


with very little trouble or expense. *A* is a 6-inch steel scale; *C* is a leather case which was purchased with the scale; *B* is a fountain pen "clip" which has been bent to fit the case and fastened in place with a little solder at *D* and *E*.

The clip should be so placed that it may grip the upper edge of the vest pocket, before the lower end of the case reaches the bottom of the pocket. W. H. K.

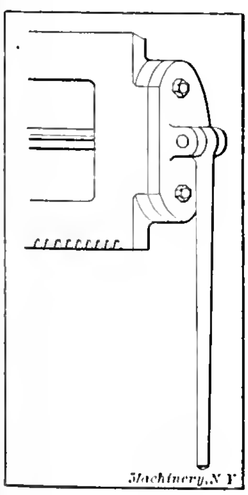
HAND PROTECTOR FOR VISE HANDLE

An excellent device for protecting the hand from a falling vise handle consists of a rubber ring *A* with a section about



⅜ inch thick by ½ inch wide, and having a hole a little larger than the handle. This ring can be stretched into place and when the handle drops it will not catch the skin and pinch it black and blue. A. G. Johnson

Two Harbors, Minn.



HANDLE FOR RADIAL DRILL ARM

Any one working on a large radial drill knows how difficult it is to move radially the arm when the head is raised. We have overcome this difficulty to a large extent by bolting a cast bracket to the end of the arm, to which is attached a handle as shown in the accompanying illustration. This handle, which is 24 inches long, is closely fitted to the bracket so that there is sufficient friction between it and the lugs to hold it in any position.

W. F. Oliver

Plainfield, N. J.

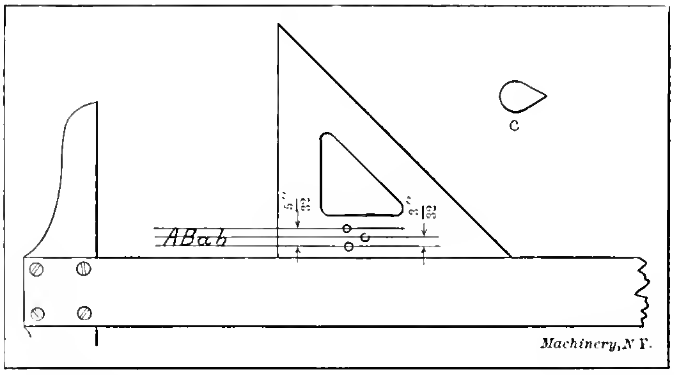
METHOD OF TESTING CANS FOR LEAKS

When searching for a leak in an automobile or bicycle tire, it is wet or placed in water so that the bubbles caused by the air will indicate the leaks. This same method is used by manufacturers of tin cans to find out if they leak before filling; but instead of putting an air pressure in the cans they are placed in a sort of conveyor, which after automatically putting a rubber cover on them, immerses them in hot water. The heated air in the cans expands, which causes bubbles to follow those which have leaks as they are carried along under the water; the defective cans are then picked out by an operator. Herman Jonson

New York City.

DRAWING GUIDE LINES FOR LETTERS

As many firms require a uniform height for the letters on drawings, the following scheme may be appreciated by those who draw guide lines for lettering in the usual way: Drill two or more 1/16-inch holes in a triangle, one above the other a distance equal to the height of the letters desired, as shown in the illustration. In this case the small letters are 3/32-inch high, and the capitals 5/32 inch. These holes are used

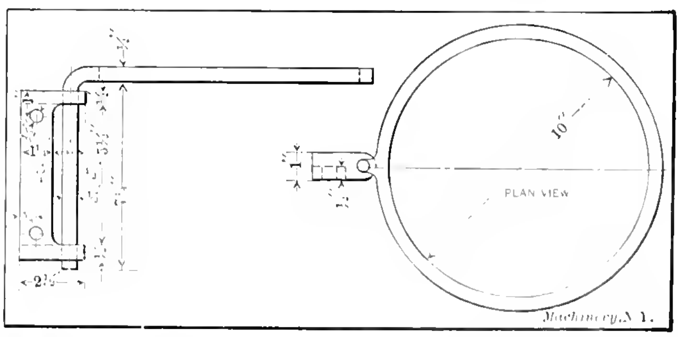


as a guide for the pencil, while sliding the triangle along the edge of the T-square. C. R.

[With round holes there will doubtless be some difficulty in drawing all lines to the same height, as the pencil point will not always be located in the same place. By making one side of the hole V-shaped, as shown enlarged at *C*, the pencil will be centered in the bottom of the V as the triangle is moved along.—Editor.]

BRACKET FOR WASH BUCKET

Many factories are without a wash room, the washing being done in buckets which are filled by a boy and set around the room in the most convenient place. By this method much water is spilled on the floor and spattered on the work. A good bracket for wash buckets is made as follows: Take a flat piece of machine steel of the dimensions shown in the accompanying sketch, and bend it at right angles at each end;



then drill one-half inch holes through the lugs thus formed. With a piece of one-half inch round iron, form a hoop to fit around the bucket, and also make a right-angle bend to fit the holes previously drilled through the lugs in the bracket. The holder is then ready to fasten to the bench, under which the bucket is swung out of the way when not in use.

E. H. Pratt

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

FORMULA FOR AREA OF LOCOMOTIVE EXHAUST NOZZLES

J. W. H.—Will you give me the formula for finding the size of the exhaust nozzles for coal-burning and wood-burning locomotives?

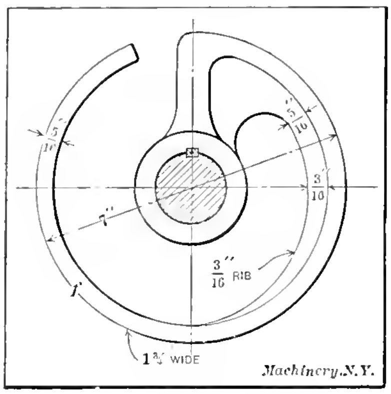
A.—The formula used by Mr. C. J. Mellin, consulting engineer of the American Locomotive Co., Schenectady, N. Y., for coal-burning locomotives is:

$$d = 0.156\sqrt{\frac{S \times R}{S + 0.3\,R}}$$

in which d = diameter of the exhaust nozzle, R = area through tubes, S = grate area. All dimensions are in inches. For wood-burning locomotives, the coefficient 0.156 is changed to 0.140. The practice varies with different railway companies, however.

DESIGN OF EXPANSION BRAKE RING

J. D. R.—The expansion brake ring shown in the sketch is closed in 3/8 inch measured on the periphery, and turned to 7 inches diameter and placed in a case bored to fit. What is the radial pressure against the case when the ring is made of Parsons cast manganese bronze? The situation is similar to that of a piston ring in a cylinder except that one end of the ring is fixed on a central shaft instead of its having both ends floating as in the case of the piston ring.



A.—The question is submitted to our readers. It may be assumed that cast manganese bronze has a modulus of elasticity of 14,000,000. A treatment of concentric and eccentric piston rings can be found in Unwin's "Machine Design," Part II.

INVENTOR OF THE SENSITIVE DRILL

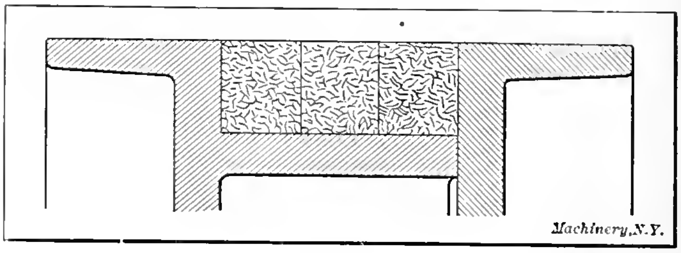
A. L. D.—Who invented the so-called "sensitive" drill, that is, the type in which the drill spindle is driven directly by a thin, narrow belt, and fed to the work by a directly connected hand lever?

A.—The invention of the sensitive drill, which was primarily made to prevent heavy breakage of small drills, is commonly credited to Dwight Slate, one time head of the well-known Dwight Slate Machine Tool Co., Hartford, Conn., who died in 1906. See MACHINERY, July and September, 1906. Mr. Slate's claim to the invention was not supported by the facts, however, and he failed to obtain a patent. In a letter by Mr. Frank H. Pierce, published in the *Hartford Courant*, August 11, 1906, shortly after Mr. Slate's death the following statement was made: "During the term of the late Hon. Ezra Clark as president of the National Screw Co., Mr. Slate was engaged as draftsman and he found there the sensitive drill set up and running as it had been for a long time before he went to work for the screw company. This drill was invented by Elijah S. Pierce, general superintendent of the National Screw Company, who also made the drawings for it and had it built and run under his personal supervision. Mr. Slate was quick to see the excellent mechanical points of the drill, and when he started a shop of his own the commercial value of it appealed to him. He began manufacturing the drill and sold a great many. He tried to get it patented but was unsuccessful."

PACKING FOR VACUUM PISTONS

E. A.—We have a vacuum pump of the vertical type that is equipped with water-packed pistons, and we have had considerable trouble keeping the vacuum pistons in good working condition. Will bronze rings work all right on a brass liner, and be an improvement on a solid piston?

A.—We would advise you to discard the water-packed pistons and replace them with ones having square fibrous packing. A packing of this kind which has been used for many years by a firm which manufactures a high grade of vacuum pumps, may be obtained from the Revere Rubber Co., 59 Reade Street, New York. The pistons should have a single groove, as shown in the engraving, that is wide enough for three of the fibrous rings. For pistons larger than eight or ten inches in diameter, a cast iron eccentric spring-ring should be inserted beneath the fibrous rings, to set them out against the cylinder wall. This spring-ring, while not absolutely necessary, should, preferably, be employed in connection with comparatively large pistons when a high vacuum has to be maintained. The groove in which the fibrous rings are placed should be somewhat wider than three times the width of the packing, as the latter is expanded considerably by the moisture which it absorbs. For the same reason the depth of the groove, when the spring-ring is not used, should be slightly in excess of the thickness of the packing. These fibrous rings should also be cut a little less in length than the piston circumference to allow for elongation. When the rings are finally inserted, the joints should, of course, be separated to prevent leakage. The amount of expansion may be determined by soaking the rings in water until they are completely saturated. If the packing swells to such an extent as to cause the piston to stick, the trouble may be overcome by removing one or more of the thin strips or layers which form the packing, from the side of one of the rings. For pistons in the neighborhood of ten inches in diameter, the size of the packing should be about 1/2 inch square. For larger pistons up to 18 or 20 inches, the packing should be from 3/4 to 1 inch square. This fibrous packing will be found more satisfactory for a vacuum pump than metallic rings, though babbitt rings, which are also set out by a cast-iron spring-ring, have been used with considerable success.



* * *

PROCESS FOR COATING STEEL WITH COPPER

Copper-coated steel has been on the market for several years and is much used where strength is required with ability to resist corrosion and erosion, as in the case of steam turbine blades. A process has recently been made public for coating steel with copper that is of interest. A steel billet that has been given a preliminary treatment is immersed in a bath of copper at a temperature so high that the surface of the billet is partially dissolved; the steel unites with the copper and forms a steel-copper alloy coating on the billet that firmly adheres when withdrawn from the bath. The billet is next placed in a mold, great care being exercised to prevent the destruction of the alloy film by oxidation, and a final coating of pure copper, which readily welds to the previously alloyed surface, is cast around it. In this way the two metals are so firmly united as to withstand sudden temperature changes, drawing, cutting and mechanical manipulation generally. When drawn through dies the reduction of cross-section areas of copper and steel is almost exactly proportional to their original areas in the billet.

* * *

A large German electrical concern uses its erecting shop for advertising purposes in a very effective way. On each large casting is painted in white letters the name of the customer of the machine for which the casting is intended, together with the size and capacity of the complete machine. Visitors and prospective customers are taken freely through the shops so as to be duly impressed in favor of the firm, as they find that their friends or competitors have already placed orders.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

MILLED SCREW AND MACHINE CO.'S UNIVERSAL THREAD MILLING MACHINE

The machine illustrated in Figs. 1 to 4 inclusive, is a universal thread milling machine, made by the Milled Screw & Machine Co., of Sayre, Pa. The points of interest in the design relate particularly to the simplicity of the mechanism, the avoidance of delicate or rapidly revolving members, and the support and driving of the work in a way which insures freedom from all avoidable strains arising from cutting or driving.

The machine consists essentially, as will be seen in Figs. 1 and 2, of a bed of the lathe type, carrying at one end a headstock mechanism by which the lead-screw is fed forward and rotated; and at the other a spindle-driving mechanism by means of which the cutter is driven, while set in any angular position required by the thread being cut. It will be seen that the work and the lead-screw are mounted on the same axis, so that the strains are taken in a straight line, with no possibility of bending or overhang. The lead-screw is of unusually large diameter to resist torsional stresses, and is mounted over the center of the bed. The blank to be threaded is gripped in a chuck connected directly with the end of the lead-screw. The screw at this end is carried by a sliding carriage, which gives it the necessary support. The blank is gripped from the outside and no centers are used or required.

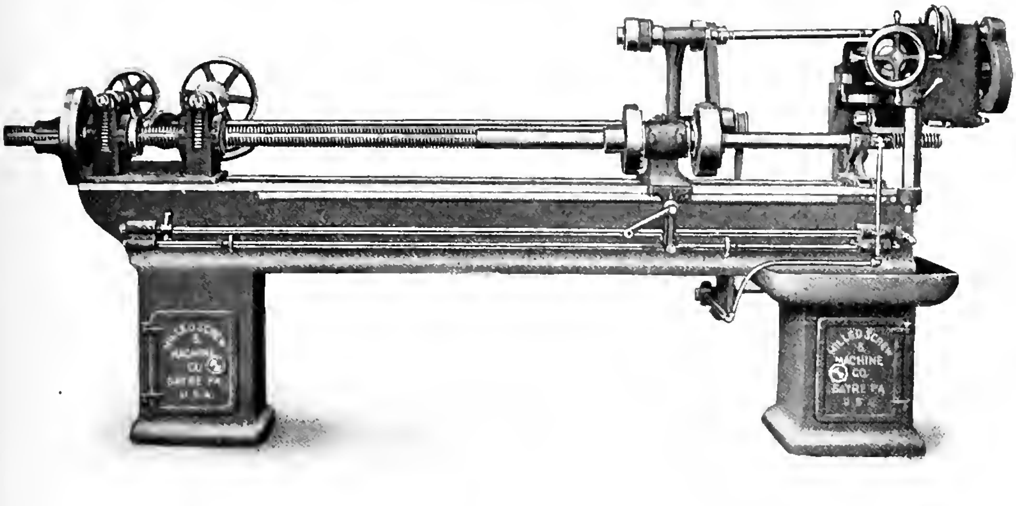


Fig. 1. Universal Thread Milling Machine, of Direct and Simple Design

The Cutter Head

Details of the cutter end of the machine are shown in Fig. 3. Power is received from the countershaft on the grooved pulley *A* at the top of the head. This is connected by suitable gearing with the cutter spindle, the whole being mounted on a swiveling bracket provided with graduations as shown at *B*, which permit it to be set to the calculated helix angle. The cutter head is supported at both the front and the back of the bed. The work is held directly beneath the cutter by a bushing in rest *C*, which is cut away at the top to allow access to the work. The adjustment for depth of cut is made by handwheel *D*, which is provided with a large diameter dial reading to thousandths of an inch.

The feed and revolving motion for the screw to be cut is obtained from driving pulley *A* through shaft *E*, with which it is connected by universal joints. The joint at the right is placed directly over the axis of angular adjustment of the cutter head, so as to make a minimum of change in the end position of the shafts. The bracket *F* supports a countershaft arrangement which, by means of the two sets of cone pulleys shown, gives nine rates of feed to the work for each cutter speed. From here the motion is conducted through shaft *G* to the feeding head at the rear of the machine, which is more clearly shown at Fig. 4.

The Lead-screw Controlling Mechanism

The lead-screw *H* of the machine is solid, of large diameter and carefully made. It passes through the hub of worm-wheel *J*, to which it is keyed and from which it receives its rotary motion. It is free, however, to slide through it axially. Worm-wheel *K* has mounted on its outer hub a disk *L*, which carries jaws *M*, bored to form a nut for engaging the thread of lead-screw *H*. By a construction very similar to that of the ordinary two-jawed chuck, these half nuts *M* may be closed down on the lead-screw or withdrawn from it, permitting the screw and the work connected with it to be freely moved in an axial direction. Worm-wheels *K* and *J* are driven from shaft *G* through worm-gearing at *N*. The worms driving *J* and *K* are connected by change gears *O* and *P* and idler *Q* as shown.

Setting the Change Gears for Various Pitches

The relation between the rotating and threading movements in the head shown in Fig. 4 will best be understood by first considering the simplest case—that of cutting a screw of the same pitch and hand as the lead-screw. For this case idler *Q* will be thrown out of engagement, so that worm-wheel *K* and half nuts *M* remain stationary. Under these conditions, as lead-screw *H* and the worm connected with it is rotated by worm-wheel *J*, it will advance through the stationary nuts *M* in the exact proportion to its lead, giving the same pitch to the work. To cut a finer pitch of the same hand as the lead-screw (which is left-hand as shown in the engraving), the disk *L* with the half nuts would be so connected with *J* through change gears *P* and *O* that it would revolve in the same direction as the lead-screw but at a somewhat slower feed. For left-hand pitches coarser than the lead-screw, the nut *M* is evidently revolved in the opposite

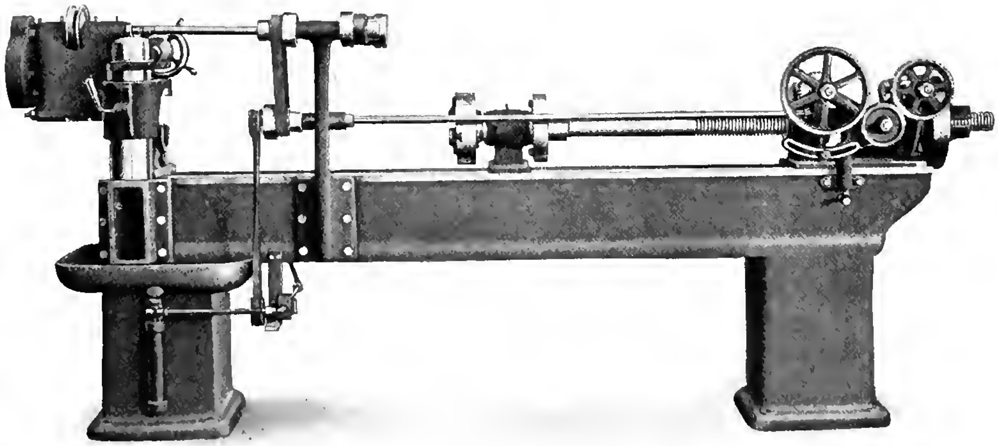

Fig. 2. Rear View of Thread Milling Machine, showing Feed Connections

direction to the lead-screw so as to give it a more rapid travel, and consequently produce a coarser pitch.

For cutting right-hand threads the work and lead-screw will evidently revolve in the opposite direction from that required for left-hand threads, if it is to feed in the regular way from left to right in Figs. 1, 3 and 4. If nuts *M* were stationary and the lead-screw were revolving in this direction, it would evidently feed to the left. In order to make it feed to the right, we must revolve nuts *M* in the same direction as the lead-screw, but at a faster rate. The faster the nut is revolved, the coarser will be the pitch.

The requirements may thus be summarized as follows: For right-hand pitches, gear *O* revolves faster than gear *P* and in the same direction. For left-hand pitches finer than that of the lead-screw, *O* revolves in the same direction as gear *P*, but at a slower rate. For left-hand threads of the same pitch as the lead-screw, gear *P* is stopped altogether. For left-hand threads of a coarser pitch than the lead-screw, gears *O* and *P* are connected so as to revolve in opposite directions. This would evidently require the introduction of another idler in addition to *Q*.

The Sliding Head and Provision for Multiple Threads

The forward end of the lead-screw is supported in sliding head *S*, where connection is made with the short spindle carrying the chuck *T*, through the medium of the flanged coupling *R*. The work is grasped by chuck *T* and supported in bushing *C* as has been previously mentioned. When nuts *M M* are released from the screw, head *S* may be rapidly adjusted to any point on the bed by means of the crank and rack and pinion movement shown. An automatic feed stop is also provided for limiting the length of thread cut. This operates a clutch which forms the connection between shaft *G* and the feed driving worm-wheel *N*, and is manually controlled by lever *U*.

The purpose of the coupling *R* is to permit the cutting of multiple threads. When the bolts in this coupling are loosened, the work may be revolved with respect to the lead-screw, making provision for double, triple, quadruple threads or worms, etc., as may be desired. The index is accurately

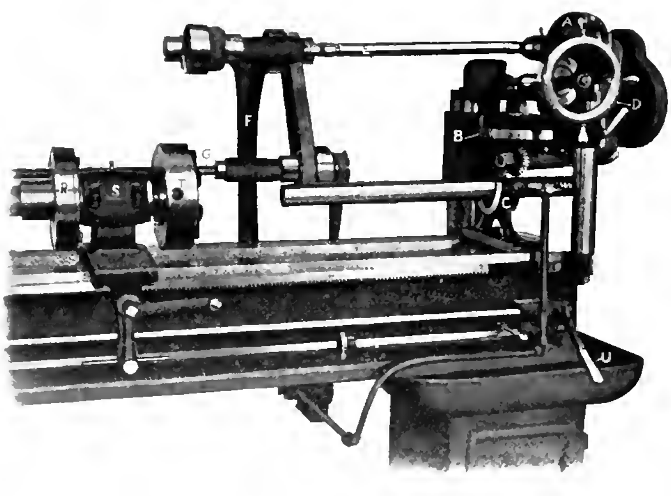

Fig. 3. The Cutter Drive and Work Support

made, and permits great accuracy in the division of the threads.

For any except complicated decimal pitches, the nuts *M* may be released and the head run back by the rack and pinion movement after the cutting of each thread of a multiple screw. In order to engage properly again, the same precautions would have to be taken as when running the carriage back by hand for threading in the lathe—namely, for odd pitches the lead-screw should be stopped and the carriage run back an exact number of inches; for even pitches, an exact number of inches or half inches, etc.

General Features of the Design

The simplicity and directness of action of this machine is one of its chief characteristics. Its simplicity enables it to be sold at a moderate price, makes it easy of operation, and reduces expense for maintenance and repair. In the matter of directness the salient point is the provision of a lead-screw of large and stiff proportions, directly over the center of the bed, with the blank to be threaded gripped in a chuck directly at the end of the lead-screw. The work is supported of the bed, with the blank to be threaded gripped in a chuck lar bushing of the exact size of the blank. All the threaded portion is therefore free from strain after passing the cutter. This arrangement avoids any bending of the blank due to the side pressure of the tool or cutter, and obviates the buckling due to the heating of the blank that would be met if it were held between rigid centers.

The simplicity of the mechanism for revolving and feeding the screw should also be noted. The double worm drive gives a smooth, direct and powerful motion to the screw, and to the work which is directly connected with it. This permits a full depth of thread to be machined at each operation with a

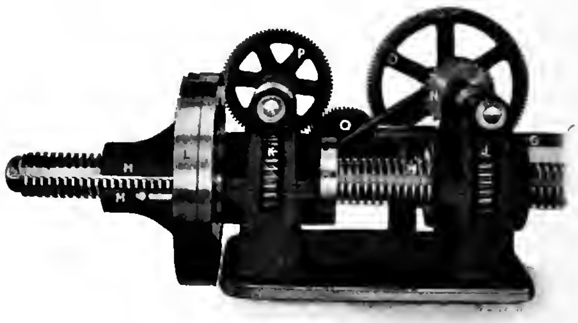

Fig. 4. The Lead-screw Revolving and Feed Mechanism

minimum of chatter. The reducing ratio of the worm drive varies from 60 to 1 on the large machine, up to 100 to 1 on the lightest size. This avoids the use of large and complicated gear trains, auxiliary shafts, movable carriage and bearings, and numerous small details, all subject to wear and strain.

This machine is built in three sizes, each having a capacity for work of maximum diameter of 6 inches, and ranging from 2 to 21 feet in length. The machine will be furnished with motor drive if required. The safety of the belt drive should be noted, however, as the failure of any or all the belts will not damage either the machine or the work under any condition.

An extra attachment will be provided if required for cutting keyways. A variation of the style of machine here illustrated provides for a vertical spindle, using a formed end mill in accordance with the method pursued in cutting the worms for some makes of Sellers drive planers.

AVERBECK 17-INCH SHAPER

In the November, 1906, number of MACHINERY, in the department of New Machinery and Tools, we illustrated a 21-inch shaper made by the H. J. Averbeck Shaper Co., of Covington, Ky. The novel features which were incorporated in the design of this shaper have recently been applied to a smaller machine of the 17-inch size, which we herewith illustrate and describe.

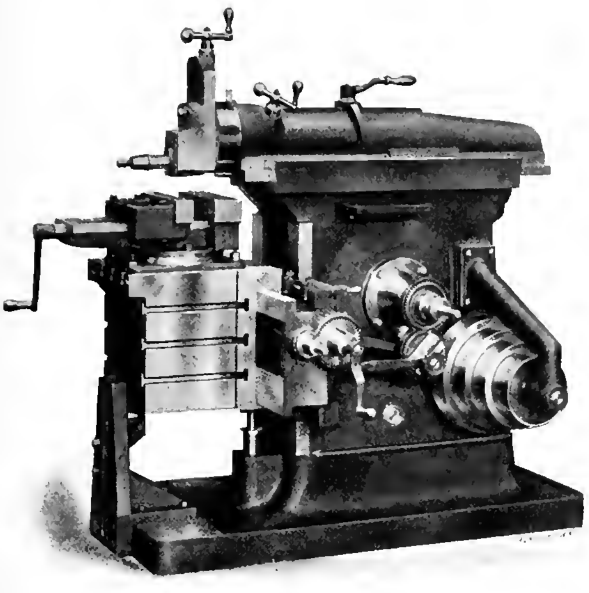
The design, of course, includes the features which have been found necessary for machine tools in the past few years in the matters of providing increased rigidity of the structural members (the column, ram, table, etc.) together with ample driving power for using high-speed steels to the limit of their capacity. The machine is back-geared. For direct connection the ratio between the gear and the ram is 5 to 1, and with the back-gears 18 to 1.

The cross-rail is of unusual construction. It is deeply ribbed and very heavy. The power cross-feed has the advantage of being provided with an automatic stop, controlled by two dogs, which may be set for use when cutting in either direction. Two stationary dogs are also provided which cut out the feed at the extreme travel of the table, avoiding any possibility of breakage at these points. The lever shown just above the gearing at the end of the rail, engages, disconnects or reverses the feed. The operation of the cross-feed screw by 2 to 1 gears provides for a slow or quick hand movement as

may be desired, as both shafts are squared for the wrench. The cross-feed screw has a graduated collar reading to 0.001 inch, and has 16 feed changes ranging from 0.008 to 0.125 inch per stroke.

The table is slotted on both top and sides. It is of such construction that, in combination with the form of rail used, bolts may be entered from the back as well as from the front. It has four T-slots on the top. These provisions facilitate the clamping of work. The vise has a graduated swivel base, and can be clamped on either side or the top of the table. When the table is removed, either the vise or the work itself can be clamped directly to the front of the apron, T-slots being provided at this point as well.

Attention should be called to the table support, which is bolted to the front of the base. The roller slide can be conveniently set to the vertical travel of the table in any position. It is evidently dirt proof, as contact with the roller is made on an inverted horizontal surface. This table support is always



Averbeck 17-inch Back-geared Shaper, with Automatic Cross Feed Stop

directly beneath the cutting tool, and so is adapted to take up the strains in the most effective way.

The down-feed screw of the tool block is provided with a double collar, one keyed to the screw and the other provided with a friction slip, and graduated to 0.001 inch. The provision of the keyed collar prevents any possible accidental change of the graduated collar from the position for which it is set. The head swivels to any angle and is graduated.

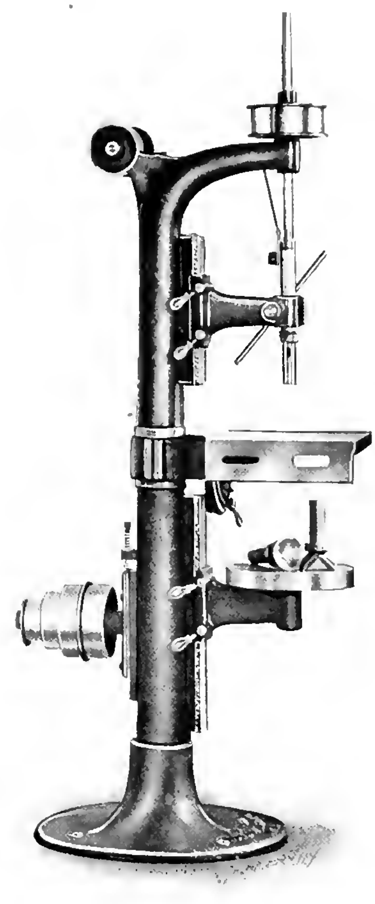
Great care has been taken in the general design and workmanship of this machine. All the shaft bearings in the column are well braced and of ample length, and are provided with suitable oil channels, fitted with dustproof plugs. All the T-slots are cut from the solid and (as may be seen from those shown on the apron in the engraving) are cut deeper than usual to prevent breaking out. All the bearings, such as those of the ram, rail, tool-block, crank-wheel slides, etc., are provided with taper gibs, so as to permit the maintenance of the accurate fit originally given these parts.

BARR NO. 7 TOOLMAKER'S DRILLING MACHINE

The No. 4 drilling machine made by H. G. Barr, 21 Hermon St., Worcester, Mass., was found so convenient for toolmakers that a heavier machine was demanded for this use. The resulting design is shown in the accompanying engraving, where it will be seen that a very stiff frame and drive has been provided, together with all the various attachments and adjustments needed in a machine which is to meet the varied requirements of the toolmaker's work.

This drill is provided with a sliding spindle head, a vertically adjustable round table, and a square table mounted on a swinging bracket. The square table can be tilted about a horizontal axis as well as swung about a vertical axis, so that it may be used for drilling holes at any angle. It is located in the horizontal position by a tapered dowel pin. One side of the table is provided with an extended bearing surface, with T-slot holes for clamping, adding greatly to its convenience in the holding of certain classes of work. It has a working surface of 13 by 14 inches. The round table is 12 inches in diameter, and can be removed from its supporting bracket to permit the use of the cup and V-centers provided. Binding handles are provided for locking the vertical adjustment, as well as for the various adjustments of the square table, and of the sliding spindle head.

The spindle is turned from a steel forging and is carefully ground to size and hand draw-polished. It is 1 inch in diameter, 35 inches long, and provided with a No. 2 Morse taper hole. The feed movement is 5½ inches, through a steel rack and pinion and a self-fastening feed lever, which does away with set- and thumb-screws. Ball bearing thrust collars are provided at the lower end of the quill and a fiber washer with a splined collar and spanner nut at the top. The cone and driving pulley on the rear of the machine is provided with a screw belt tightening adjustment as shown. All the pulleys are turned inside to give correct balance. All sliding surfaces are carefully scraped to their bearings and given a frosted finish. All the machines in this builder's line are tested to 0.00075 inch in 10 inches as the maximum allowable amount of error in lining up the spindle with the surface of the work-table.



Universal Sensitive Drill for Toolmaker's Use

The No. 7 size here shown weighs 515 pounds with the countershaft. It will handle any drill up to ¾ inch in diameter.

DUDGEON "UNIVERSAL" HYDRAULIC JACK

The hydraulic jack is so old and so simple a piece of mechanism that there would seem at first thought to be little chance for the display of ingenuity in improving its construction. The original inventor, however, Richard Dudgeon, Broome and Columbia Sts., New York City, has succeeded in developing a new construction which is of enough interest to warrant the description and illustration here given.

An example of one of the various styles of this new "universal" jack, as the maker calls it, is shown in Fig. 1. It is similar to older designs in its external appearance with the exception of the small valve handle in the head of the ram. This handle operates the lowering mechanism, and also controls a system of valves which, through the action of a double piston, gives two rates of pumping for the jack, permitting it to be used for the maximum load at regular speed, or for one-half the load at twice the speed. This double-pump arrangement is also useful, of course, in rapidly bringing the ram to any desired height before the load is applied. The functions controlled by this handle operate through an extremely simple construction, and this simplicity and directness of construction, in combination with the double pump

and the improved lowering connections, constitute the main points of interest in the new design.

The Universal System of Pistons and Valves

In describing the action, attention is first called to the diagram shown in Fig. 2, where is shown the pump as set for the rapid movement under one-half the normal load. The cistern or water supply is located at A, while the ram B is lifted by the water in cylinder C. The pump plunger is shown at D. This has two diameters, as shown, the full diameter working in chamber E, and the reduced diameter in the lower chamber F. The larger diameter is so proportioned to the smaller that it gives twice the area. The effective area of the pump plunger in chamber E, however, is the same as in chamber F, the area of the smaller diameter being subtracted from it.

Fig. 1. Dudgeon Double-pump Plain Hydraulic Jack

A continuous passage extends from cistern A to cylinder C. In this passage three valve seats are provided as shown, closed by valves G, H and J, which may be simply held upward in their seats by water pressure as shown, or by springs. With the usual construction, the lower valve J is the only one provided with a spring. By the operation of plunger K, as will be described later, one, two or three of these valves may be forced from their seats.

Fig. 2, as stated, shows the arrangement of the parts when the pump is working at its highest speed under one-half the normal load. As plunger D is pressed downward, the liquid is forced out of the chamber E, past the valves H and J into C; and out of chamber F, past valve J alone into C. When plunger D is raised, the pressure in C seats valve J firmly, while valves G and H drop from their seats, allowing a new supply from the cistern A to flow into chambers E and F. The repetition of the up and down strokes evidently forces the water from A into C, and raises the ram. It will be noted that under these conditions valve H is open on both up and down strokes, being thus inoperative when the jack is working as a double-plunger pump.

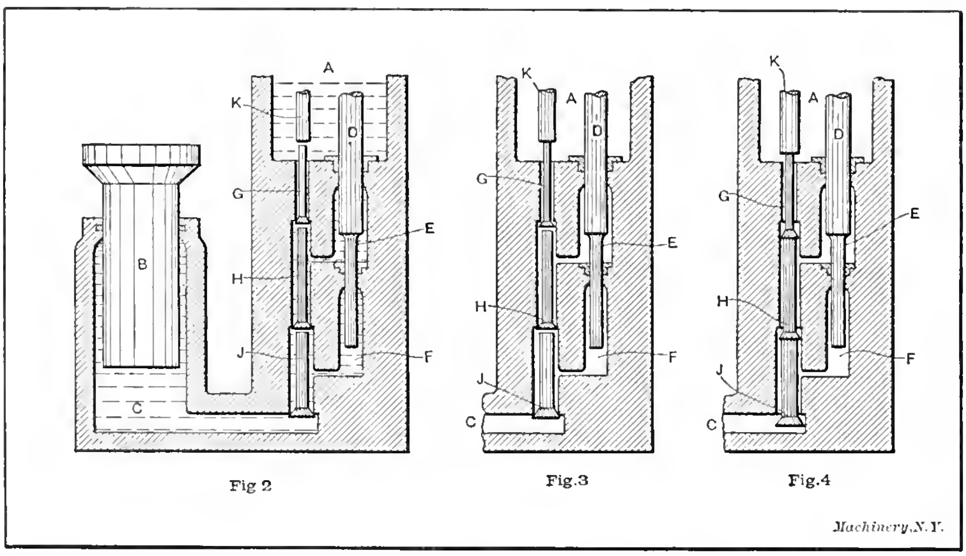
Fig. 3 shows the pin K pushed down far enough to hold valve G open permanently. Under these conditions it will be seen that when the ram is forced down, the water in chamber E is pushed back past valve G into the cistern again, instead of into the cylinder, while that in chamber F passes valve J into C as before. In this way, valve H is seated during the downward stroke and thus becomes operative. On the upward stroke, the pressure in C seats valve J as in the previous case, to close communication with the cylinder, while water is drawn into E and F through G and H, the latter of which drops from its seat to permit the flow. Under these conditions the continued up and down movement of the ram forces water from chamber F only into cylinder C, thus giving one-half the rate of movement of Fig. 2 and twice the available pressure. The higher pressure is due, of course, to the fact that the same pressure on the ram is applied to only the smaller area at the lower end in chamber F, instead of in both E and F as before. The water in chamber E, it will be seen, is merely churned in and out of cistern A without going to the cylinder.

For lowering the jack under the load, pin K is pressed still further downward as shown in Fig. 4 until it has unseated all three of valves G, H and J, permitting the liquid to flow directly back from C into A. The raising of K again far enough to permit the seating of valve J at once checks the lowering of the ram and holds the load at any desired position.

Application of the Principle to the Jack

The mechanism whose principles have thus been illustrated is practically applied to the jack in a way seen best in Fig. 5, where a vertical cross-section is shown. The cistern or reservoir is located in the head and barrel of the ram. The piston is operated as usual from a rockshaft and an outside lever, pivoted in the head. The chambers for the large and small diameters of the pistons are formed in a pump cylinder bored out in the lower end of the ram. In this ram is also formed the passage in which the three valves are mounted. The pressure valve, which is the last of these, is provided with a removable seat and a spring for holding it in the closed position.

Instead of using a pin K, as in Figs. 2, 3 and 4, for forcing down the valves for the various conditions of operation, a sleeve is used. This is forced down to the double stroke, single stroke, or lowering positions by the operation of the valve handle, which carries a cam on its inner end, operating on the upper edge of the sleeve. The latter is held up against this



Figs. 2, 3 and 4. Diagrams showing Double Pump and Valve Mechanism as set (Fig. 2) for High-speed Pumping using Both Pistons; (Fig. 3) for Slow Speed and Maximum Capacity, using Lower Piston only; (Fig. 4) with all Valves held open for Lowering the Load

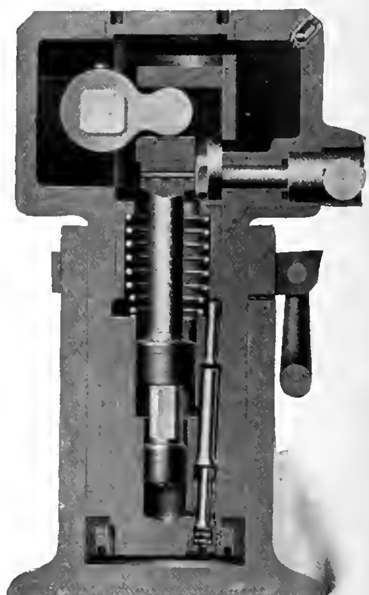


Fig. 5. Ram with Pump and Valve Mechanism operating on the Principle Illustrated in Figs. 2, 3 and 4

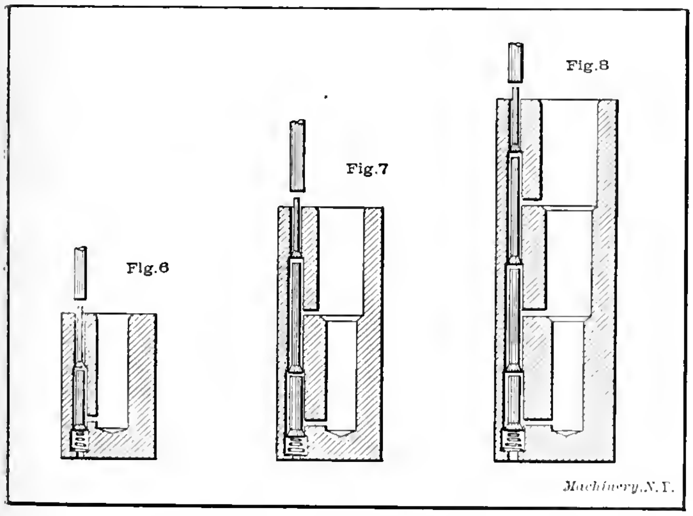
cam by a spring under its lower end, as shown. The lower edge of the sleeve bears on the top of the valve stem, which is thus operated in a manner identical with that shown in the diagrams. The sleeve may also be depressed for lowering by throwing the pump-lever to the extreme lower position. When this is done a pin on the crosshead strikes the top of the sleeve, opening all the valves and bringing about the conditions shown in Fig. 4. To permit the lever to take this extreme downward position, it is reversed in the socket as with the ordinary construction of jack, so that the lug is upward. This lug in the operating position stops the movement before the lowering position is reached. The exterior construction is plainly shown in Fig. 1.

The Adjustability of the Jack

The reason for having a sleeve instead of a rod, *K*, as shown in Fig. 2, for operating valves *G*, *H* and *J*, is to permit the head to be turned on the ram, or the cylinder to be turned in the same member, and still have the controlling mechanism for the valves operative. Whatever the positions of either, the cam on the valve handle and lowering pin *P* are always in line with the upper edge of the sleeve; and the stem of the valve is always in line with the lower edge. This is necessary, because the joint between the head and the ram is a threaded one, so that no assurance can be given that it will be re-assembled in exactly the position it had when originally put together.

The same thing applies, in other styles, to the cylinder ram. The ram in such cases is provided with a pin which may be entered in any one of four holes in the cylinder flange, which may thus be given four positions. This construction is of especial advantage when using the ram horizontally. As the tool is regularly assembled, the ram when used horizontally has the lever projecting straight up, while the three valves are on the lower side of the ram. This permits the use of sufficient water from the cistern to permit the use of the full stroke of the ram. In some places, however, it would be more convenient to have the pump lever project to one side or the other, or even (in special cases) vertically downward, in order to give room for easy manipulation. To meet



Figs. 6, 7 and 8. Diagrams showing the Application of the "Universal" Plunger and Valve Construction to Single-, Double- and Triple-action Pumps

these exigencies this provision of four positions has been made. To change the position it is only necessary to withdraw the ram from the pump, unscrew the pump retaining ring, and shift the position of the dowel pin in the flange of the cylinder. The ability to use the ram for the full stroke any side up in the horizontal position, is an important advantage of this new design.

It should be noted that the particular ram shown in Fig. 5 is designed for car inspectors' work and always used in a vertical position, so does not clearly show the nature of the adjustment when applied to jacks of other styles.

The Points of Improvement

The points of novelty in this universal jack may be summarized as follows: It provides a double-pumping mechanism giving two rates of lift, applicable to a general purpose hydraulic jack. When the load is light, the double pump will raise it with twice the rate of speed for a single pump. When the load is heavy, one-quarter turn of the handle will throw out the action of one pump, and will give the action of a single pump jack.

It provides for this double-pump action and the control of the lowering by the simplest valve construction imaginable. The valves are assembled in one chamber and only three are needed (two suction and one pressure valve) of which only two are ever in use at one time. Other double-pump jacks require at the least five valves, and three passages between the pressure chamber and the reservoir, and each closed by a separate valve, and the failure of any one of these valves or

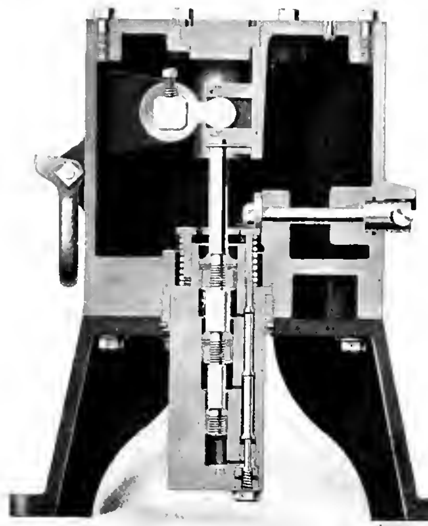


Fig. 9. Hand-operated Cistern Pressure Pump, embodying the Triple Plunger Principle shown in Fig. 8

of either cylinder packing renders the pump inoperative. It will be seen by referring to Figs. 2 to 5 inclusive, that two cylinder packings or three valves would have to be thrown out of commission before the load would be released with this type of jack. The advantage of the construction from the point of safety and the prevention of serious accidents is undeniable.

It can be lowered by either the lever or the valve handle. As the valves can be operated by the handle independently of the pumping mechanism, they may be opened and cleared of any obstruction which prevents their proper seating by the working of the pump. This often obviates the necessity for dismantling the mechanism.

Ease of dismantling the pumps, valves, etc., for this jack is another advantage of its construction. This will be best appreciated from Fig. 5. Access to all the valves is provided by the removal of but one bonnet. When the ram is removed from the cylinder, the unscrewing of this bonnet permits the three valves, and the removable seat, to drop from the passage in which they are confined. Furthermore, to remove the piston for the examination of the packings of the plungers, it is only necessary to unscrew the cap in the top of the ram, when it may be freely withdrawn.

The instant and absolute control of the lowering mechanism by the handle should also be included as one of the advantages of this jack. This control of the lowering is, in fact, one of the prime advantages that the hydraulic form possesses over the mechanical types of jacks. With the latter the lowering is hardly less laborious than the raising. No additional valves are required for this releasing movement. The position of the valve lever indicates at all times whether the lowering valve is open or closed.

The general design of this tool has been carefully looked out for, to preserve the qualities of lightness, portability, simplicity and reliability. It will stand rough usage, and not get out of order. It has the minimum number of parts. These are so assembled as to be easily replaceable when necessary. The whole device can be easily taken apart and put togther without special tools.

Triple-action Pumps built on the "Universal" Principle

That the new design of plunger and valve mechanism used in this jack is, as its name indicates, "universal" will be appreciated after a study of Figs. 6, 7 and 8. Fig. 6 shows the single plunger, single chamber and double valve arrangement. Here, evidently, the plunger is single-acting and the ram has but one rate of speed. The depression of the two valves under the action of the lowering pin would permit the release of the load. In Fig. 7 is shown diagrammatically the arrangement shown more elaborately in Figs. 3 and 4. Here we have two chambers, two rates of pumping speed, and provision for lowering.

In Fig. 8 the construction is carried still further, and provision is made, as shown, for three chambers and four valves arranged as before. With all the valves free to act, all three chambers would be forcing water into the cylinder. By depressing the uppermost valve, two chambers only would be in operation. By depressing still further the two upper valves, but one chamber would be in operation. And finally, by depressing all four valves, the load would be lowered. It would be possible, but perhaps not practicable, to carry this multiplicity of valves and pistons to any extent, giving three, four or any number of rates of pumping speed. Two, however, is sufficient for all the practical purposes for which a portable jack is used.

Fig. 9 illustrates a pressure pump for hydraulic work in which the triple piston arrangement shown diagrammatically in Fig. 8 has been used. There are thus, in this case, four working positions to the handle, giving three different rates of pumping, in addition to the lowering position. This cistern pump may be used for a great variety of purposes, such as for making tests, or on the operation of variable pressure hydraulic presses, etc. It may be connected to any piece of hydraulic apparatus by means of flexible copper tubing. It will be furnished to give any combination of pressure required—such as, for instance, 1,000 pounds to the square inch with three pumps in operation, 2,000 pounds with two pumps, and 6,000 pounds with one pump.

Other Hydraulic Machinery

A wide variety of other hydraulic apparatus has been designed by the makers of these jacks, incorporating the principles of the mechanism we have described. Horizontal jacks, jacks for bridge builders, car inspectors, etc., hand hydraulic pumps, power hydraulic pumps, jack cylinders for hydraulic presses, etc., are some of the various styles. In the last case, the ram is provided with a rack and pinion adjustment which permits the rapid bringing down of the platen against the material to be pressed, without requiring the tedious operation of the pump for this idle movement.

All these pieces of apparatus are composed of parts which are simple in themselves and which may be replaced when necessary at a low cost. The parts are interchangeable, being made by automatic machinery, and are easily dismembered without the use of special tools.

IMPROVED DESIGN OF BINSSE BORING MACHINE

The boring machine built by the Binsse Machine Co., Newark, N. J., is of the standard type in which the spindle is mounted in fixed bearings on a column or headstock, while the work is clamped to a table adjustable by both longitudinal and cross motions on a knee, which latter member is itself adjustable vertically by means of two connected elevating

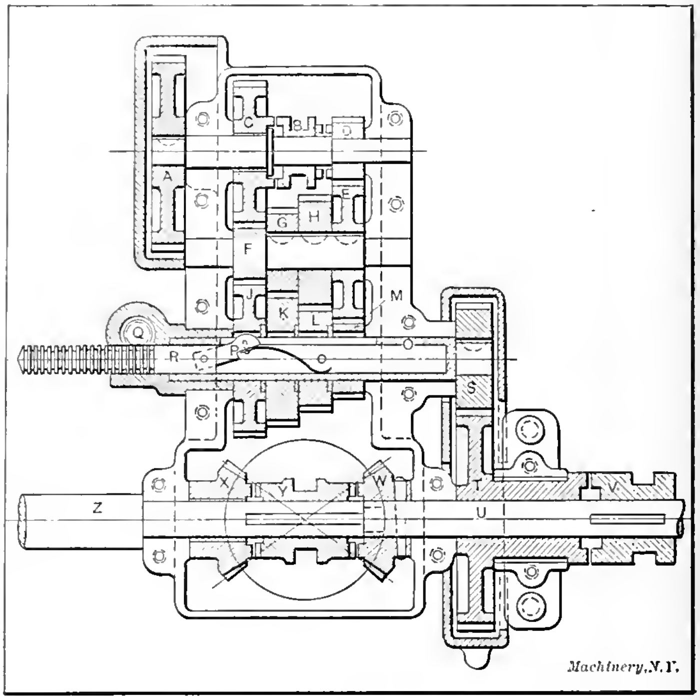

Fig. 2. Arrangement of Gears in Quick Feed Change Mechanism

screws. The type will be readily recognized from Fig. 1. The makers of this machine have recently made important improvements in the design, which should add to its convenience and productiveness.

One of these improvements consists simply in lengthening the arms of the pilot wheel at the extreme left of the machine, by which the boring-bar is advanced toward or withdrawn from the work. This improvement, simple as it would appear to be, is yet of great advantage, as it permits the workman to shift the bar without moving from his position of observation at the working end of the spindle. He is thus enabled to center the spindle to a punch mark, and do similar work accurately to dimensions, without the inconvenience of stepping back and forth between the pilot wheel and the working point.

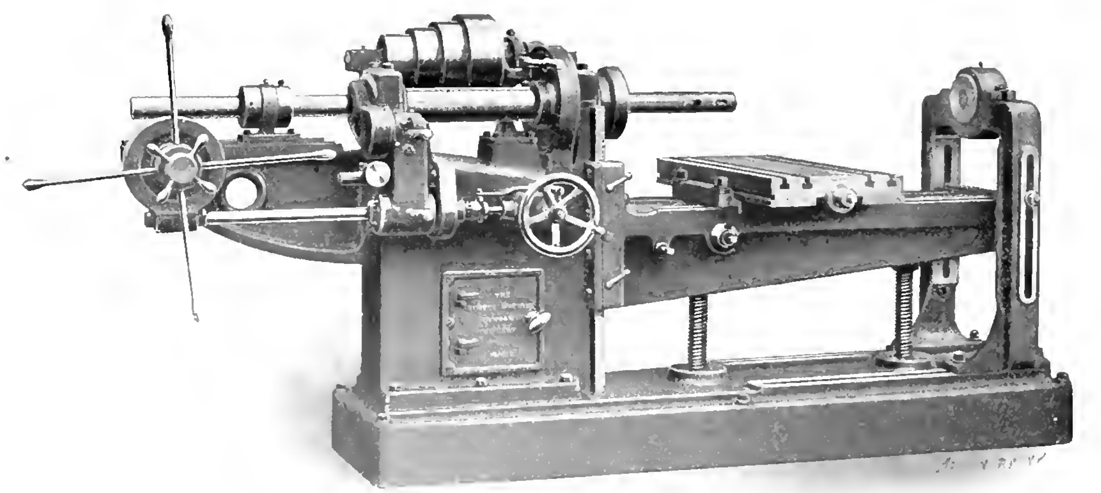

Fig. 1. Binsse Boring Machine with Improved Feed Gearing and Other Details

A second improvement relates to the means provided for clamping the work-table to the saddle and the saddle to the knee. This provision consists of four bolts, one passing through each corner of the saddle. The lower end of each is provided with heads fitting in T-slots on top of the knee, while the nut on the upper end tightens down on a clamp, which enters the gib slot in the edge of the work-table. When the nuts are screwed up, it will be seen that with this arrangement the table is clamped to the saddle and the saddle to the knee simultaneously, the strain being taken directly down from the table to the knee, giving the most rigid possible construction. This is similar in principle and effective-

ness to the method which has always been provided on this machine for clamping the outer end of the knee and outboard support together. This consists, as may be seen, simply of a through bolt laid on the top of the knee, and passing from side to side of the outboard support through slots formed to receive it. When the nut on the outer end of this bolt is tightened up, the sides of the support are drawn against the knee and the whole structure is clamped together. It will be noticed that square locked gibbed surfaces are used throughout the machine. This is the construction that gives the greatest rigidity and the best fitting sliding bearings.

A third and the most important improvement is the provision of a geared feed drive of the quick change variety. This change gear mechanism has been worked out in very attractive form. As may be seen in Fig. 1, it is compact and designed in harmony with the rest of the machine. It is also very easily manipulated. It provides for a reverse motion and for eight feeds, any one of which may be instantly obtained. These changes are effected by the operation of two levers and a knurled knob.

Fig. 2 shows details of the construction of this change gear device. Gear *A* is driven by intermediate gears from the spindle of the machine. On the shaft to which it is keyed is also keyed sliding clutch member *B*, which may be set to engage with clutch teeth in either of gears *C* and *D*. The clutch is operated by the upper of the two short levers shown on the feed box in Fig. 1. Gears *D* and *C* mesh respectively with gear *E*, and an integral pinion on the shaft *F* to which it is keyed. *F* may thus be given two speeds depending on whether *B* is engaged with *C* or *D*. *F* also carries two other gears *G* and *H*. *F*, *G*, *H* and *E* mesh respectively with gears *J*, *K*, *L* and *M*, which revolve loosely on the hollow shaft *O*. Either of these four gears may be connected with *O* by means of the diving key *P*, which may be moved from one to the other of its four positions by means of a pinion *Q*, meshing with circular rack teeth turned in the outer end of the plunger *R*, in which *P* is pivoted. *R* is operated by the knurled knob shown at the side of the feed box in Fig. 1, and thus controls four changes, which, in combination with the upper crank, give the eight for which the mechanism provides.

Gear *S*, keyed to shaft *O*, meshes with gear *T* running loosely on shaft *U*; the latter is connected by bevel gears with the handwheel at the right of the column. To connect or disconnect *T* with *U*, and thus start and stop the feed, clutch *V* is provided. Bevel gears *W* and *X* and clutch *Y* control the direction of the feed. Gear *W* is pinned, as shown, to shaft *U*, and *X* is connected with *W* by an idler bevel gear so that it revolves in the opposite direction. Clutch *Y* is keyed to shaft *Z*, which extends backward to drive the worm on the pilot wheel shaft. It will be noted that shafts *Z* and *U* are separate, the former having a pivot bearing in the latter at their junction.

It would be very difficult to effect the same number of changes, with a smaller number of gears than that used by the combination shown in Fig. 2. Ten gears only, as may be seen, are required for giving the eight changes of speed. All the mechanism is enclosed in a dust and grit proof casing, with ample provision for lubrication.

The means provided for clamping and centering the boring-bar in this machine is original and effective. A split and tapered bushing surrounds the bar in the nose of the spindle. A steel collar, threaded on the outside and tapered to fit on the inside, surrounds this bushing. When the collar is screwed into the spindle, its taper presses in on the bushing, forcing it together and tightly gripping and centering the bar.

This tool retains all the features which have become well known in the boring machine made by this firm. The base is of unusual depth and rigidity, as may be seen. This gives stiffness to the whole machine. The driving cone is mounted on a shaft, separate and to the rear of the spindle, and is provided with internal back-gears. The arrangement gives a drive particularly suited to heavy facing cuts and other hard service, and relieves the spindle of the belt pull.

The makers have found that it is possible with this type of boring machine to maintain a high degree of accuracy in the alignment of the spindle with the top of the table. The maximum error in parallelism between them allowed is 0.0005 inch per foot, and most of the machines turned out come considerably within this limit.

The machine illustrated in Fig. 1 is the No. 2B size. The boring bar of this machine is 2¾ inches in diameter and is made of high carbon steel with a No. 5 Morse taper hole. The direct gearing ratio between the cone and the spindle is 1 to 4½; and through the triple gearing, 1 to 18. The eight feeds range from 0.001 to 0.100 inch per revolution. The bar is held by friction at any point and can always be given the full length of feed at one setting.

PAWLING & HARNISCHFEGER HORIZONTAL DRILLING AND MILLING MACHINES

The firm of Pawling & Harnischfeger, of Milwaukee, Wis., has developed a line of horizontal boring and drilling machines comprising three different sizes and two different designs. Examples of each of the designs are illustrated herewith: Fig. 1 shows the largest or No. 7 size with the solid box casting column, while Fig. 2 shows the No. 5 machine with a column built up of cylindrical members. The feed and driving mechanism on the spindle saddle is similar for the two machines, although in Fig. 1 the motor is mounted on the saddle while in Fig. 2, it is placed on the top of the column. The two designs are also similar in that the column is bolted in place on the floor, while the work is mounted on a table which rolls on a track, thus giving the required longitudinal adjustment.

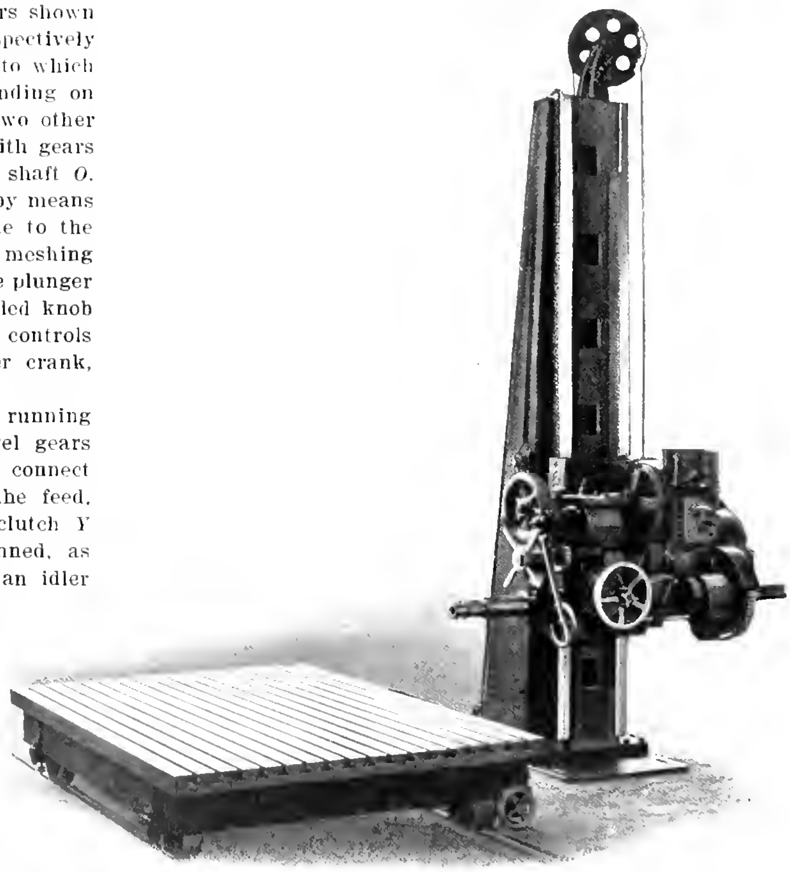

Fig. 1. No. 7 Horizontal Drilling and Milling Machine, with Box Type of Column

The No. 7 machine, shown in Fig. 1, will cover a working surface area of 65 square feet, for drilling and tapping holes up to 3 inches in diameter. The saddle has a vertical movement of 7 feet 8 inches on the column. The speed and feed control is arranged conveniently with relation to the operator's position. A positive clutch engages the motor pinion and is operated by a lever at the front of the saddle. This also controls the reverse as well. The feed is locked or unlocked and the spindle advanced or withdrawn by one hand-

wheel. The spindle is of high carbon forged steel with extended bearings which assure alignment at the extremes of travel. The end thrust is taken up by dust-proof ball bearing. The saddle is balanced by a counterweight inside the column.

The table has a length of 8 feet, and a width of 6 feet. It is adjusted by barring the capstan heads provided for the purpose on the axles. The table is fitted with improved roller bearings, large diameter axles and chilled wheels. A clamping brake on one axle, operated by the handwheel shown, provides for locking in position when desired. For boring with long bars, an adjustable outboard bearing is used, clamped to the table and lined with the work and the spindle.

The machine is easily adapted to portable use, as it may be unbolted from its base and swung by the crane into any desired position for operating on large castings. A three-horse-power motor is required for the No. 7 machine. Eight changes of spindle speed are furnished, ranging from 7 to 200 revolutions per minute. The spindle is 2 7/16 inches in diameter, has a No. 5 Morse taper hole and a feed of either 24 or 30 inches as may be ordered. Four feed changes are provided for each spindle speed. The weight of the machine itself is 8,300 pounds; the weight of the table is 9,250 pounds.

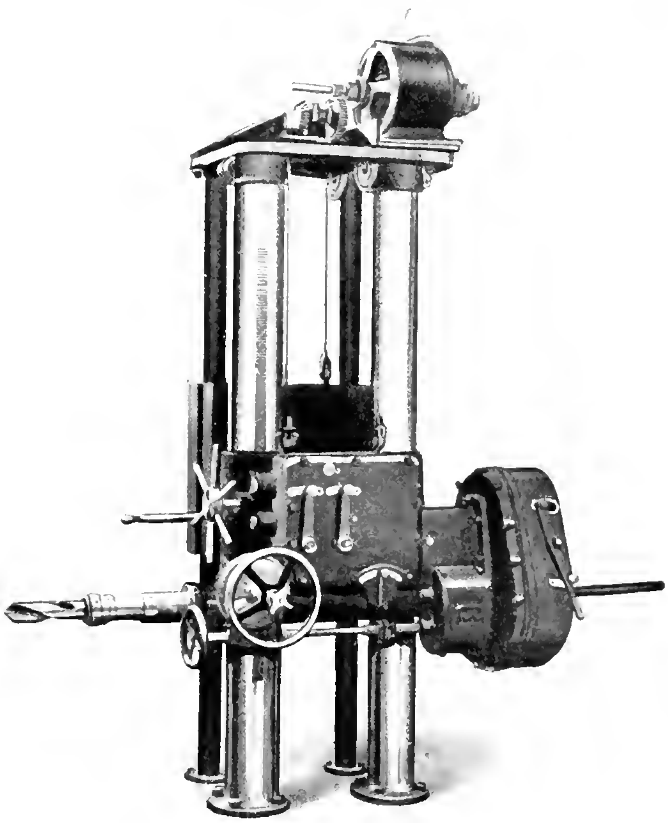

Fig. 2. No. 5 Machine, with Frame built up of Cylindrical Members

The No. 5 machine, shown in Fig. 2, has about the same capacity as the No. 7 machine so far as size of spindle and maximum diameter of drilling is concerned. The work-table, not shown in the engraving, is 8 feet long and the vertical adjustment of the spindle carriage is 5 feet, giving approximately 40 square feet of area available for a working surface. The columns of which the frame is formed are held in position by top and bottom plates, the latter of which is bolted to I-beams embedded in the floor. These are extended to support the two rails on which the work-table travels. The counterweight for the saddle is guided by two pipes that are also retained in the top and bottom plates, making the machine practically self-contained.

As in the previous case, the machine is driven by a three horse-power motor through mechanism which gives a similar range of speeds. The rotation is reversible for tapping and for back counterboring, by the operation of a lever within convenient reach of the operator.

The weight of machine, counterweight and table combined is 12,841 pounds. It will be noted that no overhead support or pit under the floor is required. The machine may be belt-driven, if desired, by the substitution of a driving pulley for the motor.

WESTMACOTT GAS FURNACES

The accompanying engravings show three new members of the line of furnaces made by the Westmacott Gas Furnace Co., of Providence, R. I. Fig. 1 shows an oven furnace which has been redesigned throughout. The burners have been improved in efficiency and the furnace has a new and more effective form of lining. The door is 12 inches wide and 6 high. The heating space is 18 inches long. It may be employed for hardening or case-hardening tools, die blocks or other pieces of carbon or machinery steel, and may be advantageously used as well for annealing metals of any kind.

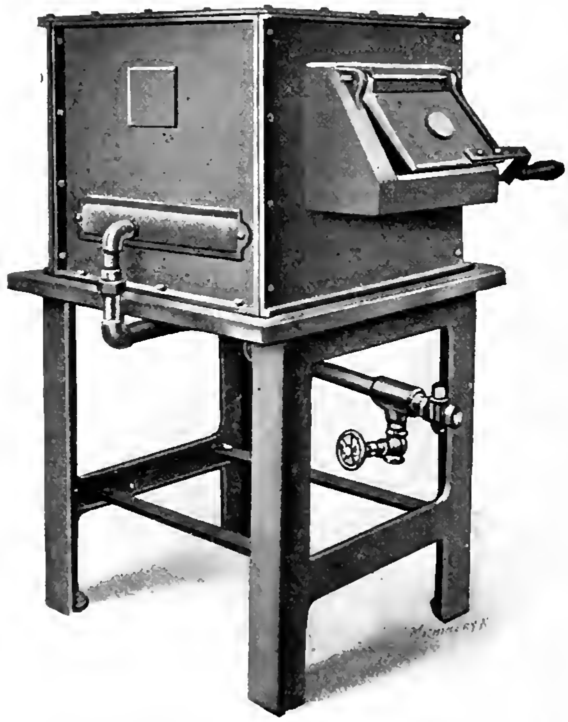

Fig. 1. Westmacott Oven Furnace for General Heating, Hardening, etc.

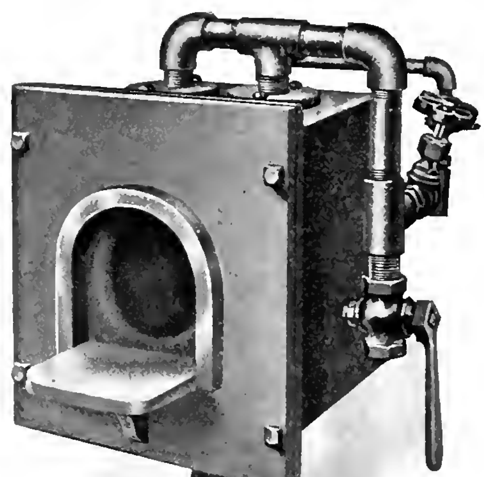

Fig. 2. A Bench Forge for Small Work

Fig. 2 shows a small forge of new construction. It is intended to be placed on a work-bench, where it occupies very little space. The heating space, front and back, has a diameter of 3 inches and a length of 6 inches. It is equipped with a pilot light, which may be left constantly burning at a negligible expense, making it unnecessary to relight the furnace every time it is used. This forge is adapted to hardening

small pieces, heating bars of stock and pipe, light forging, brazing, etc.

The brazing table shown in Fig. 3 is equipped with two blast blow pipes. These have a universal adjustment, allowing them to be placed in any position. This, in combination with the movable bricks, allows the flame to be directed and confined on the work in the most efficient manner. The variety of sizes of the bricks furnished is a convenience in "walling in" the work. The top of the slab stands up 30 inches from the floor. This table is adapted to a wide variety of operations, though intended primarily for brazing. It can be used for hardening or annealing small pieces, heating bars of stock and pipe for bending, and other light work of a similar nature.

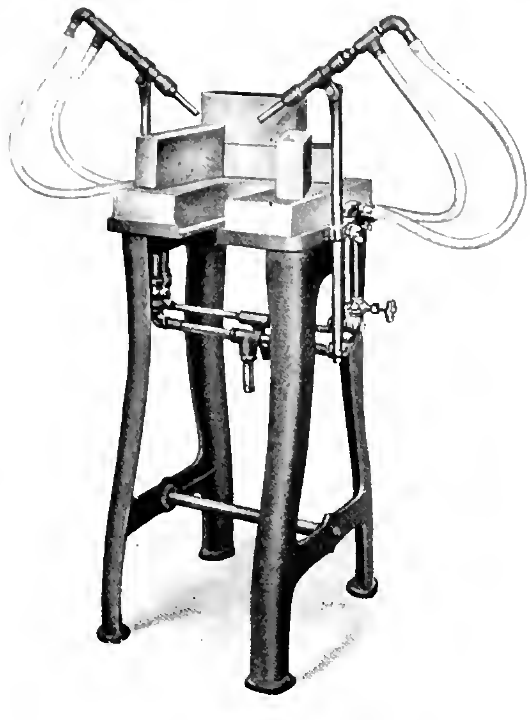

Fig. 3. Brazing Table with Adjustable Blow Pipes

SELLS ROLLER BEARING

The Sells roller bearing herewith illustrated and described is being sold by the Royersford Foundry & Machine Co., of Royersford, Pa. It is the design of Mr. John D. Sells, for many years identified with the "Standard" roller bearing, and is therefore the product of a long experience in this line of work. This bearing is universally adaptable, can be applied to any hanger or pillow-block of corresponding size either for new installations or for substituting in a plant previously equipped with the old style of plain or oil bearings; and it also possesses the advantage, as may be seen from the engraving, Fig. 2, of being applicable without requiring to be pushed on over the length of the shaft from one end to the other.

The construction will, perhaps, best be understood by reference to Fig. 2, which shows the successive operations of putting the bearing in place. First the split sleeve is put on the shaft. This is formed in two parts, with the split running diagonally, as shown, so that the rolls may pass over the joint without shock or irregularity of motion. Next this sleeve is clamped in place onto the shaft by two collars, see *B*, which are provided with counterbores fitting the edges of the sleeve so that they are thus themselves truly located. Next, as shown at *C*, the two halves of the split cage are placed around the sleeve between the collars. Then, as shown at *D*, the box itself is put over the whole and fastened. The application of the bearing will thus be seen to be as simple as the application of a split sleeve or wood pulley.

The bushing is of hardened steel, and absolutely protects the shaft from being cut or scored by the case-hardened steel rollers. Injury from this cause is of common occurrence in other designs. These bushings are so constructed as to vary in thickness, allowing the same size of bearing to be fitted to different diameters of shafts. Each roller cage structure is adapted to three such changes of bushings. This makes it unnecessary for the dealer to carry a large stock of these bearings, as odd-sized bushings will take care of the intermediate sizes.

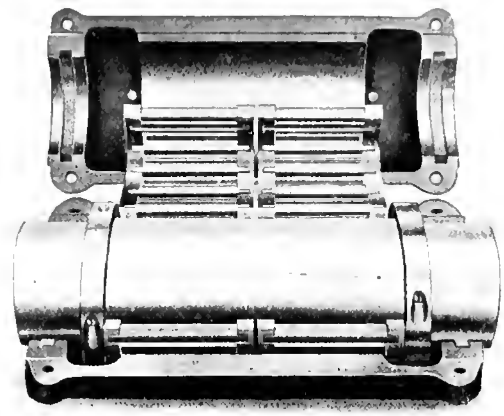

Fig. 1 The Selle Roller Bearing, of the Double Cage Type

The rolls, as plainly shown in Fig. 2, are contained within a roller structure or cage. This separates them from each other, and eliminates the friction caused by the rolls running in contact. It also holds them parallel to each other so that it is impossible for them to get cramped diagonally in the boxes.

This bearing, as may be seen, is of the full floating type, so that none of the customary trouble from end-thrust friction in roller bearings is met with. The two halves of the case are fitted together with milled joints to make them dust-proof, and to give further assurance in this matter a heavy felt wiper is used at each end of the box, which at the same time

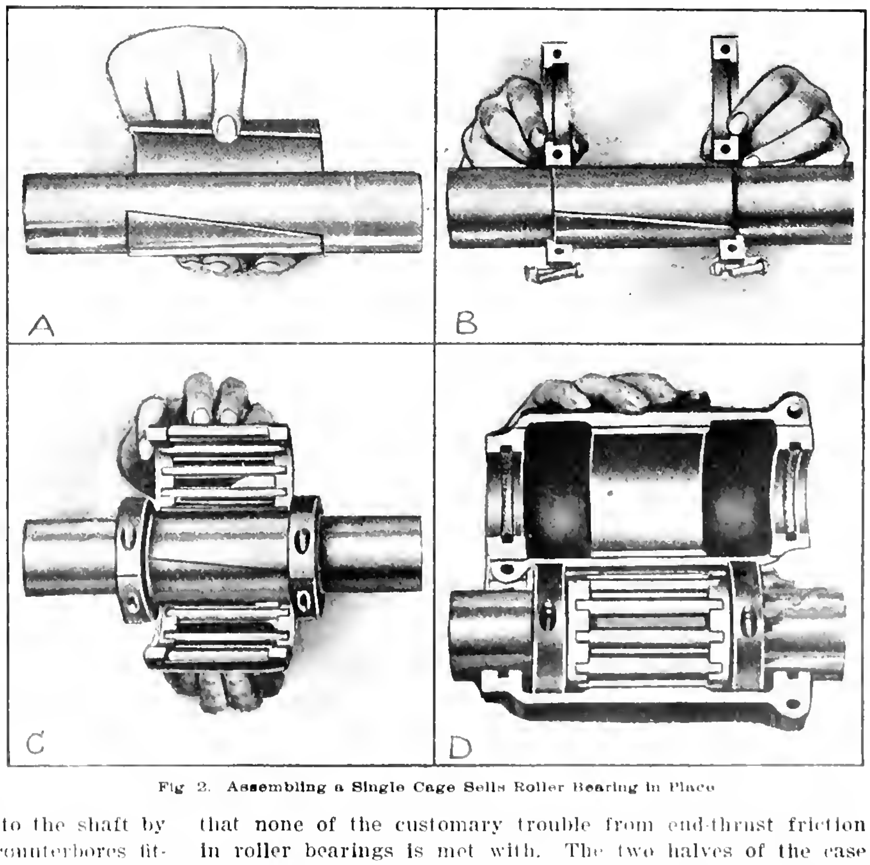

Fig. 2. Assembling a Single Cage Sells Roller Bearing in Place

prevents the loss of oil. Drain holes are also provided so that the case can be flushed with kerosene or other cleansing fluid when the oil gums. Holes are tapped in the top of the box to provide for oil cups. For head- or jack-shaft use, on shafts 3 11/16 inches in diameter or larger, this bearing is provided with a double roller structure as shown in Fig. 1. This gives a greater bearing area for heavily loaded shafts. All parts are made interchangeable. In case any part of the bearing becomes mislaid or broken by accident, it can be easily replaced, avoiding the expense of a new complete bearing.

For the present, at least, the manufacturers intend to sell this form of bearing for fifty per cent less than the price asked for any other similar device on the market.

FERRACUTE TOGGLE PRESS OF UNUSUAL SIZE

The "largest ever built" in the way of various forms of power presses have come along very rapidly in the past two or three years. We are beginning to get familiar with the application of these machines to larger and larger work, and the picture of a new press of unusual size does not, perhaps, excite the same interest that it would have a few years ago. The accompanying illustrations, however, show a double-action drawing press of such enormous size and capacity that the builder, the Ferracute Machine Co., of Bridgeton, N. J., has good reason to call attention to it. This press was built particularly for seamless burial caskets of the largest size, drawn from sheet steel 1/16 inch thick. It is equally well adapted, however, for forming other large drawn work, such as automobile bodies, bath tubs, metallic boats, etc.

The bed is a massive, internally ribbed and trussed casting weighing 18 tons. The width of the bed, right to left, be-

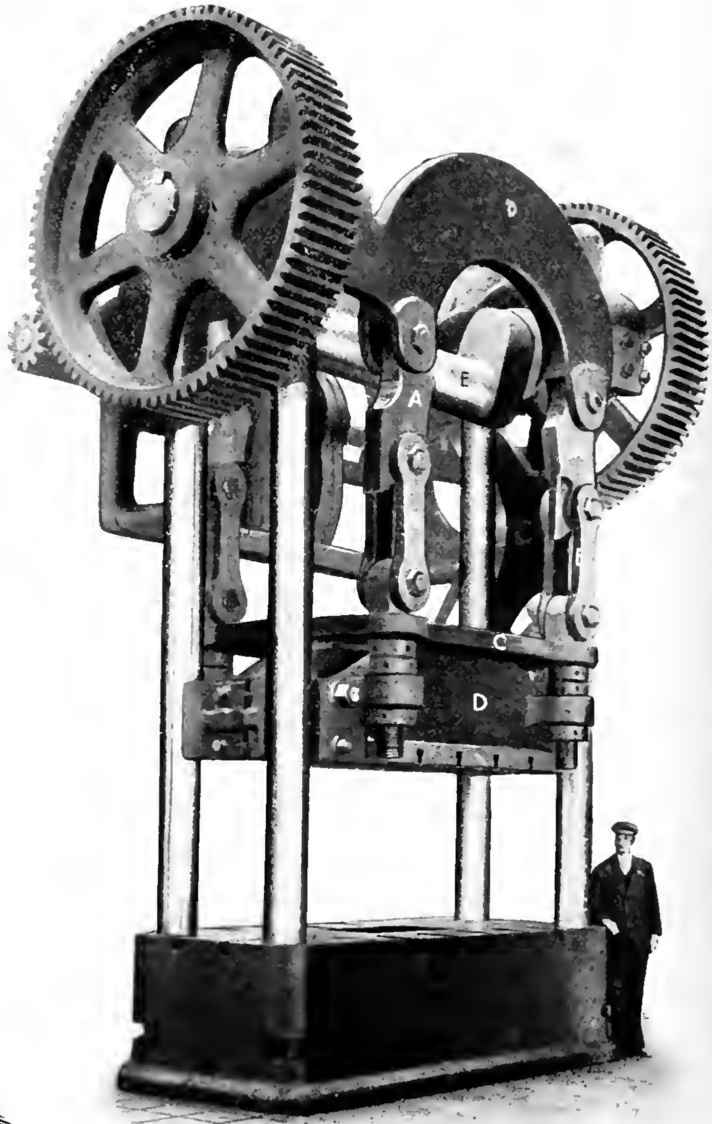

Fig. 2. The Press Partially Erected, showing Cam and Toggle Mechanism for Operating Blank Holder

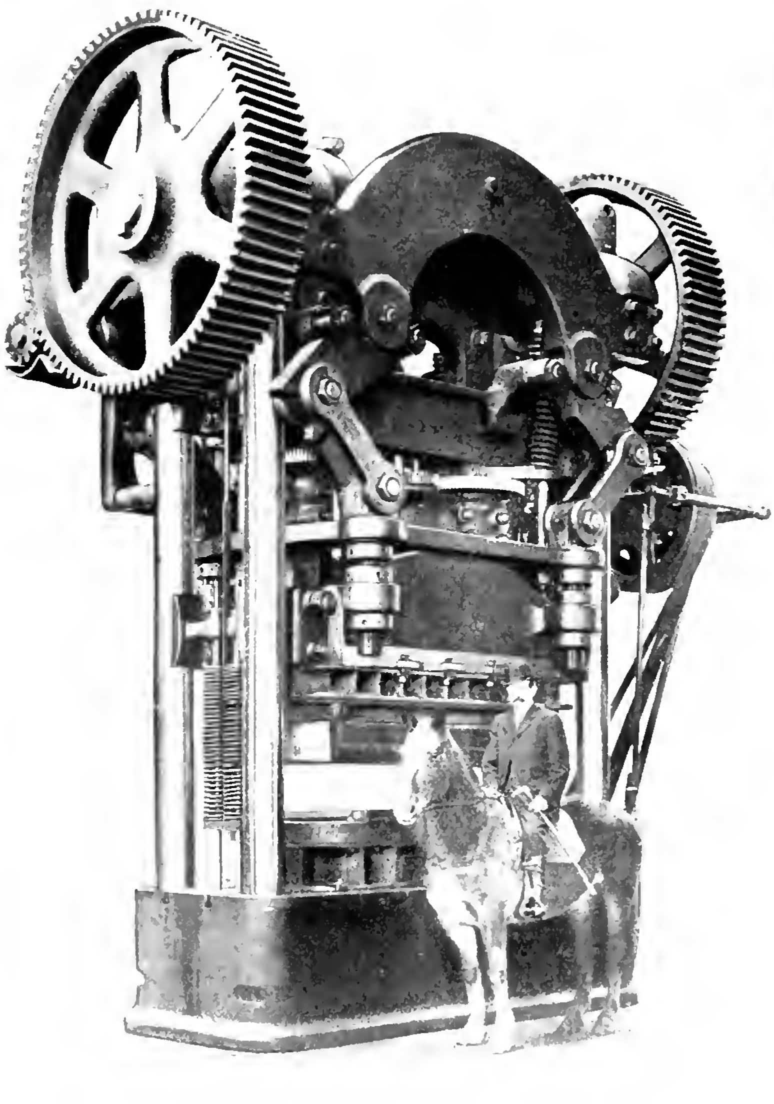

Fig 1. An Enormous Double-action Drawing Press

tween columns is 9 feet 4 inches and extreme depth of bed front to back, 4 feet 6 inches. Projecting upward from the corners of the bed are round steel columns, 10 inches in diameter, supporting the upper framework, taking the tensile stresses, and also serving as slide-bearings for the outer ram. These columns are connected at the top by heavy stays, the crank-shaft (see *E*, Fig. 2) being journaled in the end stays. The crank-shaft is composed of forged steel, is 15 inches in diameter and weighs 5 tons. Twin gears, each 7 feet 2 inches diameter by 1 foot 6 inches face, are keyed to the ends of the crank-shaft. These gears are steel castings, the teeth being cut. The weight of each gear is 4¼ tons. The back-shaft is driven by a gear at the middle of the shaft instead of at the end, the torsional strains thereby being balanced and the pressures at the end of the shaft equalized.

The upper toggles *A* are pivoted to the front and back frame trusses, the lower toggles *B* being connected to the outer ram or blank-holder *C*. There are four sets of these toggles, giving pressure to the outer ram at four points. The crank-shaft is connected to the inner ram or plunger by pitman strap and pitman, as usual, there being two bearing points in the plunger.

Rollers on studs projecting from the plunger bear against the upper toggles *A*, causing them to straighten out when the plunger descends, forcing the outer ram down. As the main ram or plunger

rises, after a stroke has been made, similar rollers on the other side of the toggles strike projections at the "knee-joints" of the toggles, causing them to resume their angular position, the outer ram being lifted by steel springs as soon as the toggles are tripped. This is shown in Figs. 1 and 2. The plunger has 32 inches stroke. As the ram has a stroke of 16 inches, it is possible to draw work of very nearly that depth. The adjustment of both ram and plunger is 8 inches.

The fly-wheel is 50 inches diameter and 12 inches face. The press is driven by a 125 H. P. motor through a powerful friction clutch, by means of which the operator has perfect control at all times, being able to start and stop the machine at any part of the stroke. The ratio of gearing is 1 to 300. The press makes about one and a half strokes per minute, giving it a great advantage in speed over hydraulic presses in which heavy work of this character is usually done. A positive knockout is connected to the ram by rods running up through the bed.

The press is 20 feet 2 inches high. It occupies a floor space of 18 feet 9 inches by 9 feet 3 inches. It weighs 100 tons, and gives a ram pressure of 1,500 tons. It was designed by Mr. Oberlin Smith, the president and mechanical engineer of the Ferracute Machine Company.

GARVIN NO. 11 2 GEARED FEED MILLING MACHINE

The milling machine herewith illustrated and described is made by the Garvin Machine Co., Spring & Varick Sts., New York City. The principal features of the design are the box construction of the knee, the arrangement of the knee bearing surfaces and those of the saddle and table, and the compact geared feed mechanism employed. These improvements have been incorporated in a machine which otherwise retains the good points of the older line of millers built by the same firm.

Improvements in the Structural Design

In regard to the general structure of this miller, it may be said that the column is built on the standard lines which have previously given good results in the matter of strength and rigidity, and consequent output of work. The first point of interest in the structural design relates to the knee, which is illustrated in Fig. 1. This is of the solid top, extended type, which has been patented by the builders. As may be seen, the top is entirely closed except for one very small hole, which does not interfere with strength and stiffness. The back of the knee, where it joins on the column, is also closed, as are the sides and end, while the lower opening is well ribbed. A stiff internal rib is also provided. The bearing on the column is extended upward, and two binders for clamping the vertical adjustment are furnished, with an extra gib screw placed close to each binder.

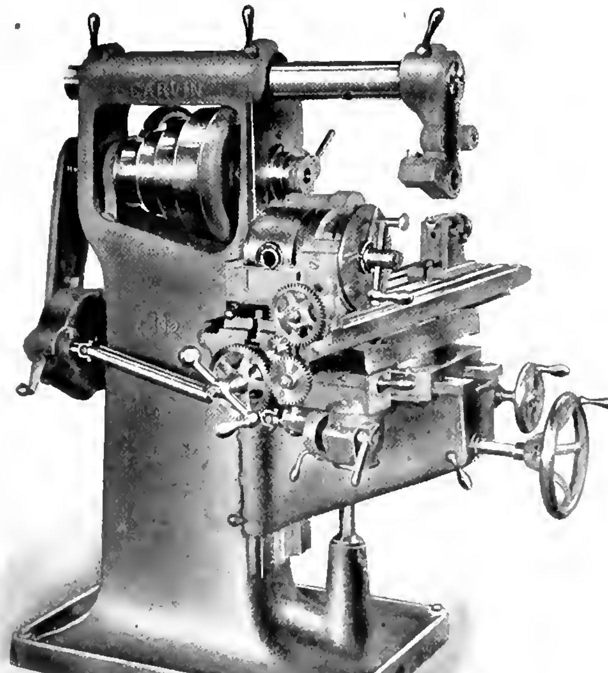

Fig. 1. Garvin No. 11 2 Geared Feed Milling Machine

This solid top construction furnishes the necessary stiffness for resisting the side pressure from heavy cuts, and checks the vibration induced by coarse tooth cutters. These troubles, and a certain amount of distortion due to overhanging work and table, are liable to be met with in designs which employ an opening in the top of the knee. The opening tends to spring together under stress, permitting the undesirable conditions noted above.

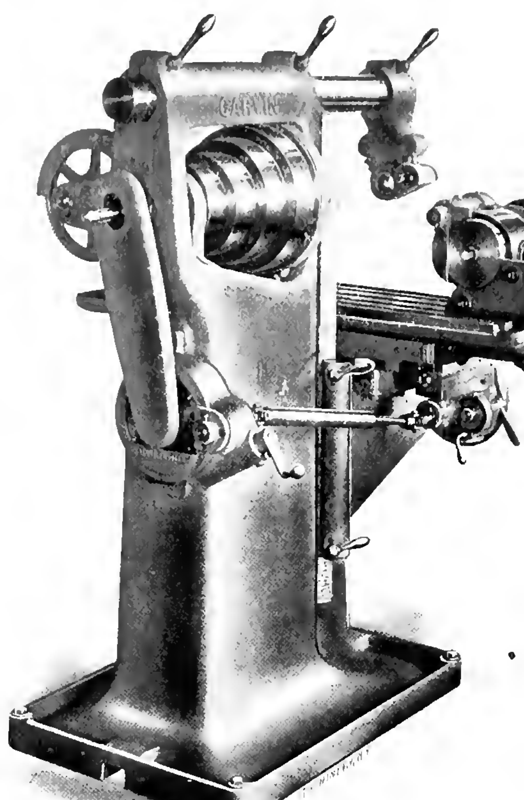

Fig. 2. Rear View of Milling Machine, showing Feed Gear-box and Connections

The solid-top design is made possible by placing the cross-feed screw just under the edge bearing on the right-hand side of the knee. Any objection which might be offered to this offset control for the in and out movement of the saddle, is answered by the design of bearing employed. This is of a type which has been generally used on gear cutting machines. The saddle is lined up by the narrow bearing on the right-hand side, to which it is confined by a strap gib beneath, which holds it down, and by a tapered gib on the edge. As this narrow guiding surface is practically central with the cross-feed screw, no canting or twisting action is possible, even should the gibs be adjusted very loosely. The resulting conditions are probably better than would be obtained by the usual method of guiding the slide across the full width of the knee, even with the cross-feed nut in the center of this wide guiding surface.

The extended bearing on the face of the column adds greatly to its rigidity, gives a larger and more durable bearing surface, and prevents a tendency to sag; and this, together with the box construction, affords a firmer and more unyielding support to the arm and arbor braces. It also permits giving more clearance between the arm brace and the face of the column without sacrificing the rigidity and accuracy of the structure.

Another interesting point in the design is shown in Fig. 3, which is a view looking down on the top of the saddle, the latter being removed. Particular attention is called to the use for the table bearing of two gibs, tapered in opposite directions. This gives assurance of a good fit at this point, and

consequently of freedom from vibration which would result from the use of a single taper gib worn at one end.

Construction of the Quick-change Feed Mechanism

The new feed-box (shown in detail in Fig. 5, and applied to the millers in Figs. 1 and 2) is unusually compact in construction, when the range and number of feeds it provides is considered. It will give 12 feed changes, varying from 0.002 to 0.080 inch per revolution of the spindle. The construction is best seen in Fig. 5.

A series of gears of different diameters, meshing with each other, is mounted on pivots extending around the periphery of a double-walled circular cage as shown. This train of gears is driven from a central gear mounted on a shaft, which receives its motion from the spindle as seen in Figs. 1 and 2. The cage in which these gears are mounted is provided with worm-wheel teeth on its periphery, meshing with a steep pitch worm mounted on a crankshaft as shown. Each revolution of this crankshaft, therefore, turns the cage to a new position; and in each of these positions a new one of the series of gears provided is brought into mesh with a pinion set in a recess in the front of the gear casing. This pinion is connected by the usual telescopic shaft with the feed gearing on the saddle.

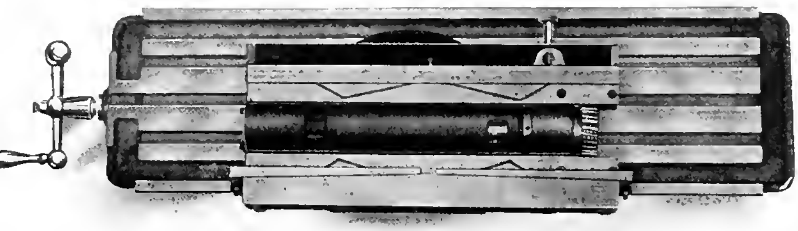

Fig. 3. Top View of Saddle (on Table) showing Double Taper Gibs

Two or three points in the construction of this mechanism should be noted. For one thing, the teeth of the gears about the periphery of the cage, and the teeth of the pinion driving the telescopic shaft, have been given special shapes. This permits them to be turned into and out of engagement freely while running at full speed, without any possible danger of interference and consequent injury. Another point that will perhaps occur to the reader as requiring consideration relates to the direction of the rotation of the feeds. The gears in the periphery of the cage, which are brought successively into mesh with the pinion on the telescopic shaft, evidently revolve in different directions. Every other one turns to the right hand, while the remaining ones turn to the left. This means that with every successive feed change, the direction of rotation is altered. This change is rectified by the feed reverse motion in the gear-box on the saddle, to which the telescopic shaft is connected. The small lever shown on this gear-box effects this reversal through a tumbler gear mechanism, similar to that commonly employed in the headstock of the engine lathe.

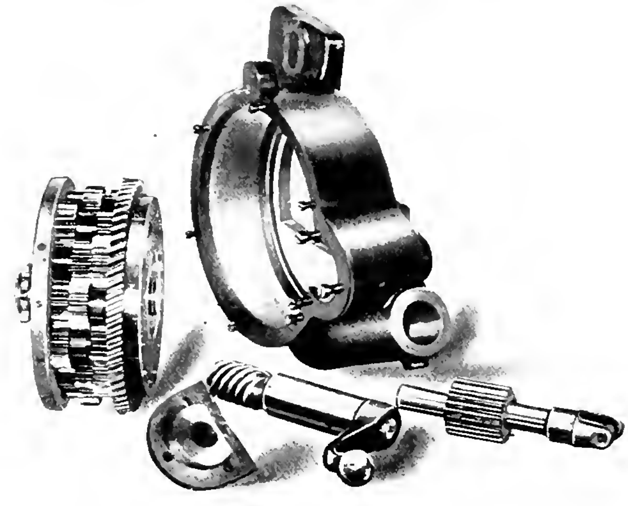

Fig. 5. Feed Gear-box Dismantled to show the Construction

The compactness of this feed change mechanism is its most salient characteristic. The ease of making the change is another as the crank, for the reasons described, can be turned rapidly and easily without meeting any perceptible resistance, until the desired feed position has been reached. Suitable graduations in connection with an index give direct readings for the rate of feed obtained.

General Features and Dimensions

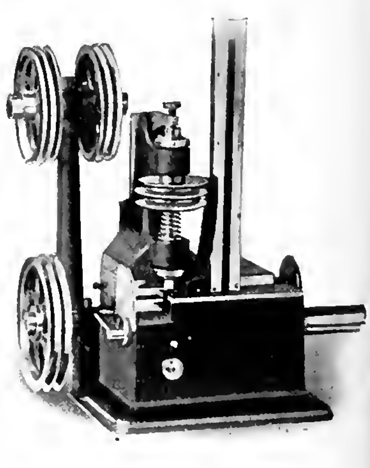
In its general construction, the remaining features of the machine come up to the standard of requirements in milling machine design. The arm is of solid steel, and overhead braces are provided. The cross, longitudinal and elevating screws are controlled by attached cranks and handwheels which give plenty of room for movement without interference with each other. The main spindle bearing is tapered, and the thrust is taken in either direction by hardened and ground washers on each side of the spindle collar. A soft packing washer is provided which may be taken out and faced off in the lathe to let the spindle in further to take up wear whenever this is necessary. A large cap holds the spindle back to its seat, and thoroughly protects the bearing from oil. The machine has a longitudinal feed of 20 inches, a cross-feed of 7 inches, and a vertical adjustment of 18 inches. The weight packed for domestic shipment is 2,300 pounds.

Fig. 4. Solid Top Extended Knee with Confined Guide Bearing for Saddle

WALTHAM AUTOMATIC VERTICAL RECESSING MACHINE

The automatic precision machine herewith illustrated is made by the Waltham Machine Works, Newton & Cutter Sts., Waltham, Mass. It was originally intended for recessing watch parts, such as bridges, etc., having a simple recess that can be roughed or finished by a revolving cutter, with the work stationary. It may be used, however, for any similar work on small flat blanks.

The blanks are placed by hand in the vertical magazine, and all the subsequent operations are automatic. The blanks are taken from the magazine by a slide, operated by compressed air, that carries them, one at a time, to a position underneath the vertical spindle carrying the cutter, where they are securely clamped, also by compressed air. The cutter spindle is then fed to the required depth by a cam attached to a shaft at the rear of the machine.



An Automatic Precision Recessing Machine

Upon the return of the cutter spindle, the slide is withdrawn, releasing the recessed blank, but leaving it directly beneath the cutter spindle. From this position it is ejected

by a blast of air with all the chips made by the operation, thus cleaning the clamp for the insertion of a fresh blank. The air valves controlling the operation of the slide, clamp and blast are operated by cams on the same shaft which carries the cam for feeding, recessing and ejecting the blank.

This machine is best adapted for brass work. A production from 12 to 20 per minute can be obtained, according to the size of the recess. The weight of the machine is 80 pounds.

WELLS SPEED LATHE FOR MANUAL TRAINING AND GENERAL SHOP USE

The firm of F. E. Wells & Son Co., of Greenfield, Mass., has developed a line of speed lathes primarily for manual training school use, but which has been found well adapted also to the general run of hand lathe work found in the ordinary machine shop. They are built either as cone pulley or motor-driven machines, and provided either with bench legs or with regular legs for mounting on the floor. The engravings shown herewith illustrate the floor type of machine.

In Fig. 1 is shown the new design of electrically-driven lathe with the motor enclosed in a special headstock. This motor is designed expressly for this lathe, with an extended spindle which is bored out with a No. 2 Morse taper, and threaded on the outside for holding chucks. A ½-inch hole is provided through the spindle for knocking out centers, holding bar stock, etc. The motor has a variable speed control by means of the starting box shown on the front of the lathe.

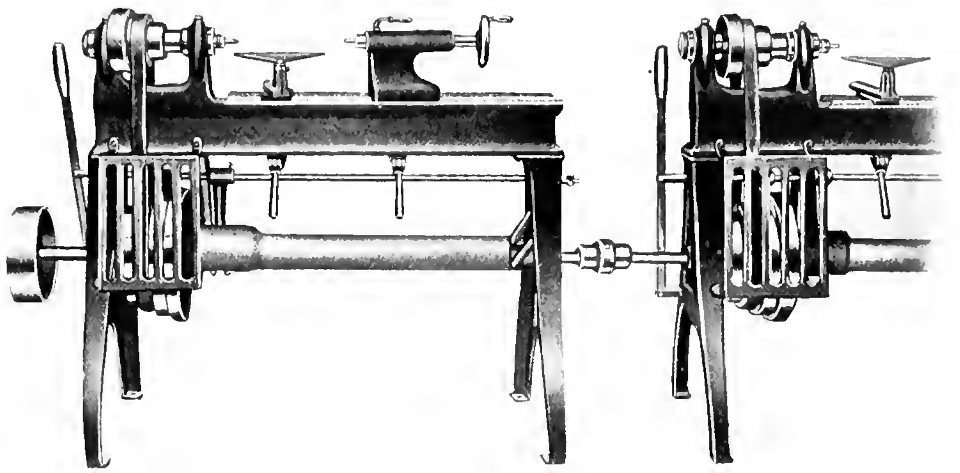


Fig. 2. Under Drive for Speed Lathes, which avoids the Use of Countershafts

One of the important new features of this line is the improved spindle bearing furnished. The box is of phosphor-bronze, split, tapered on the outside and provided with nuts at each end for adjustment in the taper seat in the headstock. This allows taking up wear without disturbing the fit on the spindle. An oil chamber in the headstock bearing furnishes a constant supply of lubricant to the spindle by means of a ring oiling device of standard construction.

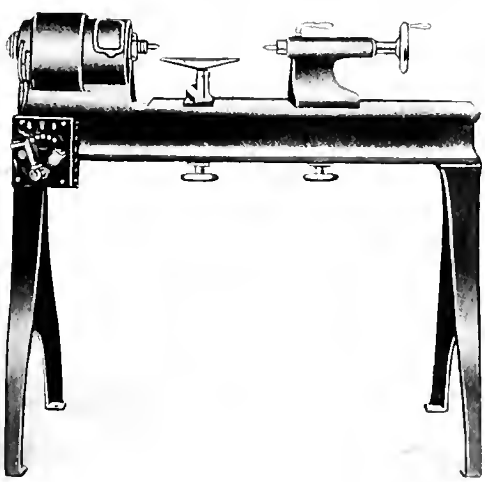

Fig. 1. Speed Lathe with Motor built into Headstock

A cone pulley type of this lathe having a novel form of belt drive is shown in Fig. 2. A lineshaft is provided, extending under as many of these lathes as it may be desired to set in a row. On this lineshaft, under each headstock, is mounted a large cone pulley which may be connected with the shaft by means of a friction clutch operated by the hand-lever shown at the end of each lathe. This lever is also connected with a brake, which goes into action when the clutch is thrown off, stopping the spindle instantly and saving considerable time. Suitable guards are provided for both shaft and pulley, obviating any danger of catching the clothing and causing consequent injury to the operator. A flexible coupling is used for connecting the lathes, so that they will run properly even though not set exactly in line. The clutch is made noiseless by hard wood bushings set in the flanges of the coupling. This makes it possible to engage or disengage them without noise while running at any speed.

On these under drive lathes the makers furnish everything except the pulley for driving the shaft, and that will be furnished if desired. Floor hangers may also be provided to extend the shaft for belting to other tools or machines.

Another method of doing away with a countershaft, and the extra belting which it requires, consists in mounting the cone pulley and friction clutch on a lineshaft directly over the lathe. The same friction is used in this case as for the under drive. By thus simplifying the overhead work and doing away with belts, countershafts, etc., complication of mechanism is avoided, the time and money spent on maintenance are greatly lessened, and the shop is made much lighter and has a more satisfactory appearance.

The engraving shows the lathe with plain screw feed tailstock, but it will be furnished with combination screw and lever feed if desired. The lathe will also, as stated, be furnished as a bench machine with short legs if preferred by the purchaser.

THE PARKER SPEED-CHANGING DEVICE

The accompanying illustrations shown the application and design of the Parker transmission and speed-changing device. This device is patented by Mr. Clark W. Parker and manufactured by the Parker Transmission and Appliance Co., Springfield, Mass. The transmission can be used for all kinds and sizes of machines that require change of speeds and is particularly applicable to machine tools and automobiles. The speed changing device is of the non-sliding gear type with positive drive, and can be operated either as a "progressive" or "selective" speed-changing device. It may be made as an integral part of the machine to which it is applied or to take the place of a countershaft, and can be placed in any convenient position. It may be made for any required number of speed changes and any ratio, and of any combination for forward and reverse speeds. In Fig. 1 the device is shown applied to a 16-inch Reed engine lathe. In this case the head-cone of the lathe has been removed and a single pulley drive supplied. The transmission takes the place of the discarded countershaft.

The principal parts of which the Parker transmission consists are two cones of gears that are in constant mesh and mounted idly on parallel shafts, the shafts being properly slotted for the sliding keys, and the shock absorber that is applied at the driven end.

The line engraving Fig. 3 shows in the lower part of the illustration a horizontal section in detail and an end view at the driven end. The upper part of Fig. 3 is the plan, and shows the transmission assembled. The lower view shows

the five gears C_1, four for the forward speeds and one for the reverse, which are mounted idly on shaft B_1, and also the sliding key E_1, which is hinged in the sliding sleeve D_1. The key E_1 is shown in its extreme right-hand position, locked in the reverse gear. The reverse is obtained by using an intermediate gear indicated in the end view. The collars between the gears are fastened tightly on the shafts and prevent any tendency that the shafts may have to spread at the slots. They also act as a device to release that portion of the key

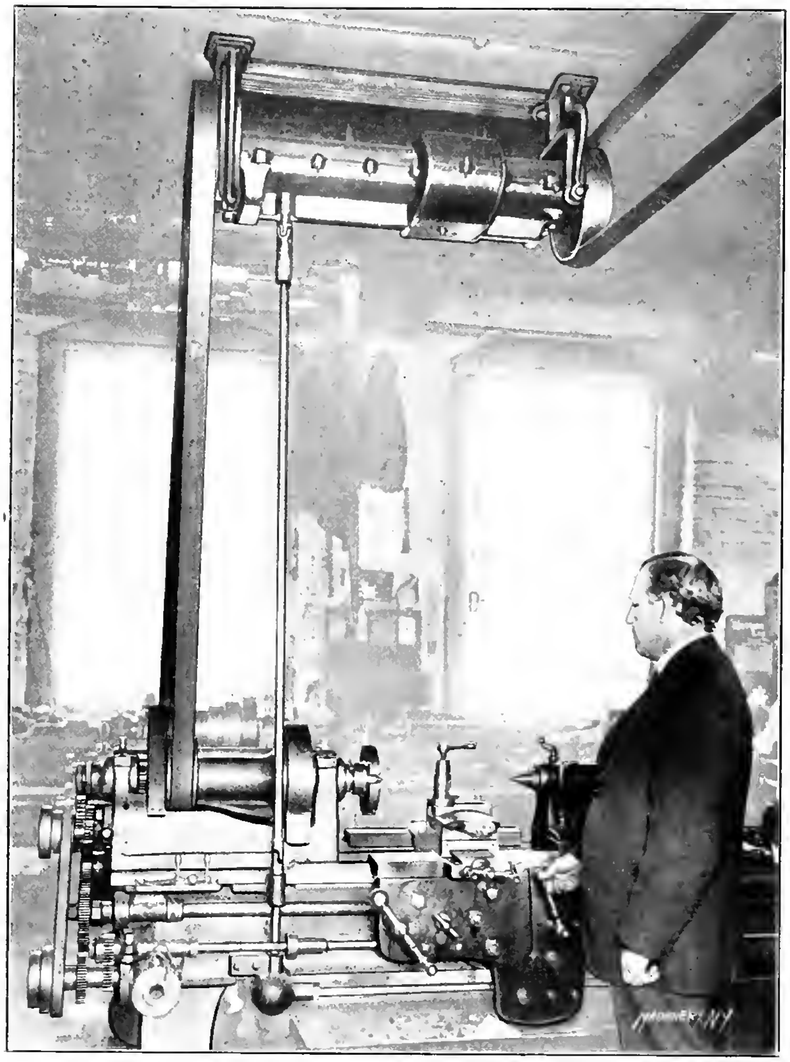

Fig. 1. The Parker Speed-changing Device applied to an Engine Lathe

that is locked in the gear slots when changing the positions of the keys of gears C and C_1 for obtaining the change of speed. The keys are moved by sliding the sleeves D and D_1 on the shafts B and B_1.

In the upper view in Fig. 3 are shown assembled both sets of cone gears C and C_1 mounted on their shafts B and B_1, the collars between the gears, the sliding sleeves D and D_1 on each shaft, the yoke F which moves both sleeves D and D_1 and the attached keys. These latter move at the same time when making a change. To the yoke F is attached a rack G which, in this case, is moved by the gear H, that is mounted at the end of the vertical rod passing up from the machine in Fig. 1.

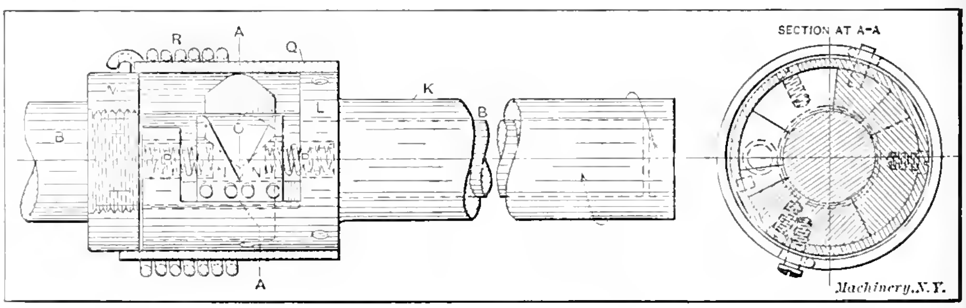

Fig. 2. The Shock Absorbing Mechanism

At the right in Fig. 3 is shown the pulley I by which power is delivered to the transmission. This pulley, through the shock absorber J, delivers the power to shaft B, and thence through the gearing and pulley W to the machine to be driven. The gears not locked by the keys are running loose only on their shafts.

The shock absorber is shown in detail in Fig. 2. This is one of the main features of the Parker transmission. It prevents any undue wear and breakage from sudden engagement. The pulley I is fastened to a sleeve K that is a running fit on shaft B. The sleeve K is enlarged at L at which place it is partly cut away. A piece M similar to L is fastened to shaft B. The pieces L and M overlap each other in a clutch-like manner and in the box-like space between them are two wedged-shaped blocks N and a V-shaped block O. The blocks N are forced together by the springs P, and the power is transmitted by block O being wedged in between blocks N. This mechanism is covered by the shell Q that is fastened to the sleeve head L. The helical spring R is at the proper tension to carry the idle load, one end of this spring being fastened to shell Q, and the other end to M. As the springs P force the blocks N together, these in turn hold the block O against its seat in M.

In operation, the shock absorber revolves shaft B only, until the key in this shaft enters the slot in one of the gears C, into which it is forced by small springs indicated in Fig. 3. Now a single pair of gears is revolved until the slot in the meshing gear C_1 comes opposite key E_1, at which time the key is forced into position in C_1 and now, when both keys are engaged, the working load is transferred to spring R which, not being strong enough to take the whole load, shifts it onto the blocks N and O, the block O forcing the blocks N apart until springs P offer resistance enough to permit the carrying of the load. The mechanism is thus engaged without shock or blow.

In Fig. 1 is shown the method of operating the Parker transmission at the lathe carriage. Changing the position of the crank-handle at the lathe carriage revolves the horizontal rod shown, and through bevel gears actuates the vertical rod from the machine to the transmission. At the top of this rod is fastened gear H, Fig. 3, which, in turn, moves the key-shifting mechanism, as mentioned. A pointer and scale near the crank-handle in the apron indicates which pair of gears is engaged. This lathe now has the same speeds that were obtained with the regular head-cone, and the belt is of the same width, but by having better belt contact on the pulleys, the lathe is capable of taking a cut more than double that possible with the cone pulley arrangement. The transmission can also as readily be operated by the ordinary shipper lever arrangement.

The transmission shown has been in constant use for two years. A transmission has also been applied to a six-cylinder Stevens-Duryea 40 H. P. automobile that has run over 16,000 miles. No repairs or adjustments have been made on either of these transmissions, and in a recent examination of the automobile transmission a wear of only 0.005 inch had taken place at the keys. This small wear, of course, in no way impairs the working or efficiency of the transmission.

One of the important features of the device is that it is very compact. The distance between the bearings for a 40-horsepower automobile is only 10 inches. When used as a machine tool drive, the size is, of course, not so important, but its other features will undoubtedly make it of interest to the machine tool trade.

GARVIN SPEED LATHE FITTED WITH AUTOMATIC CHUCK AND TWO-HOLE TURRET

The speed lathe shown herewith was built by the Garvin Machine Co., Spring and Varick Sts., New York City. The simple attachments with which this lathe is provided adapt it to the operations of drilling and tapping, in a way which should produce a surprisingly high output, considering the simple nature of the special devices employed.

As shown in Fig. 1, the headstock is provided with two loose and one tight pulley, together with a belt shifter operated by a treadle, so that the direction of rotation of the spindle can be controlled by the foot, leaving the hands free. This reversal is provided for the tapping operation.

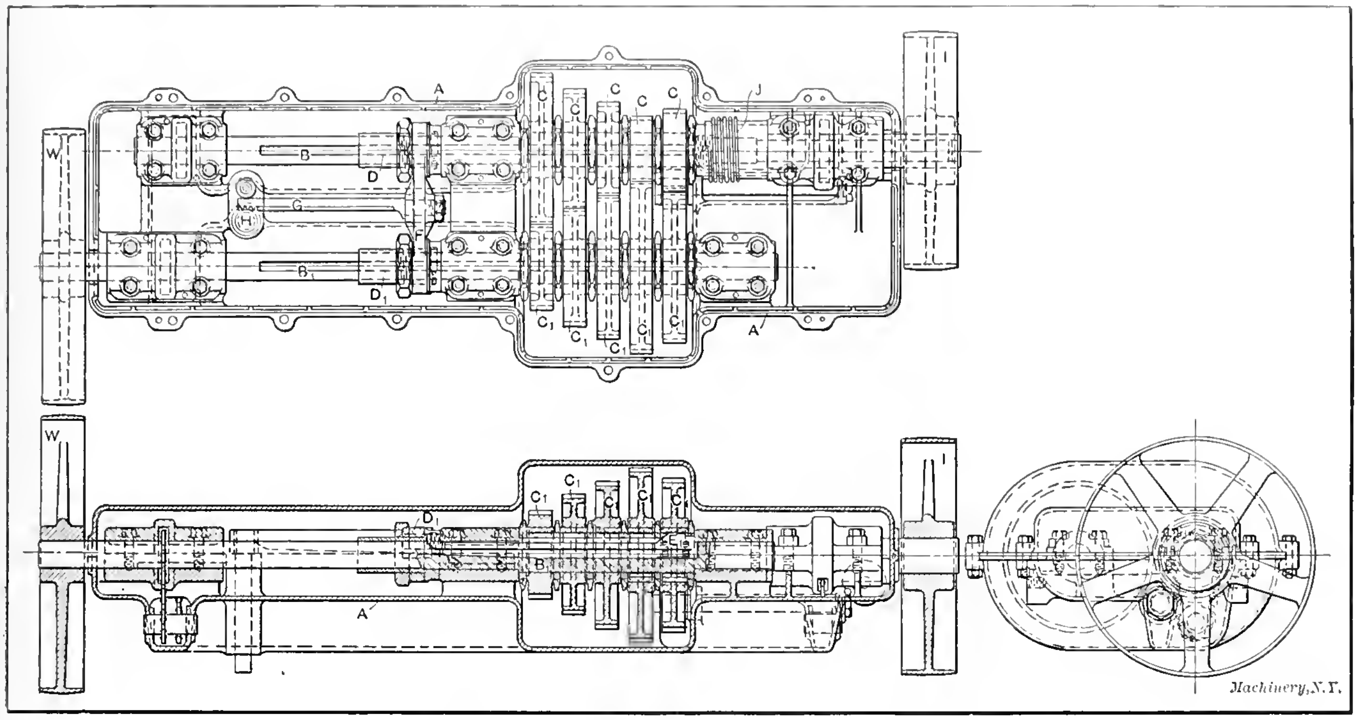

Fig. 3. Section through Speed Changing Device, showing Construction

The spindle nose is fitted with a Jacobs chuck, having a leather or canvas faced brake band around it, which can be tightened down on the knurled sleeve by the operation of the lever shown at the front of the headstock. This provision of a brake on the chuck and a reversing mechanism for the spindle, allows the chuck to be opened and closed automatically without stopping the spindle. When this is running forward and the work is inserted between the jaws of the chuck, the tightening of the brake screws these jaws down onto the work. After the spindle has been reversed to back the tap out, the tightening of the brake works in the other direction, releasing the jaws and allowing the work to drop out. This evidently facilitates to a high degree the operation of the machine. A tap holder of the pull-off type is used, so that absolute accuracy in reversal is not necessary.

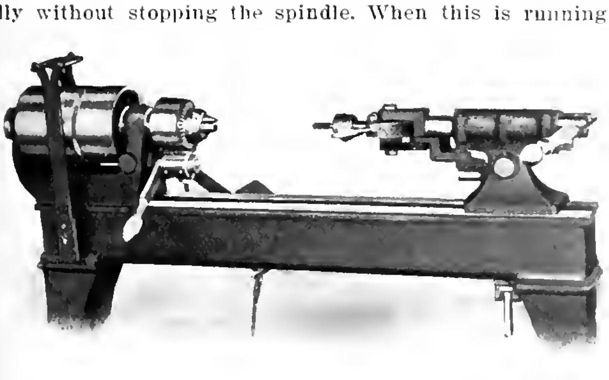

Fig. 1. Automatic Chuck Control and Two-hole Turret, applied to Speed Lathe

A very simple and ingenious mechanism, shown in detail in Fig. 2, is used for operating the two-hole turret, which carries a drill and a tap. This turret, *A*, is pivoted in the forked end *B* of the tailstock spindle. Plunger *C* in the center of this spindle is provided with a point which enters either of the two V-notches shown in the rear edge of the turret, locating it with either one of the two holes in line with the spindle of the lathe.

The turret *A* is alternately thrown from one position to the other by means of the crab-claw shaped piece shown at *D*. This has just thrown the turret to the position shown in the plan view, by the engagement of its rear prong with the kite-shaped dog *F*, which is pinned to the turret. As the tailstock spindle is moved forward, feeding the tool into the work, pin *E* on the lower side of the turret strikes inclined surface *c* of the crab claw, turning it about pivot *G* and bringing the front prong in a position to engage with the front projection of dog *F*. When the turret is again drawn back, this front prong operates on *F* to throw the turret around to bring the other hole in line with the spindle, and it is held in this position by the bearing of spring plunger *C* in the other V-notch. When the turret again moves forward, pin *E* has been shifted to engage with the inclined surface *c*, on the front prong, and the crab claw is thus thrown back again to the position shown in the engraving.

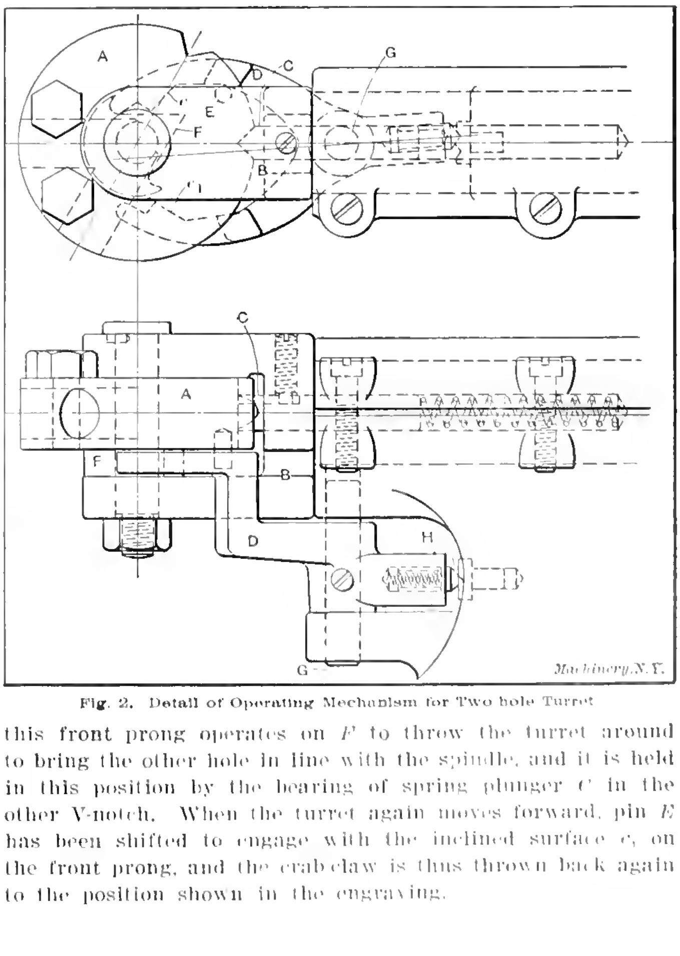

Fig. 2. Detail of Operating Mechanism for Two-hole Turret

Spring plunger *H* enters V-notches cut in the plug shown, and holds *D* in each of its two positions. It will be seen that this can be worked rapidly and without attention, other than is required to make sure that the tailstock lever is thrown clear back at each stroke. The forward movement is limited by an adjustable stop as shown in Fig. 1.

This mechanism is evidently not designed for work requiring extreme accuracy; but in the ordinary case, in which it is simply required to drill and tap a hole, a high output is made possible. The combination of foot and hand lever movements, the automatic changing of tools, and the opening and closing of the chuck, reduce the time required for idle movement to the lowest possible figure.

MIAMI PLAIN AND UNIVERSAL CUTTER AND TOOL GRINDERS

The Miami Valley Machine Tool Co., of Dayton, Ohio, has redesigned its plain and universal tool-room grinders, adding considerably to their convenience. The universal machine is shown in Fig. 1, while the plain machine with the cylindrical grinding attachments, etc., removed, is shown in Fig. 2.

On both the machines the table is traversed by a crank-handle at the front, which operates through a rack and pinion movement. This takes the place of the hand lever arrangement formerly used, gives a more even feed, and is conveniently operated by either hand. On both machines the tables swivel for grinding tapers, graduations being provided at one end for quickly setting to the proper angle. The emery wheel head also swivels, instead of having the body of the machine adjustable as formerly. This gives a quick adjustment, and permits the grinders to be placed in a more restricted space than formerly. This is an item of considerable importance where the floor space is limited. The bearings are of phosphor-bronze, compensated for wear, and protected from grit by felt washers revolving inside the dust ring caps. The machine is designed so that the only time that the vertical adjustment of the wheel spindle is required, is when backing off taper reamers. This vertical adjustment is provided by turning the adjusting nut shown under the base of the wheel-stand in Fig. 3. The universal machine shown in Fig. 1 is provided, as shown, with a live spindle headstock and a spring tailstock for cylindrical grinding. An internal attachment is also permanently mounted on the head, in the position best shown in Fig. 3. When operating the internal attachment, the drive belt on the wheel-head is run as a cross-belt, so that no change is required. The handwheel at the right of the column operates the cross feed, while that at the left gives a fine adjustment to the table movement permitting the accurate squaring up of shoulders, thrust surfaces, etc.

Among the other attachments furnished with this style of machine are, an indexing holder for grinding formed cutters, etc.; a universal holder for angular mills, end mill teeth, etc.,

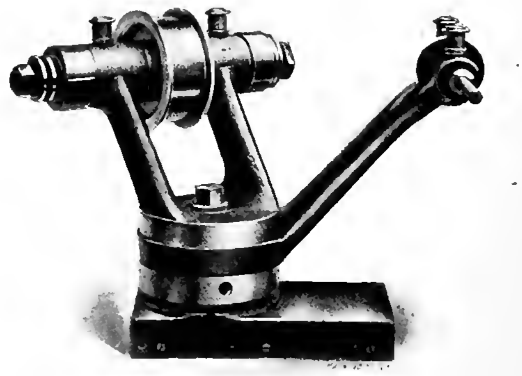

Fig. 3. Wheel Head of Universal Machine showing Vertical Adjustment and Permanently Mounted Internal Grinding Spindle

and a universal chuck, driving dogs, plain centers for reamers and similar work, vise, dead center driving pulley, tooth rests, wrenches, etc. The countershaft provided has a cone pulley driven drum, for belting to the live spindle headstock for cylindrical grinding.

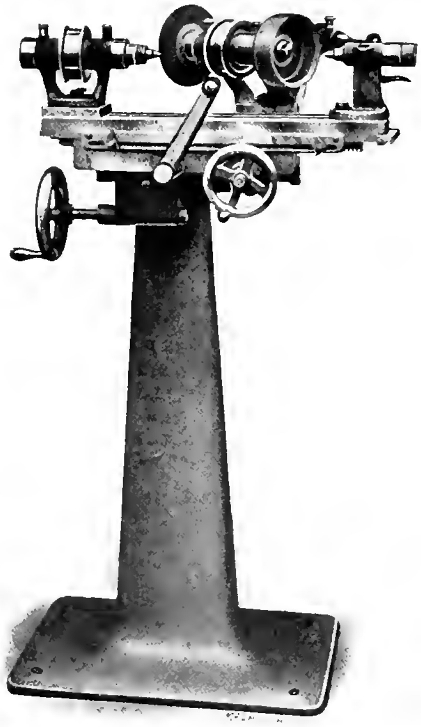

Fig. 1. Universal Cutter Tool and Cylindrical Grinder for Tool-room Use

Fig. 2. Plain Machine for Cutter and Reamer Grinding

The plain machine shown in Fig. 2 is particularly adapted to cutter and reamer grinding. For this work it is provided, as shown, with a pair of plain centers. Suitable wrenches and tooth rests are also furnished, together with a universal indexing attachment for sharpening formed cutters, end and angular mills, and similar work. In this design of machine, the double countershaft is not required, nor is the fine longitudinal adjustment for the table. In each case stops are provided at the front of the table, as shown, to limit the movement in both directions.

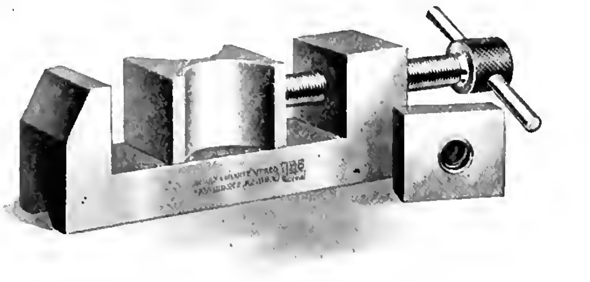
The universal machine will take work between the centers 8 inches in diameter and 16 inches long. The table swivels up to 4 inches taper per foot. Milling cutters, angular or straight, up to 16 inches in diameter can be ground. The internal attachment will operate on holes up to 6 inches in diameter and 4 inches long. The formed cutter centers will take 5 inches diameter up to 11 inches long. The vise has jaws 3 inches long, opening up 2 inches wide. The machine weighs about 500 pounds. The plain machine takes work up to 8 inches in diameter and 20 inches long, but will sharpen milling cutters, angle or straight, up to 16 inches in diameter. The table swivels the same as the universal machine, up to 4 inches taper per foot. This style weighs about 400 pounds.

BROWN & SHARPE TOOLMAKER'S VISE

The device herewith illustrated is a recent addition to the line of small tools made by the Brown & Sharpe Mfg. Co., of Providence, R. I. It is a toolmaker's vise and is intended

particularly for holding work for drilling and other light machining operations, and also for fitting and laying out on the surface plate. Many other uses will readily occur to the user of the tool.

The body is made of steel, drop forged and case-hardened. The screw is hardened to provide against wear. It has a knurled head for easy manipulation, and is provided as well with a short cross-bar through the head, by means of which a firm grip may be had upon the work. Two interchangeable jaws of different size are furnished, which readily slip on and off the end of the screw and provide for holding work of any dimensions up to 2 inches wide. While this vise is light and convenient to handle, it is still made strong



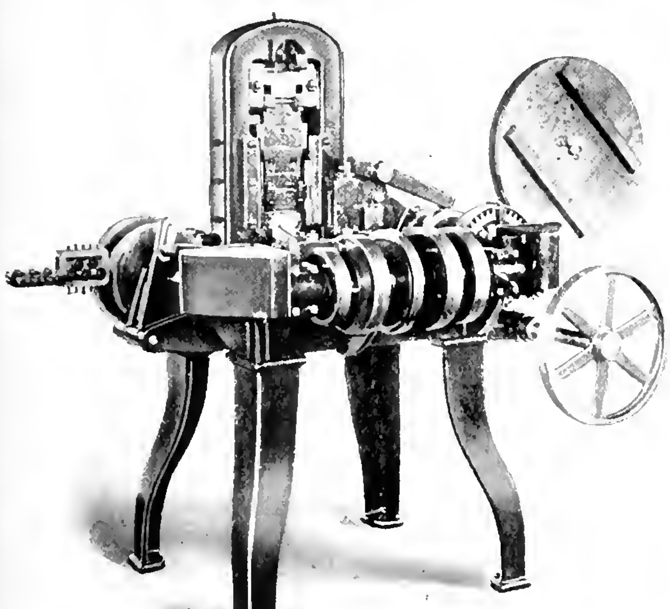
A Toolmaker's Vise for Laying-out, Drilling, etc.

enough to withstand the severest usage it is likely to be subjected to.

The V-groove cut in the under side of the body of the vise makes it useful as a V-block for centering round bars, supporting round work in the drill press, and other operations that an ordinary V-block is used for. The vise can be employed for this purpose by simply turning it over. The V-groove is machined very accurately. This is true of all the surfaces of the vise, whose usefulness is thus extended in laying out and similar careful work, where it is convenient to lay the tool on its side, stand it on end, or place it in other positions without interfering with the accuracy of the setting.

BAIRD WIRE FORMING, FERRULING AND STAMPING MACHINE

In the issue of MACHINERY for January, 1910, we illustrated a machine made by the Baird Machine Co., Oakville, Conn.,



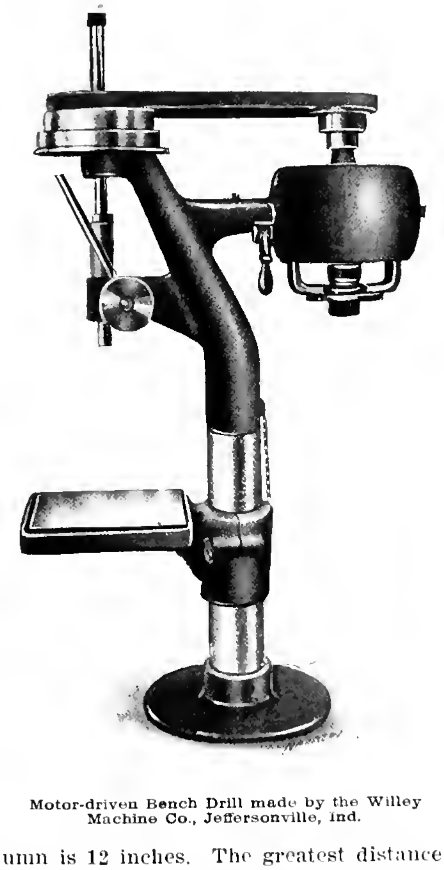
An Automatic Machine for Making Parts from Wire requiring Several Operations

for forming and stamping parts made of wire. In the February, 1910, number was illustrated and described a machine built by the same firm for forming and ferruling wire parts. The machine herewith illustrated combines the functions of the two previously described. It will take wire from the coil, straighten, feed and cut it off, form it into shape, attach to it a ferrule made from a strip of metal wound from the reel at the right of the engraving, and carry it to a press incorporated in the mechanism, where it is flattened and stamped as may be required.

While the machine was first designed to be used particularly on dry goods novelties, it has found many other uses in general manufacturing work. Such articles are made at the rate of 60 to 80 per minute according to size and shape and are dropped from the machine completely finished. It is made in several sizes to cover a wide range of work. The makers state that particular attention is given to the materials and workmanship used, with an idea of making it a serviceable and durable machine.

WILLEY MOTOR-DRIVEN BENCH DRILL

In the department New Machinery and Tools Notes, in the October, 1909, issue of MACHINERY, a brief description was given of a motor-driven sensitive drill built by the Willey Machine Co., Jeffersonville, Ind. This company has now brought out a bench drill built on the same principles as the 12-inch sensitive drill then referred to. The motor is connected to the spindle by a belt and cone pulley, three changes of speed being provided. The motor is adjustably mounted for tightening the belt, and the starting switch is placed within the motor frame, thus eliminating outside connections. Any type of motor can be used, and the motor can be easily detached and exchanged for another of different voltage if required. The table is square and its weight is counterbalanced by a weight inside of the column. When not required it can be swung out of the way. While the tool is very simple and reliable, it is adapted to a wide range of work. The most important dimensions of the machine are as follows: The distance from the center of the spindle to the column is 12 inches. The greatest distance from the spindle to the table is 14 inches. The traverse of the spindle is 3 inches. The power of the motor is 1/3 horsepower, and the weight of the machine, 180 pounds.



Motor-driven Bench Drill made by the Willey Machine Co., Jeffersonville, Ind.

KERN 25-INCH HIGH-SPEED UPRIGHT DRILL

This machine is of an entirely new design and is provided with a number of important improvements in construction. Among these may be mentioned the use of a three-step cone drive with double back-gears, and an improved construction of vertical reverse for tapping and similar operations. A power quick change feed is also provided. In its structural design, and in the proportions of its details as well, it is intended to fully meet the severe requirements imposed by the use of modern high-speed drills.

The three-step cone and double back-gears provide nine changes of spindle speed. This gives a sufficient range for all the work for which the machine should be used, and at the same time gives more power than with the ordinary construction. Wide cone steps of large diameter are possible, giving a greatly increased belt capacity. At the same time,

the belts themselves are always running at a high speed and thus transmit nearly their maximum power even when the spindle is on the slowest speed. This is particularly advantageous in the drilling of large holes where, with the ordinary low ratio single back-gears, a comparatively slow belt speed would have to be used.

The arrangement of the driving gears is best shown in Fig. 3. *A* is the three-step cone pulley, which is belted to the countershaft on the base of the machine. The shaft on which *A* is mounted is bored out to form a bearing for driving shaft *B*, which revolves loosely in it. Keyed to the cone pulley shaft *C* is a gear *D*, which, through idler *E*, is connected with gear *F* on back-gear shaft *G*. Also keyed to shaft *G* is a large gear *H*, meshing with pinion *J*, which is keyed to *B*. The hubs of gears *F* and *D* are provided with friction clutches operated by sliding collars *K* and *L*. These are connected together and operated by the lever which extends down back of the main column of the machine in Fig. 1, and is furnished with a lever in back of the spindle head as shown. This lever is so connected with the clutches that when one is thrown in the other is released.

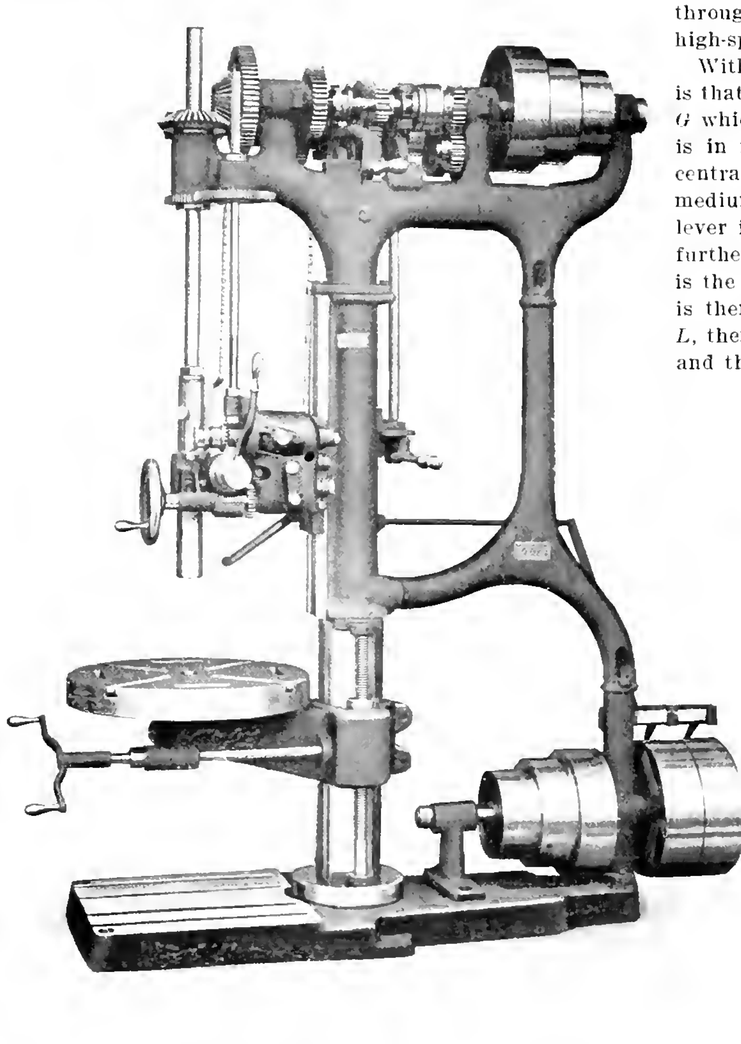


Fig. 1. High-speed Drill Press with Gear Guards Removed

The mechanism thus described is for reversing the spindle motion, and the lever just described is therefore the one used for tapping. The operation is as follows: When the clutch *L* is thrown in at gear *D*, driving shaft *B* is directly engaged with shaft *C* and runs at the same speed. When clutch *L* is thrown out and *K* is engaged, the motion is from gear *D* through *E* to *F* and then through shaft *G* to gear *H*, which drives pinion *J* at a higher speed and in the opposite direction, for backing out taps, etc. It will be seen that shaft *G*, with this construction, revolves constantly whenever *B* is revolving, but at a slower rate of speed.

The double back-gears are operated by the handle shown at the top of the main column in Fig. 1. This controls sliding gears *M* and *N* and positive clutch *O*, in such a way as to give either a direct drive from shaft *C* through to bevel gear *P*, or else one of two back-gear ratios. When the lever is thrown to the left, clutch *O* engages mating clutch teeth in the face of gear *Q*, which is keyed to the sleeve hub of gear *R*; this being keyed, in turn, to bevel gear *P*, drives the spindle. It will thus be seen that on the forward motion, with clutch *O* thrown in, the drive is direct from pulley *A* through to bevel pinion *P*, without transmitting the power through any gears whatsoever. This is the condition for high-speed work.

With the back-gears arranged in the second position, which is that shown in the engraving, clutch *O* is disengaged. Shaft *G* which, as has been pointed out, revolves constantly when *B* is in motion, has keyed to it sliding gear *M*, which in this central position is in mesh with gear *Q*. By this means a medium back-gear speed is obtained. When the back-gear lever is thrown to the extreme right, gears *M* and *N* are still further shifted until *N* is in engagement with gear *R*. This is the slowest speed, and on the forward direction the motion is then transmitted from pulley *A*, through gear *D* to clutch *L*, thence to shaft *B*, then through gears *J* and *H* to shaft *G*, and then from pinion *N* to gear *R* and bevel pinion *P*.

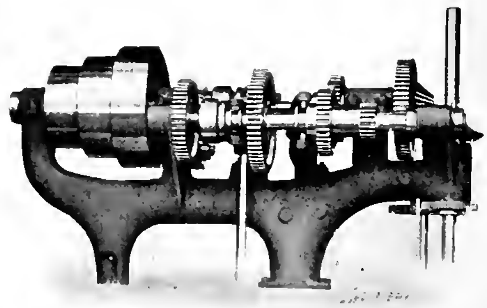

Fig. 2. View of Back and Reverse Gearing

The placing of the friction reverse mechanism between the cone pulley and the back-gears, instead of between the back-gears and the spindle, is unique on the upright drill press so far as we know, although the construction has been common for some time in radial drill press practice. There seems to be fully as much need for it on the upright drill. It gives the great advantage, of course, that on heavy tapping operations in which the highest back-gear ratio is thrown in, the torsional strain is transmitted through the friction at comparatively high speed, and with a correspondingly low torsional strain. With the usual construction, the frictions have to carry the load at low speed and under a greatly increased torsional strain. The frictions are originally designed to be of great strength and durability, and this location gives them an added advantage. The greatest gear ratio between them and the spindle is 12$\frac{1}{2}$ to 1, in which case they are required to exert less than 1/12 of the actual torque exerted on the spindle. This insures long life, as the possibility of slipping is entirely avoided.

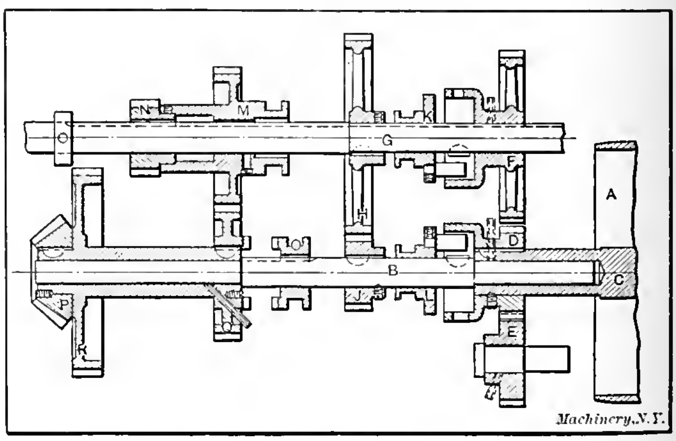

Fig. 3. Arrangement of Gears and Clutches for the Speed Control

In comparing the driving power of this drill with others of the same size, but of orthodox design, it should be noted that

with this machine the cone diameters are 9, 11 and 13 inches for a 3½-inch belt, with the driving cone running at 440 revolutions per minute. Ordinary proportions for the 4 step cone with single back-gears give cone diameters varying from 5 to 11 inches, with a 2½-inch single ply belt, seldom running over 350 revolutions per minute. Under these two conditions the belt power for the 3-step cone on high speeds will be seen to be about double that of the 4-step cone, while on slow speeds it will have nearer three times the power.

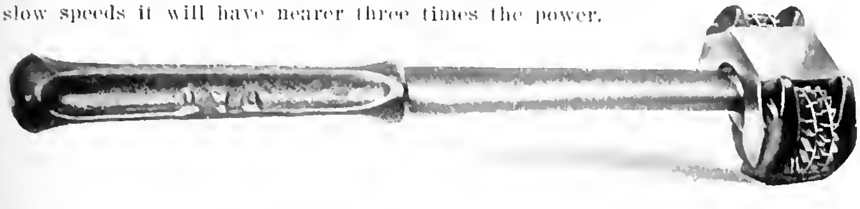
The operating lever of this reversing or tapping attachment, being mounted directly behind the sliding spindle head, is in a convenient position to be used for starting and stopping the machine, as well as for reversing. When thus stopped, only the the countershaft and the cone pulleys are in motion, thus saving unnecessary wear on the gearing and other revolving parts. On the standard machine without the tapping attachment, this lever operates a single clutch for starting and stopping only. The back-gear changes may be effected if desired while the machine is in operation, though the convenient position of the tapping attachment lever makes it easy to stop the machine for making the change.

The geared feed change mechanism is mounted on the sliding head. It gives eight variations, ranging in geometrical progression from 0.006 to 0.050 inch per revolution of the spindle. It is of simple construction, but seven gears and two levers being required for its operation. A feed plate is attached to the frame in a convenient place, indicating at a glance the correct position of the lever for any desired feed. All the gears are of steel, and have wide faces and coarse pitch. An automatic stop and depth gage for the feed is furnished. These features, in combination with the graduations on the spindle sleeve, permit tripping the feed at any desired depth from any given position within the limits of the travel of the sleeve, allowing any number of holes to be drilled within fixed dimensions. It should be noted that the feed control lever, as well as the other operating levers of the machine, are placed at the right-hand sides where they may be manipulated by the workman without change of position.

The total height of the drill is 89¾ inches. The column is 6½ inches in diameter, and the spindle 1 9/16 inch. It drills to the center of a 25½-inch circle. The greatest distance from the spindle to the baseplate is 45½ inches, and from the spindle to the table, 32 inches. The spindle has a feed of 10 inches in the head. The table has a vertical adjustment on the column of 15 inches. The spindle is bored to No. 4 Morse taper. This drill requires a floor space of 30 by 70 inches, and has a net weight of 1,900 pounds. For motor drive the cone pulleys may easily be replaced with single pulleys, permitting the speed range to be obtained through the back-gears when using a variable speed motor of commercial design. It should be mentioned that the machine is fully provided with gear guards, though these are shown removed in the illustrations. This drill is made by the Kern Machine Tool Co., Cincinnati, Ohio.

MARBACH EMERY WHEEL DRESSER

The tool herewith illustrated is designed for truing emery wheels, making use for this purpose of the well-known and effective combination of hardened steel star wheels and washers, mounted on pivots so as to revolve freely in contact with the emery surface. The improvement in the construction relates to the provision made for safeguarding the workman from injury in the operation of dressing the face of the wheel. In this operation two dangers are met with, one of which is that of grit getting into the eyes of the operator. If he wears glasses they become so pitted almost immediately that they have to be discarded, owing to the fact that he stands directly in the path of the flying particles and receives them in the face. Besides this there is the further and more serious danger of the breakage of the wheel under the strain of dressing it. This breakage is almost sure to mean injury or even death to the operator, and great expense to the manufacturer.

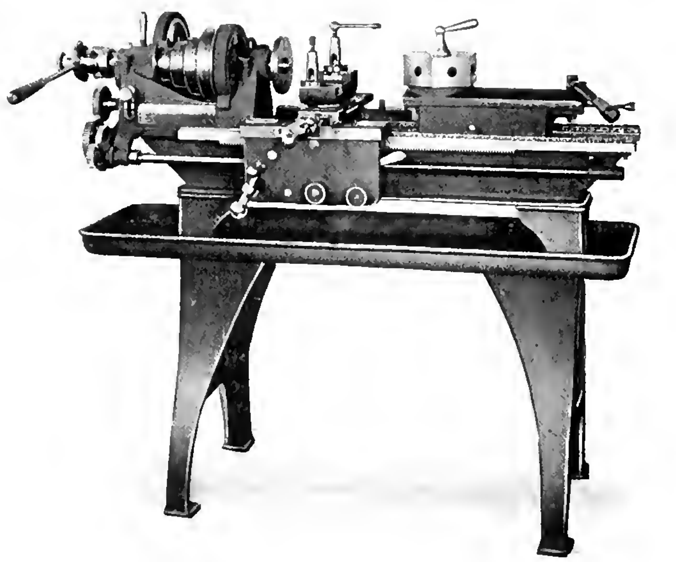


An Emery Wheel Dresser which safeguards the Workman

These dangers are avoided in the dresser shown, simply by providing the tool with a handle extending out to the side of the machine instead of directly in front as usual. This brings the operator out of the line of flying parts of emery or pieces of broken wheel. In order to enable him to exert the proper pressure, horns or projections are provided under the star wheel bearings, which may be hooked under the face of the wheel-rest, permitting him to get a strong leverage by twisting the handle of the tool. Two sets of rolls are provided, as shown, doubling the effective life of the tool. The metal clip spans the ends of both pivots and holds them in place. This permits the rolls to be readily assembled. This tool is made by the F. G. Marbach Co., Medina, Ohio.

ATTACHMENT FOR "STAR" LATHES

In the September, 1909, issue of MACHINERY, the "Star" lathes built by the Seneca Falls Mfg. Co., 330 Water St., Seneca Falls, N. Y., were illustrated and described. It will be remembered that these lathes have 9- and 11-inch swing. In the accompanying illustration is shown one of these lathes provided with three new attachments, lately brought out by the company, which practically convert the lathe into a hand screw machine capable of rapidly producing small duplicate pieces in large quantities. These three attachments consist of an automatic turret, a draw-in chuck and rod feed attachment, and a double tool-block or cutting-off and forming slide.



"Star" Lathe, provided with Turret Attachment, Draw-in Chuck, Rod Feed and Cutting-off and Forming Slide

The automatic turret, placed on the bed as shown, is operated by a hand lever, and the turret head automatically revolves when the lever draws the slide away from the work. An adjustable stop is provided and the sides of the hexagon turret are finished square with the ways of the bed, so that the face may be drilled and tapped for bolting on special tools, if required. A hole through the turret post permits a bar to pass through the turret head when machining long pieces.

The draw-in chuck and automatic rod feed attachment permits of the feeding and chucking of the bar stock operated upon without stopping the machine. By moving the hand lever operating this attachment to the left, the split collet or chuck is released and the feed fingers are brought back; by moving the lever to the right, the feed fingers are brought to bear on the stock and feed it forward until at the end of the movement the split collet is closed. This device is simple in its construction, but it is very effective and facilitates rapid production to a considerable extent.

The double tool-block or cutting-off and forming slide is attached to the cross slide and is interchangeable with the plain and compound rests. When this tool block is used in connection with the turret and draw-in chuck attachments, the lathe is practically transformed into a complete hand screw machine, being in addition a screw-cutting engine lathe. The machine undoubtedly will be highly appreciated in shops where the requirements do not make a special hand screw machine necessary, but where considerable work for which this machine is adapted is to be done from time to time. These attachments are somewhat of a novelty, and as far as we know, there is no other maker of similar sizes of lathes who furnishes attachments of this kind. Of course, the automatic draw-in chuck and rod feed is similar in principle to that regularly employed by some makers of small hand screw machines on their regular type of tool, but this attachment to so small a screw cutting engine lathe is unusual, and will be appreciated by the users of the machine.

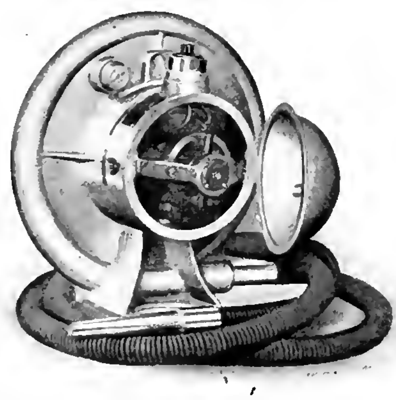


Fig. 1. Sturtevant Electric Dust Blowing Set

STURTEVANT ELECTRIC DUST-BLOWING SET

A dust-blowing set composed of a small light aluminum fan and driven by a direct-connected electric motor, built to operate from lighting circuits, has recently been brought out by the B. F. Sturtevant Co., Hyde Park, Mass. The device with a 1¼-inch diameter flexible reinforced air hose and a 10-inch long polished tapered aluminum nozzle is shown in the accompanying illustration, Fig. 1. The runner or fan-wheel is shown in Fig. 2. It is designed especially for the blowing out of dust from around motors, switchboards or other machinery, and also for the removal of chips and dust in the working of metals. While the blower does not give as high a pressure as would a regular compressed air system, the larger volume of air at the lower pressure in most cases accomplishes the same results without there being the hard severe blast necessary from such a system. The larger volume of air also enables a greater area to be covered in less time than would otherwise be the case. The device is portable, weighing only 55 pounds and provided with socket and cord for attaching it directly to a lamp socket. It can also be used as a vacuum cleaner in cases where a dust-collector is not required. All that is necessary for changing it from a blower to a vacuum cleaner is to attach one end of the hose to the inlet of the fan, and another hose can be connected to the outlet through which the fan may discharge the dust or chips removed. As there is no dust collector, however, used with this arrangement, care should be taken that no objects are picked up which would work injury to the fan.

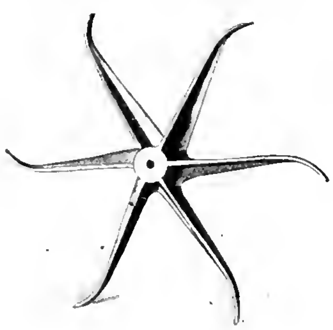

Fig. 2. Runner of Sturtevant Dust Blower

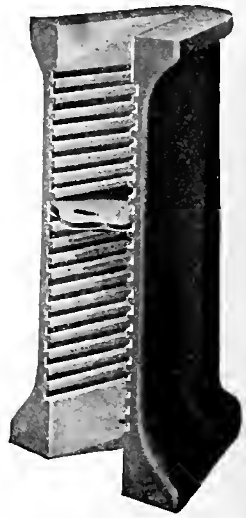
NICHOLSON DRIVING BLOCK

The device herewith illustrated shows itself on first sight to be a variation of the orthodox form of driving block, which has been in use for many years. The mechanic will readily see, however, that the makers, W. H. Nicholson & Co., Wilkes-barre, Pa., have incorporated several refinements in construction which greatly increase its usefulness.



A Driving Block with Adjustable Shelf for Retaining Arbor

The driving block is of the type provided with V-shaped center, which supports the work close up to the arbor with any size of hole. The interior of this V has formed in it, as shown, a series of cored slots, in any pair of which may be inserted a shelf for the arbor to drop onto. In driving the mandrel out of the work without the shelf to catch it, it would fall to the floor, instead of having the short drop of an inch or two allowed with this construction. The shelf is of iron, covered with leather, so that there is no danger of bruising the arbor. Of course, the hammer used for knocking out the arbor should be of leather, rawhide, wood or similar soft material. This driving block is 28 inches in height, weighs 225 pounds, and is sold for $15.00.

NORTHERN MACHINE WORKS "LITTLE GIANT" CUTTING-OFF SAW

The cutting-off saw shown herewith is intended by its builders, the Northern Machine & Repair Works of Wausau, Wis., to be simple and inexpensive enough to take the place of the power hack-saw, on work for which this latter machine is largely used—namely, the cutting off of stock. The advantage of the circular saw for this work is, of course, the fact that it cuts off the stock squarely, leaving the ends ready for accurate centering. At the same time it permits the stock to be cut to exact length without waste for truing up. A circular saw, when properly driven, also cuts very much faster than the hack-saw.

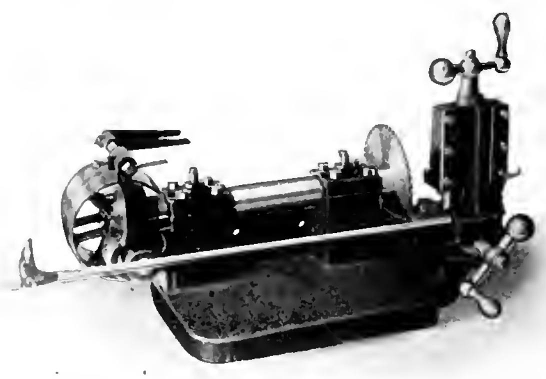


Fig. 1. A Simple and Efficient Cutting-off Saw

As may be seen, the machine has been simplified to the last degree in the point of mechanism; but at the same time, as is shown particularly in Fig. 2, the construction has been made very rigid, so that a cut up to the full capacity of the saw blade can be taken. The power feed, automatic stop, etc., have been eliminated, giving the machine a simplicity which adapts it to the requirements of smaller shops and for use on odd jobs and miscellaneous work in stock-rooms of large plants.

Its use is also suggested by the inventor in key fitting, to lessen the time required to file down and fit the battered ends resulting from driving the key in and out. The key may be made a little longer than the finished size for fitting, permitting the upset ends to be cut off before finally assembling it in the machine. This can be done in much less time than is

required to file these ends down to accuracy. The machine is provided with a vise which will grip either square or round stock, up to 2 inches in width or diameter. The worm drive provided, and the ample belt power, permits it to take a cut

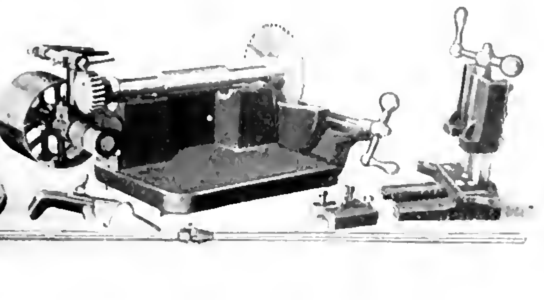

Fig. 2. Machine Dismantled to Show Construction

to its full capacity in two minutes, without crowding the saw. The machine is of simple construction and takes very little floor space. It can be bolted to a post or mounted on a bench.

* * *

NEW MACHINERY AND TOOLS NOTES

HEATING FURNACES FOR DROP FORGINGS, ETC.: Billings & Spencer Co., Hartford, Conn. This is a strongly and durably built line of furnaces, adapted to the use of either oil or gas as fuel. They are intended to be used in heating work for drop forging or other hot working processes.

SMALL INCLINABLE POWER PRESS: T. W. G. Cook, 2 Reade St., New York City. This line of small power presses is built on the inclinable plan, so arranged that the machines may be swung from the vertical clear down to the horizontal, or to any angle in between. The change can be quickly made. The length of the slide has been increased by placing the crankshaft at the back of it, allowing the slide bearings to extend clear to the top of the frame.

HAND-OPERATED COMBINATION SHEAR AND PUNCH: Peck, Stow & Wilcox Co., Southington, Conn. This is a bench machine having separate handles for the shear and punch. The shear blades have a cutting length of 6 inches, and will cut bar iron up to ¼ by 1½ inch, or ½ inch square; it will cut sheet iron as thick as No. 8 gage for the full length of the blades. Holes can be punched to the center of a 10-inch circle, up to ⅜-inch diameter in ⅜-inch iron.

"VULCAN-BIJAW" CHAIN PIPE WRENCH: J. H. Williams & Co., Brooklyn, N. Y. The well-known chain pipe wrench made by this firm is now furnished in a double-ended, modified design, which permits the jaws to be turned end for end. This gives a new, sharp set of teeth for use when the old ones have become worn, doubling the useful life of the tool. The wrench is made in both cable and flat link chain styles, in sizes adapted to pipe and fittings from ⅛ inch to 12 inches.

"TWIN-GRIP" AUTOMOBILE WRENCH: Burkley Supply Co., 27 Old Slip, New York City. This tool is really a collection of four wrenches mounted together in a clamping holder, which permits them to be handled and kept as one tool. Closed, the measurements are 6 inches long by 1¼ inch high over all. The variety of wrenches provided takes in eight sizes of nuts, ranging from ¼ to ⅞ inch; one of the wrenches is furnished with a screw-driver end. The material used is case-hardened steel.

BENCH TAPPING MACHINE: S. A. Stewart Co., Waltham, Mass. This is a vertical machine of light but rigid construction. The spindle pulleys are made of aluminum for the sake of lightness. The reversing is effected by hand lever or treadle, either of which may be used without interfering with the other. The machine will tap to the center of a 12-inch circle, and will take in a maximum height of 7¾ inches from the chuck to the table. It may be used for any tap up to ¾ inch in diameter.

"SPARTAN" CHAIN PIPE WRENCH: Drop Forging Co., West Side Ave. & Fisk St., Jersey City, N. J. This pipe wrench is made of drop forged steel. Both handle and jaws are specially designed to give the maximum degree of strength for the amount of metal used. The teeth are milled at an angle so as to draw the jaws together when the pressure is applied, preventing excessive strain on the bolts, and giving a better gripping action on the pipe or rod to be turned. The wrench is made in five sizes, adapted to pipe from ⅛ to 12 inches diameter.

FRICTION TAPPING CHUCK: Woodstock Safety Chuck Co., Woodstock, Ill. This device employs a friction slipping mechanism, which is adjusted to give a driving power adapted to the diameter of tap being used. The adjustment is made by the turning of a knurled nut to agree with graduations provided. The driving power thus furnished is said to be nearly up to the strength of the tap a point which cannot be reached, however, without the slipping of the driving surfaces. The chuck has a round body without projections of any kind.

RADIAL POWER HAMMER: Radial Power Hammer Co., Los Angeles, Cal. This hammer is especially designed to permit one man alone to perform a wide variety of forging on work which has hitherto required the assistance of a helper. The hammer head is mounted on a swiveling bracket, so that it can be brought over a vise, an anvil or a swage-block. The latter may be rotated to bring various shapes into position beneath the hammer. The head weighs 75 pounds and has a vertical adjustment of 15 inches. It requires 3 horsepower to drive the hammer.

PORTABLE ACETYLENE WELDING APPARATUS: Oxy-Carbi Co., New Haven, Conn. The apparatus made by this firm, which was noticed in the January issue of MACHINERY, has now been put on the market in a portable form. The oxygen and acetylene generators are mounted on a truck, in combination with a reservoir and regulating apparatus for automatically controlling the supply of gases to the nozzle. This outfit is adapted to welding and cutting operations of all kinds by the oxy-acetylene process, and is said to be very economical and simple in operation.

PORTABLE STOCK RACKS: American Die & Tool Co., Reading, Pa. This stock rack resembles a type which has been used in various machine tool building firms and has been previously illustrated in the technical papers, but it is now for the first time placed on the market. The racks are formed of a solid casting with wide bases whose shape provides three backs each for lengths of bar stock to rest in. These racks will stand on any floor and do not need to be fastened. Each opening will hold fifteen round bars 2½ inches diameter. The weight of each casting is about 115 pounds.

POWER CHIPPING HAMMER: Coates Clipper Mfg. Co., Worcester, Mass. The makers of the Coates flexible shaft and mongrel gear drive (described in the November, 1909, issue of MACHINERY) have applied this drive to a new portable tool—a power-operated chipping hammer. This is of simple construction, giving 2,000 blows a minute, through the action of revolving hammers on the chisel head. It is operated by a ½ horsepower motor and, it is stated, will perform all classes of chipping work in a manner which competes with the performance of the pneumatic hammer.

CLUTCH PLANER DRIVE: American Twist Drill Co., Laconia, N. H. This firm has devised a friction clutch drive for planers, which is operated by the regular reversing dogs. It obviates the shifting of the belt, which requires considerable power and is a matter of great difficulty, particularly with wide and heavy belts. The wear of the belts due to the shifting is also obviated by the use of this clutch. It is stated to be very positive in its action, causing the platen to come to a stop at very nearly the same point at the end of each stroke. It is designed for application to standard planers.

FOUR-BELT PLANER DRIVE: Niles-Bement-Pond Co., New York City. The difficulty of shifting the wide belts required for heavy planers has led to this new design. The wide forward and reverse driving belts are each replaced by two narrow ones, which have to be shifted but one-half the distance, and which offer considerably less resistance to the movement as well. This gives a greatly increased ease of operation to the planer, and greater surety of action in the automatic reversal of the stroke. There should also be, it would seem, a gain in the reduction of wear and tear on the belts themselves.

LAMINATED LEATHER BELT: American Laminated Belt Co., New York City. This leather belting is built up of strips of leather bound side by side, and so arranged that the cut edge of the leather forms the surface in contact with the pulleys. This construction, it is claimed, gives much greater wearing qualities than when the ordinary construction is used with the fibers of the belt running parallel with the direction of movement. It at the same time brings the wearing surface on a stronger portion of the leather, and one not likely to be affected by improper tanning, or to be burned when the belt slips.

COLD CUTTING-OFF SAW: American Die & Tool Co., Reading, Pa. This is a machine of the type in which the saw is mounted on the carriage and fed in the work. It is spur-gear driven, the gears on the carriage being forged in one piece with their shafts and made of 60 carbon steel. Changes in feed are obtained from a gear box giving a range of from ⅛ to 1 inch movement per minute, all controlled by a single lever. The driving pulley is provided with a clutch, so the machine may be driven direct from the line shaft if desired. An automatic stop is furnished. This machine will take 9 inch round stock. It weighs about 2,200 pounds.

BORING MACHINE FOR LOCOMOTIVE WORK: Niles-Bement-Pond Co., New York City. This tool, made at the Bement Works of the builders, is designed for simultaneously boring and facing both ends of cylinders up to 6 inches in length. The spindle is driven by a gear of large diameter close to its outer end, giving a powerful drive. The work table is 54 inches wide, and 72 inches long in a direction at right angles to the machine. It has a cross feed of 30 inches and a longitudinal

hand traverse of 18 inches. A 20-horsepower motor is required to drive it. Power handling is provided for the raising and lowering of the table, and the rapid traverse of the bar.

Special Machine for Milling Automobile Front Axles: Beaman & Smith Co., Providence, R. I. This machine comprises a long bed on which the work is clamped, and which is also provided with ways on which slide four heads, equipped with suitable cutters for milling the faces of the spring-supporting pads and the bosses for the steering knuckles. Power quick return is applied to all the feed movements, which are so connected as to operate simultaneously. Six feed changes are provided, varying from ½ to 6 inches per minute. A cone pulley gives three speed changes for the spindle, ranging from 17 to 23½ revolutions per minute. Speeds and feeds are all gear-driven.

Swivel-joint Pneumatic Hose Coupling: Caskey Valve Co., 99 John St., New York City. This is a coupling for pneumatic hose of the quick connection type; it has the advantage of being provided with a swivel joint, so that all tendency toward kinking in the hose is avoided. The coupling is kept locked by a powerful spring, and it is impossible to open it by jarring. The joints are packed with leather and are tightened by internal air pressure entirely, it not being necessary to jam the surfaces together to insure freedom from leakage. The capacity of this coupling is equal to that of the full area of the hose to which it is attached. They are made for ¼ to 1¼-inch diameters.

Hand-Power Punching and Shearing Machines: Little Giant Punch & Shear Co., Sparta, Ill. This firm has recently completed a line of hand-power punch and shearing machines adapted both to actual use in the hand, and, in the larger sizes, for mounting on the bench or floor. They are made both as separate punches and separate shears, and also in combined form; the latter machine is of the floor type and has separate levers for the punch and shear, so that both can be operated simultaneously without interference. This machine will cut round iron up to ½ inch and bar iron up to ¼ by 2½ inches, while the punch has a capacity for 5/16-inch holes in ¼-inch material.

Punch Presses with Westinghouse Motor Drive: Toledo Machine & Tool Co., Toledo, O. This firm has recently furnished a complete motor-driven stamping press equipment for making metal boxes, requiring operations like perforating, shearing, blanking, forming, etc., on the various angles, corner braces, sides, bottoms and covers used on steel-bound, wood packing cases. These machines have been equipped throughout with electrical drive, giving a considerable advantage in ease of operation, freedom from countershafts, etc. This results in a clean, well-lighted shop, free from ceiling obstructions. It is stated that the electrical operation has also resulted in a reduction in operating costs.

Drawing Stand: Shartle Bros. Machine Co. Middletown, O. This is a table of the tripod stand variety, adjustable both for height and angle of the board. It may also be revolved at will to any position required to get a favorable light. A special feature of the construction is a tool shelf, which is so connected with the column by a link arrangement that it is kept horizontal whatever the angle to which the board itself is set. This obviates the accidental dropping of instruments, ink, etc. Special provision is also made for rapidly changing drawing boards. This is a convenience where two or three jobs are kept in hand at one time, as it is unnecessary to remove the paper from the board each time a change of work is made.

Tool-room and Vertical Grinder: Blake & Johnson Co., Waterbury, Conn. This grinding stand is provided with a table adjustable for height, and has a tilting adjustment for this table about a pivot, operated by a fine pitch screw and nut, giving an additional fine adjustment for height of 1½ inch. By this means it is possible to use the machine as a surface grinder, sliding the work on the table back and forth under the wheel. This adapts it to the grinding of blanking, stamping and piercing dies, etc. The table is 18½ inches long and 9¼ inches wide. The bracket carrying the table has a vertical adjustment of 6 inches, permitting it to be raised within 3 inches of the spindle center. The spindle boxes are dust-proof.

Kelly Sand Blast: High Pressure Sand Blast Co., New York City. The difficulty of using high pressures for sand blast work has been principally that of the erosion of the nozzle surfaces by the combined air and sand passing through it at a high velocity. In this apparatus the difficulty has been overcome by leading the sand and the air to the nozzle by separate hose, and providing the nozzle with a removable tip at the orifice. The cost of these tips is insignificant, and they may be quickly renewed as often as needed. Working with 100 pounds pressure, about 70 cubic feet of free air is used per minute. It is stated that the low pressure machines require from three to six times as much sand for the same work as when the higher pressures are used.

"Rapid" Screw Slotting Machine: Garvin Machine Co., Spring and Varick Sts., New York City. This screw cutting machine works on a different principle from the orthodox construction, in that the body of the screw is grasped in a split chuck, and fed directly in toward the wheel. The latter is guarded to protect the fingers of the operator, and is equipped with a self-contained reservoir to provide the lubricant. A lever operates the plunger, tightening the chuck when the work is fed toward the saw and loosening the chuck and ejecting the work when the plunger is drawn back again. It will slot screws from ¼ to ½ inch in diameter. Suitable supports are provided for the work-boxes, into the lower one of which the slotted screws fall without help from the operator.

Cam Grinding Attachment for Vertical Grinder: Pratt & Whitney Co., Hartford, Conn. The well-known vertical grinder made by this firm has been provided with an attachment for grinding automobile cams, particularly those of the type that are formed integrally with the shaft. The flat lower surface of the ring-wheel is used to finish the work. This preserves the constant shape of the cam as the wheel wears down; in this particular it is an improvement over the method of grinding with the periphery of a disk wheel, which gives a changing shape to the work as the diameter decreases. The attachment is easily placed on the machine or removed from it. It is provided with an indexing mechanism for timing the cams. The operating parts are carefully protected from dust and dirt.

Nut Castellating Device: Garvin Machine Co., Spring and Varick Sts., New York City. The screw slotting machine manufactured by this firm may be provided with a simple attachment for castellating nuts. When so used, it is provided with a hexagonal chuck, fitting the work and mounted in a head, which may be rotated by a convenient handle to three different positions for cutting the successive slots. The chuck is self-ejecting, and the machine is provided with all the conveniences found on the regular screw slotting machine. A device acting on similar principles is also made for use in the milling machine. This, however, carries four spindles, and is designed to be used for four saws on the cutter arbor. All four chucks are opened and closed and indexed simultaneously.

Die and Surface Grinder: Hemming Bros., New Haven, Conn. This machine is of the vertical spindle, cup-wheel type, which has lately come into extensive use for die sharpening and surface grinding. It is a hand-operated machine, and offers in this respect the particular advantage on certain work of permitting the operator to feel the cut and thus be sure of what the wheel is doing. The spindle is driven through bevel gears and a self-contained countershaft. Rubber wheel guards and a trough surrounding the work-table, keep the cooling water within bounds. The vertical feed handwheel is graduated to thousandths of an inch, on a circle of large enough diameter so that fractions of thousandths can be easily read. This tool will be furnished, if required, with magnetic chuck and automatic feed.

Slotting Machine: Pottstown Machine Co., Pottstown, Pa. This firm builds a slotting machine of improved construction, giving adjustments which should be particularly useful in tool-making, die work, etc. The slotting head can be swung to an angle and the work-table can be also tilted around to an angle of 45 degrees. This makes it possible to cut miter gears or do similar work. A hole is provided clear through the circular table, the work-slide and the knee, permitting long work to be held without interference. In its general design, the structure of the machine is similar to that of the ordinary column and knee type milling machine, with the cutter spindle replaced by the slotter ram. The distance from the column to the center of the tool is 12 inches. The circular table is 14 inches in diameter and the tilting table has a vertical adjustment of 16 inches.

"Perkins" Combined Protractor and Level: Florence Iron Works Co., Florence, Col. This instrument consists essentially of a V-block on which is mounted a disk graduated in degrees and carrying a level; the V-block also carries a prick punch in a central seat. The tool is useful in a number of ways. It is adapted particularly, for instance, to the laying out of keyways on shafting. By means of the level, the V-block may be set on the shafting so that the prick punch point will indicate the vertical center. It is thus possible to locate a line of keys along a shaft having varying diameters. By setting the protractor properly, it is also possible to locate keyways at any desired angle with the horizontal and vertical, clear around to the bottom. It should be useful among other things for quartering locomotive axles, and for laying out eccentric keyways when the angular advance is given.

New Designs of Forge Blowers: Buffalo Forge Co., Buffalo, N. Y. This firm has added two new designs to its line of forge blowers. One of these is intended for use particularly where compressed air is available, and consists simply of a tuyere and jet made on the injector principle. With this construction, a small high-pressure stream of air sets in motion a large volume of air at a low pressure, giving the required condition for the forge fire. The second design is of the rotary fan type, driven by a direct-connected motor. Great care has been taken in this set to have the efficiencies of the motor, the fan and the rotating members in their bearings

all very high, so that the air will be delivered with as little power expense as possible. These sets are made in sizes varying from 1/32 to 1/2 horsepower. They are adapted to direct connection with a lamp socket in shops where electricity is available.

Multiple Drilling and Tapping Attachment: Rockford Drilling Machine Co., Rockford, Ill. This attachment is applied directly to one of the maker's regular 14-inch drills with tapping attachment, and makes possible the drilling of six holes in a circle simultaneously. It was originally designed for drilling and tapping 54 holes, spaced equi-distantly in a circle about 6 inches in diameter. The drilling of these 54 holes required, therefore, nine indexings of the work, which was effected by the special type of jig used. For tapping, the work was spaced around by hand from one series of holes to the next. The multiple head is clamped directly to the spindle sleeve, and is lined up by guides on the jig base clamped to the table. A spring support is provided which, with the spindle counterbalance, permits the head to return freely after each drilling operation. By the use of this attachment 54 holes, 1/4-inch in diameter are tapped at an average rate of 50 seconds for the set. The drilling operation is, of course, much more quickly performed.

Axle Cutting-off and Centering Lathe: Fawcus Machine Co., 2820 Smallman St., Pittsburg, Pa. This machine is, of course, a specialized lathe, following the general lines of the machines previously used for this purpose. It has a number of advantages incorporated in its design, particularly in the strength and rigidity of the structure, the power of the drive and the convenience of manipulation provided. Complication of the driving mechanism is avoided by the use of separate motors for the main drive, and for each of the two centering spindles. Each carriage has a centering spindle and a cutting-off tool, and is provided with a quick operating lever for bringing either one or the other into position. The double driving heads are adjustable for length to suit different lengths of axles, although, of course, in ordinary work where the standard gage is employed, this adjustment is not altered. Two rates of driving are provided through friction clutches and simple geared connections, and controlled by a hand lever operated from the front of the bed. These machines were originally designed and furnished for the new axle mill of the Indiana Steel Co., at Gary, Ind.

Steam Turbine Driven Centrifugal Boiler Feed Pump: De Laval Steam Turbine Co., Trenton, N. J. The development of the centrifugal pump has reached a point which makes it practicable to apply it to boiler feeding. The latest pump designed by the above makers will overcome a head of 700 feet with two stages only, and will give efficiency of over 60 per per cent when working at 1,600 gallons a minute. It can be governed to generate any desired constant pressure, or any desired fixed excess pressure, and it will maintain these conditions without vibration, hammer or shock in the feed line. The advantages of such a pump are numerous. The inflow of water can be regulated at the boiler without reference to the pump. There are no valves and only two packings of small diameter to be kept tight against the hot water. The high efficiency of the design of the propeller has made unnecessary the use of guide vanes, with their mechanical and theoretical disadvantages. Simplicity of construction and accessibility for inspection have been carefully looked out for. The steam turbine driving it can be modified to operate on exhaust or live steam or both as may be required. The pump is, of course, as well adapted to motor drive as to direct connection to steam turbine.

* * *

The famous mine fire in the Greenwood Colliery near the village of Summit Hill in northeastern Pennsylvania, which had been burning for almost exactly fifty-one years has finally been checked. This subterranean fire had resisted all efforts to smother or drown it out and thousands of dollars have been expended in vain efforts to stop its spread (see Machinery, October, 1904). It is estimated that $25,000,000 worth of coal has been burned and probably if the last effort had not succeeded, many millions more would have been destroyed. The spread of the fire was checked by building a clay barrier across the basin extending down to the water level. The barrier was approximately 900 feet long and it extended down to a depth of about 220 feet. The work was conducted under great difficulties, the fire being so close at places that the heat and bad ventilation made the work exceedingly arduous. For part of the time the men had to work on half-hour shifts, and work was only possible because of elaborate ventilating apparatus which was installed at heavy cost. Canvas flues were let down into the shaft, which being flexible, could be shifted so as to supply fresh air in the exact spot needed. Fifty thousand cubic yards of clay were required to make the barrier and 8,000 cubic yards of concrete.

ELECTRICAL HEAT STORAGE

A scheme for storing heat generated electrically has been devised by Mr. C. G. Bell, member of the British Institute of Electrical Engineers that may be useful to electric lighting companies in supplying a daylight load. The futility of electric storage batteries for large power stations is generally recognized—Mr. Edison's excepted, of course and Mr. Bell has tried to solve the problem by converting electricity into heat and storing it for domestic use. Electric heating at regular commercial rates is too costly for all but certain special uses but if a large market for heat could be found in the daylight hours only, a very favorable price could be made by the lighting companies with profit to themselves and satisfaction to customers.

The apparatus in the present form consists of an iron block about eighteen inches high and a foot in diameter. This block is incased in a thick magnesia jacket to prevent radiation. In the center of the block is placed a removable heating unit of several sections. When the current is turned into the heating unit the iron block is raised to a temperature of 600 or 700 degrees F. in a few hours, and will remain heated almost indefinitely, except for what is used. In its original form it was designed for hot water alone. Its present development not only does away with tanks and kettles, but provides hot air, steam, or hot water for heating, with great saving of space, and provides unlimited heat for cooking. Boiling water is instantaneously on tap day or night, even though all the current may be in use at the time for lighting. The system does away with storage of hot water. Instead, an iron coil is cast inside the metal block. As the block is at a normal temperature of 600 degrees, this coil is full of superheated steam. The steam is regulated so that a small or great quantity may be introduced into the water pipe, giving, instantaneously, water at any desired temperature.

The system is to be used with a house feeding device that makes each customer a consumer of a constant quantity of electricity throughout the twenty-four hours of the day. When the current is being used for lighting, fans, or other purposes, it is switched off the heating unit perhaps entirely, and as soon as ordinary uses stop, the current is switched back again into the heater. The advantage of a constant load thus made possible is obvious. It is claimed that it would more than quadruple the efficiency of the machinery in the average lighting power house by making it produce useful current all the time instead of having a large amount of equipment idle save during four or five hours a day.

* * *

EDISON STORAGE BATTERY

The new storage battery which Mr. Thomas A. Edison has been experimenting with for a number of years has recently been subjected to a series of tests to determine its efficiency. In order that the tests might be made under actual working conditions, a special car suitable for street railway service was constructed and in this car the batteries were installed. Two 7 1/2-horsepower motors were used for driving, and a maximum speed of 20 miles an hour was attained. It is stated that this car, which weighs about 5 tons, will run 150 miles at an average speed before the batteries need to be recharged. In outer appearance the cells of this battery do not differ, except in minor details, from the original cell which was brought out in 1901. The structure of the positive plate, however, has been radically modified, and other improvements embodied, to increase the capacity and durability. These batteries are made at present in two sizes. The smaller size gives about 14 watt-hours per pound of cell and the larger size 16 watt-hours. The weight of such a battery for a car requiring an average of 12,000 watts (it being assumed that the battery is to be in service for even five hours without recharging) would be 3,750 pounds. When the additional power required for hauling this dead weight is considered, it is evident that the present system of imparting the electrical energy from the power station to the motors of the street car is not likely to be changed by the present form of this new storage battery.

CINCINNATI AUTOMOBILE SHOW

The First Annual Automobile Show given under the auspices of the Cincinnati Automobile Club, opened Monday

morning, February 21, with two hundred cars on display representing sixty exhibitors; the floor space given to the machines was 30,400 square feet. Of the cars on exhibition, fifteen were of Cincinnati manufacture, and were made by the Enger Motor Car Co., Haberer & Co., and the Schact Mfg. Co.

Besides automobiles, there were motor-cycles, motor boats, accessories, balloons and aeroplanes. The aero exhibit was strictly local, being furnished entirely by the Holz Balloon Co. of Cincinnati, and consisted of small aeroplane models, a large glider without a motor, and a large, complete, air-inflated balloon model, showing basket, ballast bags, anchor and drag ropes.

Much credit is to be accorded General Manager Ruthford H. Cox, Charles L. Bonifield, Wm. M. Perin and the various committees for placing this show in a class well up towards those of New York and Chicago.

The show closed Saturday, February 26, after a week of continuous success.

MEMORIAL OF DR. ROBERT H. THURSTON

A beautiful bronze memorial tablet in high relief of Dr. Robbert H. Thurston, one-time head of Sibley College of Engineering, Cornell University, one of the founders of the American Society of Mechanical Engineers and the society's first president, was dedicated in the reception hall of the society at 29 West 39th St., New York, Tuesday evening, February 8. It is a replica of the tablet by Herman H. McNeil, presented to Sibley College by the students and alumni. The tablet bears the inscription:

1839—ROBERT HENRY THURSTON—1903
FIRST PRESIDENT
AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Dr. Thurston was an international authority on the steam engine, thermodynamics, friction and lubrication, materials of construction, etc. He was a voluminous writer, being a frequent contributor to the technical press, the society's proceedings and the author of several standard works. He died October 25, 1903. See MACHINERY, November, 1903, for an account of his life.

WORCESTER ANNUAL EXHIBITION

The second annual exposition of the mechanical, electrical and textile industries of New England was held in Mechanics Hall, Worcester, Mass., during the week beginning February 7. Two large floors were completely filled with exhibits representing improvements in machinery and appliances in these industries, and the attendance from all over New England was large. It was generally conceded that the exposition was much better than the first one, held last year. Many new machines were shown. It is proposed to continue the exposition as an annual event.

* * *

PERSONALS

Edward Schwartz has been made superintendent of the Toledo Electric Welder Co., Cincinnati, Ohio.

C. G. Heiby, machine shop foreman for the H. Mueller Mfg. Co., Decatur, Ill., has been promoted to the position of tool-room foreman.

R. K. LeBlond, president of the R. K. LeBlond Machine Tool Co., Cincinnati, Ohio, has gone to the West Indies for two months' vacation.

Fred A. Bigelow, formerly New England representative of the Carpenter Steel Co., has been made manager of the company's Cleveland branch.

P. C. Benedict has been made district salesmanager for the Bessemer Gas Engine Co. of Grove City, Pa., with headquarters at 719-721 First National Bank Building, Cincinnati, Ohio.

E. R. Johnson, until recently master mechanic of the Rock Island shops at Horton, Kansas, has been made general foreman of the Illinois Traction System's shop at Decatur, Illinois.

Henry Morris, manager and treasurer of the Western Tool & Mfg. Co., Springfield, Ohio, will sail early in March for a ten weeks' trip to Italy, Germany, France and Great Britain for business and pleasure.

H. E. Obenshain, who has been secretary and treasurer of the Screw Cutting Company of America, Philadelphia, Pa., for some time, resigned February 1 to become president of the Roanoke Iron Works, Inc., Roanoke, Va.

Roy V. Wright, for several years editor-in-chief of the *American Engineer and Railroad Journal*, has joined the editorial staff of the *Railway Age Gazette*. Mr. Wright will supervise the mechanical department of the journal.

E. G. Matter, connected with the office of the National Acme Mfg. Co., Cleveland, Ohio, on Indiana territory, for several years, has been transferred to the Detroit and eastern Michigan territory formerly covered by Mr. W. C. Lang.

James Brown, formerly department foreman for the Cincinnati Milling Machine Co., Cincinnati, Ohio, and later superintendent of the Oesterlein Machine Tool Co., of the same city, has taken the position of superintendent for M. L. Andrew & Co., Cincinnati.

Fr. W. Sebelin, general foreman of the mechanical department of the Cleveland Twist Drill Co., Cleveland, Ohio, has resigned the position to become superintendent of the P. A. Geier Co., Cleveland, general jobbers and manufacturers of automobile parts.

Eph. Smith, who has been the New England sales manager of the Colonial Steel Co. since its organization in 1901, has resigned on account of long continued ill-health. E. P. Fitzgerald, who has represented the Boston office with headquarters at Springfield, Mass., for the past five years, has been appointed successor, the appointment taking effect March 1.

Following the consolidation of *Industrial Engineering* of Pittsburg, Pa., and the *Engineering Digest*, New York, with the title *Industrial Engineering and Engineering Digest*, Mr. Robert Thurston Kent assumed the editorship of the consolidated publication, succeeding Mr. Harwood Frost, who was the founder of the *Engineering Digest*. Mr. Frost has been forced by the pressure of his duties in connection with the *Engineering News* to devote the whole of his time to that publication.

Frank A. Foster, Providence, R. I., will sail from Seattle about March 22 for China where he will take a position as representative of the American Locomotive Co., in which he will have to do largely with machinery and the mechanical parts of railroad work. He requests catalogues and full information regarding products from American manufacturers of machinery. Mr. Foster is a graduate of the Worcester Polytechnic Institute, and his address will be Davenport Road, Tientsin, China, care of Albert C. Lee.

Alfred Spangenberg, Plainfield, N. J., a well-known contributor to MACHINERY, will lecture before the students of the mechanical engineering classes of Columbia University, May 9, on the subject "Assembling in a Manufacturing Line," treating of the following topics: 1.—Elements of Assembling Operations: Definition of assembling, methods and processes of assembling, concrete examples. Assembling a motor-driven planer by two methods with approximate difference in cost. Factors leading to economical production. Machine processes versus hand processes. 2.—Effective Organization in the Assembly Department.

Caleb Rutter, who for the past eleven years was foreman of the machine department of the Pennsylvania Iron Works Co., Eddystone, Pa., has resigned to take charge of one of the tool-rooms of the Autocar Co., Ardmore, Pa. At the noon-hour of February 11, Mr. Rutter was presented with a smoker's case of stering silver, beautifully engraved, by the employees of the works as an evidence of their regard. Mr. A. E. Exton, assistant chief engineer of the plant, who made the presentation, said in part: "There is no donbt that this change means the addition of one more live man to the ranks of the great army of automobile builders."

* * *

OBITUARIES

Fayette Brown, president of the Brown Hoisting Machinery Co., Cleveland, Ohio, died January 20 in his eighty-seventh year.

Freeland Oakley, well-known in his day as an expert builder of water wheels, died in Springfield, Mass., January 17, aged eighty-two years. Mr. Oakley was for years a member of the firm Phelps & Oakley, which built many of the paper mills in Massachusetts. His reputation was made in the construction of large over-shot and under-shot water wheels.

* * *

COMING EVENTS

April 5-7.—Joint convention of the Southern Supply and Machinery Dealers' Association, and American Supply and Machinery Manufacturers Association, Jacksonville, Fla., Seminole Hotel, headquarters. Alvin M. Smith, secretary and treasurer of the Southern Supply and Machinery Dealers Association, Richmond, Va.

April 13-14.—Annual convention of the National Metal Trades Association at the Hotel Astor, New York. Robert Wuest, commissioner, 605 New England Building, Cleveland, Ohio.

April 17-June 1 (April 4 to May 19, O. S.).—International exhibition of internal combustion motors under the auspices of the Imperial Russian Technical Society of St. Petersburg on the premises of the society Panteleimonskaia No. 2. The object of the exhibition is to acquaint the consumer as well as the general public at large with the development and present condition of internal combustion motors, and to show the comparative advantages of each of the existing systems. The exhibit will be divided into sections as follows: Motors for agricultural purposes, motors for artisan in small industries, and domestic use, motors for factories, motors for marine, railway, tram-

car, automobile, aeronautical and similar purposes, motor details and accessories, literature on motors, drawings, diagrams, etc.

May 4-5.—Annual meeting of the Iron and Steel Institute at the Institution of Civil Engineers, London. G. C. Lloyd, secretary, 28 Victoria street, London.

May 10-13.—Seventeenth annual convention of the Air Brake Association, Indianapolis, Ind., Dennisson Hotel, headquarters. An interesting program has been prepared on air brake construction, air pumping, piping inspection and cleaning, triple valves and brake cylinders, recommended practice, etc. F. M. Nellis, secretary, 53 State St., Boston, Mass.

May 14-22. Prague agricultural exhibit intended to comprise all the leading innovations that have been introduced in agricultural practice, agricultural machinery and mechanical appliances in dairying, etc. Arthur Goblet, director, Karalinenthal, Prague, Bohemia.

May 31-June 3. Spring meeting of the American Society of Mechanical Engineers, Atlantic City, N. J.

June 1-August 31. American Exposition in Berlin, to stimulate trade relations between Germany and America. This will be the first all-American exposition ever held in a foreign country and will be of interest to all Europe as well as America. It will be held during three of the best months of the year for an exposition, being at the full tide of foreign travel, when people will be attracted in large numbers. Max Vieweger, American Manager, 50 Church street, New York.

June 6-10.—Convention and exhibition of the Foundry and Manufacturers' Supply Association, Detroit, Mich., C. E. Hoyt, secretary, Lewis Institute, Chicago, Ill. Cadillac Hotel, Detroit, headquarters of the association convention week.

June 7-9.—Convention of the American Foundrymen's Association and American Brass Founders' Association, Detroit, Mich. Headquarters, Hotel Ponchartrain. Richard Moldenke, secretary, American Foundrymen's Association, Watchung, N. J. W. M. Corse, secretary, American Brass Founders' Association.

June 13-16.—National Gas and Gasoline Engine Trades Association convention at Cincinnati, Ohio, Hotel Sinton, headquarters. Albert Stritmatter, secretary.

June 15-17. Annual convention Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-22.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 23-28.—International Congress of Mining, Metallurgy, Applied Mechanics and Practical Geology at Dusseldorf, Germany. For information apply to G. C. Lloyd, 28 Victoria street, London.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in Birmingham and London, England.

SOCIETIES AND COLLEGES

THE CIVIL AND MECHANICAL ENGINEERS' SOCIETY AND SOCIETY OF ENGINEERS have been amalgamated under the name Society of Engineers, Inc. A. S. E. Ackerman, secretary, 17 Victoria Street, Westminster S. W., England.

UNIVERSITY OF KANSAS, Lawrence, Kans., dedicated a new engineering building, February 25. Addresses were made by Frank Warren, dean of the school of engineering; Richard C. Maclaurin, president of the Massachusetts Institute of Technology, and Ernest R. Buckley, president of the American Mining Congress. Chancellor Frank Strong presided.

COLUMBIA UNIVERSITY will present four lectures in the course in works management, by Charles A. Carpenter, March 5, 10, 12 and 17; two lectures by H. L. Gantt, March 31 and April 12; one lecture by Walter N. MacFarland, April 7; three lectures by Harrington Emerson, April 14, 16, 17; three lectures by Richard T. Lingley, April 30, May 5 and 7, and one lecture by Edwin J. Prindle, April 14.

THE SHEFFIELD SCIENTIFIC SCHOOL OF YALE UNIVERSITY, New Haven, Conn., has received a gift of $250,000 for the construction and equipment of the new mechanical engineering laboratory from Mr. George G. Mason of New York, and his brother, Mr. William S. Mason, Evanston, Ill. The new laboratory will have a frontage of about 85 feet and depth of 200 feet. It will be four stories in height, constructed of Indiana limestone and brick. It will contain approximately 50,000 square feet of floor area and 880,000 cubic feet of space. The entire equipment will be new and will consist of the most modern appliances for assisting the students in studying those fundamental principles of applied science which are closely related to mechanical engineering, such as the strength of materials, the combustion of fuel in furnaces and in internal combustion engines, the making of steam in boilers of different types, the using of saturated and superheated steam in engines or steam turbines, the artificial production of cold, the production, transmission and use of compressed air, the pumping of water, transmission of power and the problems of heating and ventilation.

NEW BOOKS AND PAMPHLETS

ENGINEERING STANDARDS COMMITTEE, 28 Victoria St., Westminster, S. W., London. British standard specifications for keys and keyways No. 46. Price 2s, 6d.

BULLETIN OF THE COLLEGE OF ENGINEERING, POLYTECHNIC INSTITUTE OF BROOKLYN. 124 pages, 6 x 8½ inches. Published by the Polytechnic Institute of Brooklyn.

REPORT OF COMMISSION OF EDUCATION FOR THE YEAR ENDING JUNE 30, 1909. VOLUME I. 598 pages, 6 x 9 inches. Published by the United States Bureau of Education, Washington, D. C.

YEAR-BOOK OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS, 1910. 365 pages, 6 x 9 inches. Published by the American Institute of Electrical Engineers, 33 West 39th Street, New York City.

BULLETIN OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY, containing the president's report for the past year. 140 pages, 6 x 9 inches. Published by the Massachusetts Institute of Technology, Boston.

FOURTEENTH ANNUAL REPORT OF THE INTERNATIONAL ASSOCIATION OF MUNICIPAL ELECTRICIANS, held at Atlantic City, N. J., September, 14-16, 1909. 153 pages, 6 x 9 inches. Frank P. Foster, secretary, Corning, N. Y.

TESTS OF TWO TYPES OF TILE-ROOF FURNACES IN WATER-TUBE BOILER. By J. M. Snodgrass. Bulletin No. 34. 20 pages, 6 x 9 inches. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill.

THE INFLUENCE OF FORESTS ON CLIMATE AND ON FLOODS. By Willis L. Moore, Chief of the United States Weather Bureau. 38 pages, 6 x 9 inches. Published by the United States Government, Government Printing Office, Washington, D. C.

PROCEEDINGS OF THE ASSOCIATION OF TRANSPORTATION AND CAR ACCOUNTING OFFICERS, Chattanooga, Tenn., December, 1909. 170 pages, 5½ x 8½ inches. Published by the Association. G. P. Conard, secretary, 24 Park Place, New York City.

STANDARD CODE OF RULES FOR INTERURBAN OPERATION. Adopted by the Transportation and Traffic Association at the 1909 Convention at Denver, Col. 99 pages, 3½ x 6 inches. Published by the Association. Office of the Secretary, 29 W. 39th St., New York City.

STANDARD CODE OF RULES FOR CITY OPERATION. Adopted by the Transportation and Traffic Association, at the 1909 Convention at Denver, Col. 44 pages, 3½ x 6 inches. Published by the Association. Office of the Secretary, 29 W. 39th St., New York City.

COMPARATIVE TESTS OF RUN-OF-MINE AND BRIQUETTED COAL IN LOCOMOTIVE BOILERS; BULLETIN NO. 412. By Walter T. Ray and Henry Kreissenger. 32 pages, 6 x 9 inches. Published by the Department of Interior, United States Geological Survey, Washington, D. C.

THE ESSENTIALS OF LETTERING. By Thomas E. French and Robert Meiklejohn. 72 pages, 9 x 6 inches. 74 illustrations. Published by the Varsity Supply Co., Columbus, Ohio. Price $1.

This book, which is already in its second edition, has been prepared as an introduction to the subject of lettering, and is intended as a manual for students and designers who use lettering either on drawings or in designs of an artistic character. The book contains chapters on the construction of letters, composition of titles, selection of styles, letters in designs, monograms, ciphers and marks, and on drawing for reproduction. That section of the book which is specially intended for the mechanical draftsman contains some very good plates showing the proper proportioning of letters used on drawings, and the chapter on composition should be of value in deciding upon neat looking arrangements for titles on drawings.

MODERN COKING PRACTICE. By T. H. Byrom and J. E. Christopher. 156 pages, 6 x 9 inches. 109 illustrations. Published by the Norman W. Henley & Son, New York City. Price $3.50.

This book contains, with some amplifications, a series of lectures delivered by Mr. J. E. Christopher, at the Wigan Technical College, to a class of men engaged in the working of coke ovens, and it is expected that the book will be as useful to others who are engaged in coke manufacture. There has been in the past too little published on this subject, and to those engaged in this kind of work the book should, therefore, prove of special value. It contains chapters on General Classification of Fuels; Coal Washing; The Sampling and Valuation of Coal, Coke, etc.; the Calorific Power of Coal and Coke; Coke Ovens; Cooling and Condensing Plant, Gas Exhausters; Ammoniacal Liquor; Treatment of Waste Gases from Sulphate Plants; Valuation of Ammonium-sulphate; Recovery of Ammonia from Coke Oven Gases, and Surplus Gases from Coke Ovens.

TEST OF TUNGSTEN LAMPS. Bulletin No. 33, by T. H. Amrine and A. Guell. 33 pages, 6 x 9 inches, 28 diagrams. Published by the University of Illinois, Engineering Experiment Station, Urbana, Illinois.

This bulletin presents the results of tests upon tungsten lamps of 25 watt size. Of the three kinds of lamps tested, one kind was of American manufacture with filaments made by the paste process, the other two being of German manufacture with filaments made by the colloid and deposition process. The tests show that when the lamps are subject to vibrations, the life depends to a great extent upon the style of filament mounting. Filaments mounted under no tension have longer life when subjected to vibrations than those having tightly strung filaments. It was found after burning 2,000 hours under good conditions, that the average candlepower of the filaments made by the paste process decreased to 88 per cent.; by the deposition process, to 89 per cent.; by the colloid process, to 77 per cent. of the initial value.

PATENTS, DESIGNS, AND TRADE MARKS. By Kenneth R. Swan. 386 pages, 5½ x 8½ inches. Published by D. Van Nostrand Co., New York City. Price $2.

This book deals with patents, designs and trade marks from the legal point of view, and being written by an Englishman, it deals in particular with the English law in relation to patents. As, however, American and English law have much in common in this respect, the book will undoubtedly be of value to those Americans who are interested in patent law, and particularly to those who have patent interests in Great Britain. In producing the book, the author has aimed at presenting its contents in such a form as to make it comprehensive to the layman unfamiliar with legal phraseology, and the subject has been handled from a commercial as well as a legal point of view. Two chapters are included touching upon the subject of patent laws in the United States, Germany and France, together with information in tabulated form of the terms, fees, and conditions as to the working of patents, in several of the larger foreign countries.

INTERNAL LUBRICATION OF STEAM ENGINES. By T. C. Thomsen. 97 pages, 5 x 7¼ inches. 24 illustrations. Published by the Technical Publishing Co., Ltd., 55-56 Chancery Lane, W. C., London. Price 2s 6d.

This book has been written with the end in view of assisting mechanical engineers directly interested in the satisfactory running of steam plants. Designers of steam plants will also find suggestions which will be of value when deciding upon the proper means of applying cylinder lubricants, and the best way of distributing them to the internal surfaces needing the lubrication. Among other things the book treats of the chemical and physical properties of cylinder oils, impurities of cylinder oils, internal lubrication of steam engines, lubrication for engines of different types, including Corliss engines, winding engines, engines using superheated steam, and locomotives, lubrication of valves, and graphite for internal lubrication. The book is of a decidedly practical character, and recommends itself to those who do not wish to go too deeply into the matter of lubrication, but who require a general working knowledge of the subject.

ELEMENTARY COURSE IN PERSPECTIVE. By Sherman M. Turrill. 71 pages, 5 x 7½ inches. 16 illustrations, printed on inserted folders. Published by D. Van Nostrand Co., New York City. Price $1.25.

In writing this treatise the author has assumed that the student is somewhat familiar with ordinary descriptive geometry, and the book is devoted to illustrating the application of the principles of descriptive geometry to the making of perspective drawings. Two methods for making perspectives are treated, the one intended mainly for the assistance of the mechanical draftsman, and the other for the artist and free-hand draftsman. A large number of problems covering the principles are given throughout the book. The subjects of parallel perspective, angular perspective, perspective of curves and perspective of shadows are dealt with. The mechanical draftsman, in general, is too little informed on the subject of perspective, which, in many cases, would be helpful to illustrate correctly the actual appearance of an object to a non-mechanical person, and the book is recommended to all who are desirous of increasing their knowledge of this method of representing objects.

THE DESIGN OF CONDENSING PLANT. By F. W. Wright. 200 pages, 5 x 7½ inches. 96 illustrations. Published by the Technical Publishing Co., Ltd., 55-56 Chancery Lane, W. C., London. Price 3s. 6d.

This book has been especially written to fill the demand for a book devoted exclusively to the various problems connected with condensing. In the various standard text-books on the steam engine, the references to the subject of condensing are very brief, and a more thorough treatment has therefore been deemed necessary. The several problems met with in the intelligent study of this subject,

such as the transference of heat from steam to water, the elimination of air leakage, and the withdrawal of air and vapor, etc., have all been dealt with. The book is practical in its character to the extent that it deals with its subject only with refereuce to practical requirements, but mechanical details of construction have not been considered except in so far as they are necessary for describing the several types of condensers, pumps, cooling towers, etc., required. The book contains chapters on heat units, jet condensers, ejector condensers, surface condensers, design of jet condensers, design of surface condensers, evaporative condensers, water-cooling plants and air pump efficiencies.

MECHANIC'S HANDBOOK. 330 pages, $3\frac{3}{8}$ by $5\frac{1}{4}$ inches. Illustrated. Published by the International Correspondence Schools, Scranton, Pa. Price in cloth binding, 50 cents; in leather binding, $1.

The first edition of this well-known mechanics' handbook was issued in 1893 in the form of a notebook containing 74 pages. It has since passed into the seventh edition and has been greatly improved and enlarged. Its popularity is testified to by the fact that the copy in review is of the 317th thousand. It was the aim of the publishers to present to the public a handbook of convenient size for the pocket, which would contain rules, formulas, tables, etc., in common use by engineers, and it will be generally conceded that this handbook answers the requirements exceedingly well. The contents comprise weights and measures, metric system, specific gravity, elements and alloys, weights of round and square rolled iron, weights of cast iron pipe, logarithms, trigonometrical functions, prime numbers, circumferences and areas of circles, use of formulas, tables of powers and roots and reciprocals, mensuration, formulas for mechanics, rules for belting, pumps, hydro-mechanics, strength of materials, boiler design, care of boilers, chimneys, machine design, change gears, screw cutting, steam engineering, machine details, rope belting, wire rope, definition of electrical units, wiring and wiring diagrams, wire tables, underwriters' rules, dynamo and motor design, batteries, electric and gas lighting, cable testing, surveying, laying out railway curves, leveling, tables of radii and curves, retaining walls, tunnels, earthworks, etc.

DESIGN AND CONSTRUCTION OF INTERNAL COMBUSTION ENGINES. By Hugo Güldner. Translated from the second revised edition with additions on American engines by H. Diederichs. 672 pages, 9 x 11 inches. 728 illustrations in the text and 26 folding plates. Published by the D. Van Nostrand Co., New York City. Price, $10.

This book presents without doubt the most complete treatment of the subject of gas and oil engines that has as yet been published. It goes thoroughly into both the theory and practice of the design of gas engines and auxiliaries. No effort has apparently been spared in making the information as complete as possible, and several colored folding charts are included, showing with great clearness the arrangement of complete gas engine installations. It is not possible in a short review to give full credit to the work, but it should be mentioned that the aim of the book is to clear the ground for placing the internal combustion engine among the machines whose design can be worked out on a thoroughly scientific basis, rather than along experimental lines. The work is founded on practical experience gathered during fifteen years in an executive capacity. Being thus written by a gas engine designer and builder, it presents to the gas engine designer a useful practical guide which is not merely descriptive of what has been done, but which analyzes the problems underlying the design of gas engines and points out the necessary requirements and the path to follow. Besides the numerous illustrations in the text, the book contains twenty-six folding plates, practically all of which illustrate existing installations of gas engines or sections and plan views of actually built successful gas engine types. Besides, there are 151 tables of data both of theoretical and practical value to the designer, ranging all the way from tables in thermodynamics, necessary for a successful design along scientific lines, down to the practical everyday shop tables required by the designer when making his drawings for the shop. The book is divided into four specific parts. Part I treats of the various methods of operating gas engines, and the gas engine cycles. Part II deals with the design and construction of internal combustion engines, and treats specifically of each part of the machine, such as the beds and frames, cylinders and jackets, cylinder heads, stuffing boxes, pistons, piston rings, piston rods, crankshafts, connecting-rods, valves, valve gearing, fly-wheels, governors and ignition apparatus. All the auxiliaries of gas power installations, such as gas producers, starting apparatus, mufflers, cooling arrangement, piping, pressure regulators and general machine parts, including screws, studs, keys, gas pipes, pipe fittings and flanges, and helical springs, are also treated. Part III deals with the construction, erection and testing of modern internal combustion engines. In this case each of the various types of gas engines in common use as manufactured by various firms are dealt with specifically. Part IV deals with gas engine fuels and the combustion in gas engines. Finally a voluminous appendix is added, giving the theory of thermodynamics and the fundamental principles of thermo-chemistry, together with details from practice, giving directions for operation, attendance, etc. To anyone who wishes to study the subject of gas engines thoroughly, or who requires a reference book on the subject which deals authoritatively with all the phases of gas engine theory, design and intallation, this book can certainly be recommended as the most complete work on this subject available.

CATALOGUES AND CIRCULARS

GENERAL ELECTRIC COMPANY Schenectady, N. Y. Bulletin No. 4589 on ornamental street lighting.

H. W. JOHNS-MANVILLE CO., 100 William St., New York. Circular of insulating coverings for steam pipes and boilers.

GISHOLT MACHINE COMPANY, Madison, Wis. Leaflet illustrating construction of friction headstock and lever control of Gisholt vertical boring mill.

MANHATTAN ELECTRICAL SUPPLY COMPANY, 17 Park Place, New York. Catalogue of electrical supplies entitled, "Something Electrical for Everybody."

HARRIMAN ENGINEERING COMPANY, 53 State street, Boston, Mass. Catalogue of Harriman rotary steam engine, rotary gas engine, and rotary compressor and pump.

ADAMS-BAGNALL ELECTRIC COMPANY, Cleveland, Ohio. Bulletin No. 85 superseding Bulletin No. 79, descriptive of Adams-Bagnall regenerative flame electric lamps.

E. G. SMITH COMPANY, Columbia, Pa. Folder containing testimonials of users of Columbia calipers. It states that over 50,000 Columbia calipers are now in use.

NATIONAL MACHINERY COMPANY, Tiffin, Ohio. Circular of National interchangeable case threading dies illustrating construction, method of grinding and the National die sharpener.

NORTH WESTERN EXPANDED METAL COMPANY, 930-950 Old Colony Building, Chicago, Ill. Bulletin of data on concrete reinforced with expanded metal as used in sewers, tanks and walls.

WAGNER ELECTRIC & MFG. CO., St. Louis, Mo. Circular illustrating the Wagner motors applied to ventilating fans, ice cream freezers, bread mixers, coffee grinders, pumping organ blowers, etc.

BOULET'S FINE TOOL WORKS, Beverly, Mass. Circular of Boulet's improved universal micrometer test indicator, and measuring instrument which, within its range, is as accurate as a micrometer caliper.

WILLIAMS TOOL COMPANY, Erie, Pa. Copy of report of results of four tests conducted by the Westinghouse Machine Company, Pittsburg, Pa., of Riblet heaters for utilizing exhaust heat of gas engines.

GREENE-TWEED & CO., 109 Duane street, New York. Advertising card of M. Covel belt fasteners, made in six sizes. These cheap and efficient belt fasteners are made of specially tempered steel wire that clinches without breaking.

B. F. STURTEVANT COMPANY, Hyde Park, Mass. Circular of Sturtevant ready-to-run ventilating sets for small and general offices, reception rooms, telephone booths, toilet rooms, sleeping rooms, kitchens, basements, laboratories, engine rooms, etc.

BARBER-COLEMAN COMPANY, Rockford, Ill. Catalogue A of high-speed steel and carbon steel milling cutters, spur gear and worm gear hobs, gear cutters and form cutters. Special cutters of all descriptions are made to order by the company.

TERRELL'S EQUIPMENT COMPANY, Grand Rapids, Mich. Circular on metal lockers for factories, foundries, shops, clubs, schools, gymnasiums, hotels and hospitals. These lockers are made in a variety of styles suitable for the uses mentioned.

LEBANON STEEL CASTING CO., Lebanon, Pa. Folder illustrating steel castings for automobiles. The characteristics claimed for Lebanon steel castings are efficiency, toughness, truth to pattern, freedom from blow-holes and smoothness of finish.

SPRAGUE ELECTRIC COMPANY, 527-531 West Thirty-fourth street, New York. Reprint of article in the *Iron Age* entitled, "Handling Coal by Electric Shovels," being an article descriptive of installations of Sprague Electric Company apparatus.

C. W. LEAVITT & CO., 39 Church street, New York. Reprint of paper by Mr. Wilhelm Borchers, read before the Pittsburg meeting of the American Institute of Mining Engineers, February, 1909, on Girod electric furnaces and the Girod steel process.

GOLDSCHMIDT-THERMIT COMPANY, 90 West street, New York. Bulletin on repairing steel and iron rolls by the thermit process, illustrating the fractured rolls, the mold, the wax pattern in position, the apparatus ready for making the weld and the finished weld.

CUSHMAN CHUCK COMPANY, Hartford, Conn. Condensed catalogue and price list for 1910 of Cushman chucks and face-plate jaws. Cushman chucks are made in a large variety of styles and sizes adapted to all classes of machine work and general manufacturing.

GENERAL ELECTRIC COMPANY, Schenectady, N. Y. Booklet on building lighting with General Electric tungsten and tantalum lamps, illustrated with views of public buildings in New York, sky-scrapers, stores, and other large buildings in New York and other cities.

WABASH GEAR WORKS, Terre Haute, Ind. Catalogue of transmission levers and cone clutches for automobiles. The gears and shafts are made from special gear steel forgings which are subjected to approved heat treatment. The shafts are mounted on roll or annular ball bearings.

GARVIN MACHINE COMPANY, Spring and Varick streets, New York. Catalogue E of screw machines, monitor or chucking lathes, automatic chucks (stop and open types), screw head shaving machine, double turret screw machines, screw machine tools and attachments. Descriptions are in English, German and French.

INTERNATIONAL EXHIBITION OF RAILWAYS AND LAND TRANSPORT, Buenos Ayres, Argentine Republic. Circular No. 17, giving list of foreign committees and commissaries, statistics of foreign commerce of Argentine Republic and other information of interest to manufacturers contemplating exhibiting products at the centenary.

GARVIN MACHINE COMPANY, Spring and Varick streets, New York. Catalogue C on universal and plain milling machines, constant drive universal and plain milling machines, hand milling machines, vertical milling machines, motor-driven milling machines, universal cutter and tool grinder, die slotting machine and milling machine tools.

TERMINAL ENGINEERING COMPANY, 30 Church street, New York. Circular of Burdon's oil-gas furnaces of portable or stationary types. The Burdon furnace operates with a Bunsen flame, produced by gas derived from crude oils, and is said to be absolutely smokeless. It is designed for heating rivets, nails, drop forgings, tubes, bolts, spikes, etc.

CHARLES T. MAIN, Boston, Mass. Copy of booklet entitled, "Approximate Cost of Mill Building," containing valuable data and information on mill building construction. Although fundamentally it refers to textile mills, its application is broad enough to establish fundamental facts regarding manufacturing buildings in the iron-working industries.

B. F. STURTEVANT COMPANY, Hyde Park, Mass. Bulletin No. 173 on the Sturtevant electric dust blowing set designed for blowing out dust from around motors, switchboards, textile machinery, type cases, and other places difficult to get at or dangerous to handle. The apparatus may also be used as a suction cleaner where a dust collector is not desired.

GARVIN MACHINE COMPANY, Spring and Varick streets, New York. Catalogue B of Lincoln and duplex milling machines and profiling machines, vertical spindle milling machines, universal cutter and tool grinder, vertical horizontal and automatic drilling machines, duplex drill lathes, gang drills, etc. The descriptions are in English, German and French.

PAWTUCKET TOOL COMPANY, Pawtucket, R. I. Circular of friction tapping chucks, which may be used to drill and tap holes, and set studs therein without change. The friction may be adjusted to suit the tap, thus insuring against breakages. It is made in two sizes; No. 0 will handle taps up to $\frac{3}{8}$-inch diameter, and No. 1 from $\frac{3}{8}$ to $\frac{3}{4}$-inch diameter.

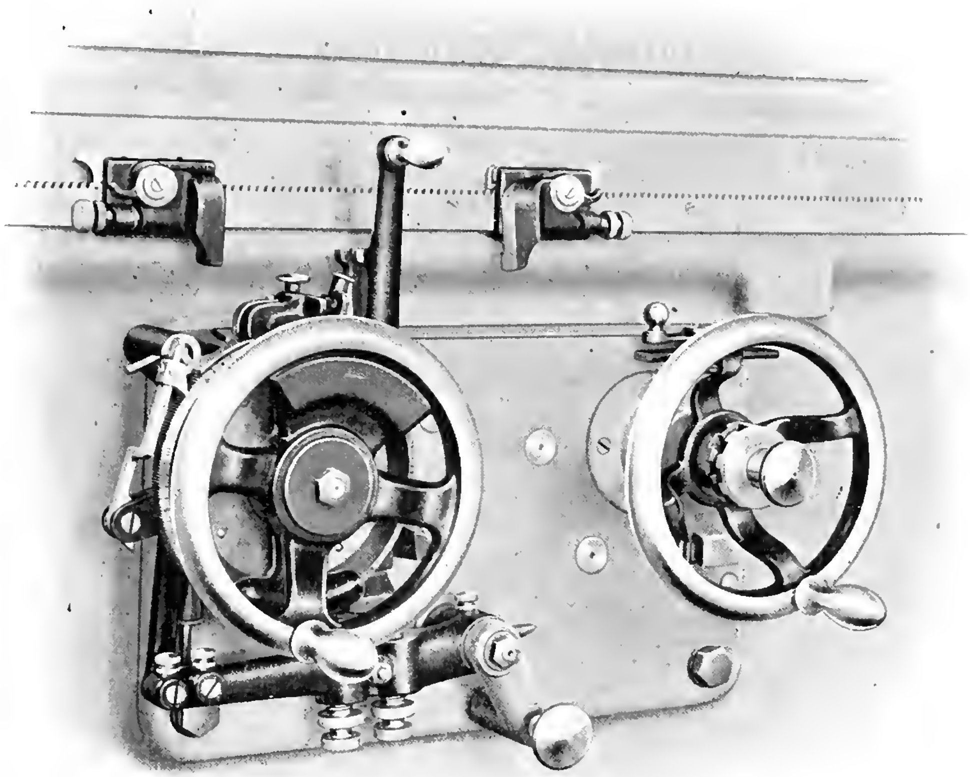
INTERNATIONAL CORRESPONDENCE SCHOOLS, Scranton, Pa. Reprint of editorial in *Colliers' Weekly* on teaching by correspondence. The editorial resulted from the personal investigation of Mr. Mark Sullivan, who found that the correspondence schools and the International Correspondence Schools in particular are doing a great work in the education of students in the arts and trades.

SWEDISH CHAMBER OF COMMERCE, New York. Bulletin containing, besides some general information regarding trade conditions in Sweden at the present time, a list of goods offered by Swedish firms in the United States, of American goods offered in Sweden, and of Swedish goods asked for by buyers in the United States. A short review of the extent of the Swedish iron industry in 1909 is given.

CARBORUNDUM CO., Niagara Falls, New York. Copy of "Revised American Statesman Series" entitled: "George Washington," by F. W. Haskell, president of the company. This number of the series is another of Mr. Haskell's satirical efforts which have attracted so much attention from those favored with copies. Copies of the Revised American Statesman series will be sent to any address upon application.

GENERAL ELECTRIC COMPANY, Schenectady, N. Y. Bulletin No. 4715 superseding Bulletin No. 4693 on General Electric No. 210 railway motor. This is a 70-horse-power, 600 volt motor of substantial construction, having brush holder and field coil supports, and is practically sparkless even under heavy over-load. The bulletin gives detailed description and contains speed table, characteristic curves and dimension diagrams.

Increase in production and decrease in cost of operation are made possible in grinding machines by a well designed and accurately controlled automatic cross-feed mechanism.



B. &. S. Grinding Machines Embody These Features:

The feed is set for any desired size by pressing the thumb latch. It can be set to feed the full amount at both ends of the table travel or it can be set to give any part of the full amount at either end. When the work reaches the size for which the mechanism is set, the cross-feed is automatically thrown out. It is particularly advantageous when a large number of pieces are to be ground accurately to size.

Send for booklet giving other details of the machine.

BROWN & SHARPE MFG. CO.

PROVIDENCE, R. I., U. S. A.

CUTLER-HAMMER MANUFACTURING COMPANY, Milwaukee, Wis. Booklet on elevator controllers, describing the Cutler-Hammer line of controlling devices designed for use with alternating and direct current motors operating passenger or freight elevators. The booklet illustrates elevator controller apparatus in detail that never before has been shown in a publication. It should be of interest to electricians and others concerned in the problem of elevator design and up-keep.

CHARLES BESLY & CO., 118-124 North Clinton street, Chicago, Ill. Pamphlet on Besly disk grinding practice giving results of comparative circle tests and Helmet spiral circles, practice of machining castings with the Besly disk grinder, showing a large number of manufactured parts that are being machined efficiently and rapidly with the Besly grinder. The pamphlet will be found of general interest by all concerned with the economical finishing of machine parts, apparatus, etc.

WESTERN ELECTRIC COMPANY, 463 West street, New York. Booklet descriptive of the manufacture of lead-covered cable in the Western Electric Company's cable department which is said to be the largest and best equipped cable plant in the world. The booklet illustrates and describes a 600 pair B. & S. gage, paper insulated lead covered cable. It also illustrates the manufacture of telephone cables, and contains a double page illustration on the Hawthorne works, a 143-acre plant.

HILL, CLARKE & CO., Chicago, Ill. Circulars of 3- and 3½-foot Western triple geared radial drills; Chicago duplex bench miller; No. 1 Chicago duplex hand miller with power feed; No. 4 Chicago duplex band miller, with power feed; No. 3 Chicago duplex hand miller, with power feed; No. 3A Chicago duplex hand miller, with power feed and screw vertical attachment to knee; and circular illustrating feather keyseating as done on the Chicago duplex band miller, with power feed.

JOHN WILEY & SONS, 43-45 East Nineteenth street, New York. Catalogue of text-books and industrial works for schools, colleges, polytechnic institutes, engineers, architects, chemists, military and naval officers, etc., comprising works on agriculture, architecture, army and navy, assaying, astronomy, chemistry, civil engineering, drawing, electricity and physics, law, mathematics, mechanical engineering, pure and applied mechanics, medicine, metallurgy, mineralogy, mining, sanitary science and miscellaneous.

LODGE & SHIPLEY MACHINE TOOL CO., Cincinnati, Ohio. Folder on the evolution of the Lodge & Shipley "patent head" lathe. A halftone of the present patent head lathe has superimposed on it three halftone illustrations of the headstock as built in the beginning with the five-step cone with narrow belt, the three-step cone with double back gears, and the all-geared head; the disadvantages of each of these three types are pointed out. The folder will interest those concerned with the development and use of engine lathes.

KOLESCH & COMPANY, 138 Fulton street, New York. Circular of the "Lewis Ideal" tape reel for engineers and surveyors. The diameter of the reel is 5¼ inches and the weight 10 ounces, the capacity being 125 feet of tape. The frame is made of aluminum alloy and the wearing parts of hardened steel with handle of bronze. It has a high-speed gear which enables the user to wind up 100 feet of tape in about 12 seconds, thus saving much valuable time. The price is $15, with a ¼-inch wide 100-foot steel tape.

MANUFACTURERS' EQUIPMENT & ENGINEERING CO., Boston, Mass. Circular of all-metal sanitary and fireproof equipment for factories, foundries, gymnasiums, public buildings, department stores, offices, hospitals, etc., comprising individual wash bowls in batteries, metal lockers, all steel stools and chairs, steel stools and chairs with inset wood seats, stock and storage racks, metal shelving, metal vault fixtures, improved soda kettles, water heaters and instantaneous mixers, work benches with bench legs, drawing stands, etc.

W. S. ROCKWELL, 50 Church St., New York. Catalogue No. 3 of fuel oil and gas burning appliances comprising Rockwell oil burners, low-pressure oil burners, steam-actuated fuel oil pumping system, belt-driven fuel oil pumping system, positive pressure blowers, steam separators, high-pressure tanks, oil hose, fuel oil storage tanks and useful data and information. The catalogue contains a diagrammatic illustration of a fuel oil furnace installation, showing tank car on switch, storage tank buried in the ground, and pipe connections to oil pump, blower and forge furnace.

ROCKFORD MACHINE TOOL CO., Rockford, Ill. Catalogue of Rockford shapers and planers, comprising 14-inch single gear, 16-inch back-gear, 20-inch back-gear crank shapers, 16-inch Rockford shaper with constant-speed belt drive, 24-inch x 24-inch, 28-inch x 28inch, 32-inch x 32-inch and 36-inch x 36-inch metal planers. The catalogue also illustrates Rockford shapers driven by constant speed and variable speed motors and the Rockford variable speed planer with four cutting speeds and a high-speed constant return. The four-speed gear box is applicable to all sizes of planers built by the company.

J. T. SLOCOMB COMPANY, Providence, R. I. Pamphlet on measurement, containing suggestions in regard to accurate and economical measuring in machine construction. The pamphlet refers to the measurement with the common rule, with inside and outside calipers of the old type and external and internal micrometer calipers of the type made by the company. The construction of the Slocomb micrometer heads is shown and the various styles for shop equipment, also measuring machines, gages, etc., that are employed in the manufacture of Slocomb micrometers to secure a high degree of accuracy.

H. W. JOHNS-MANVILLE CO., 100 William St., New York. Bulletin No. 2, illustrating and describing the "Linolite" system of electric illumination, including a new line of desk lamps recently placed on the market. Proper illumination of desks is a difficult problem to solve. Most of the lamps used for the purpose to-day are the ordinary incandescent bulb lamps placed in a small reflector which throws the light all on one section of the desk, leaving the balance insufficiently lighted. The tubular "Linolite" lamps are 12 inches long between centers and distribute light more evenly and over a larger section of the desk than bulb lamps.

GEORGE H. GIBSON COMPANY, Tribune Building, New York. Pamphlet entitled, "Advertising and Its Service," being a reprint from the New York *Evening Post*, describing the economics of advertising, especially as regards the engineering and mechanical industries. It shows that contrary to academic opinions, properly directed advertising reduces the cost of distribution of goods. It provides the salesmen with a great number of selling opportunities in a given territory and in a given time. It performs a preliminary, but necessary work of informing and educating the prospective user as to the nature, possibilities and profitableness of improved machinery.

NATIONAL BRAKE & ELECTRIC CO., Milwaukee, Wis. Catalogue of National motor-driven air compressors, type "3VS." This type has three vertical cylinders with pistons driven by a three-throw crankshaft, direct-connected to an electric motor. The construction of a compressor is shown in detail by illustrations of the upper and lower half of the frame with crankshaft in place, herringbone gear and pinion, piston connecting-rods and cylinders mounted and disassembled, suction and discharge valves, etc. The catalogue also illustrates direct and alternating current motors, combined automatic controlling devices, air pump governor, air compressor equipment mounted on wheels for railroad service operating rock drills, pneumatic drills, etc., and the air lift well system of pumping water from wells by compressed air. It concludes with tables of dimensions, capacities of cylinders and air receivers.

TRADE NOTES

ROCKFORD LATHE AND DRILL COMPANY, Rockford, Ill., has increased its capital stock from $20,000 to $50,000.

HAMPDEN BROTHERS COMPANY, Springfield, Mass., maker of brass, composition and aluminum castings and specialties in these metals is building an addition to its foundry, 36 by 132 feet.

DUCKWORTH CHAIN AND MANUFACTURING COMPANY, Springfield, Mass., maker of chains for bicycles, automobiles, etc., and specialties, has built an addition that will increase its capacity about 75 per cent.

CARPENTER STEEL COMPANY, Reading, Pa., announces the appointment of Mr. Fred. A. Bigelow, formerly its representative in New England, as manager of its Cleveland branch, with office and warehouse at 1304 West Sixth street, Cleveland, Ohio.

COLUMBUS PNEUMATIC TOOL COMPANY, 1432 Parsons avenue, Columbus, Ohio, has changed its name to the Dunlap Engineering Company, with T. C. Dunlap president and treasurer, W. J. Dolan, sales manager, and J. H. White, superintendent, as heretofore.

J. A. FAY & EGAN CO., Cincinnati, Ohio, has sold to the Wright Bros., Dayton, Ohio, for use in their aeroplane factory, ten woodworking machines. Among these are a high-duty planer that will cut wood so thin that it is transparent, a special shaper, cut-off saw, mortiser and tenoner.

M. L. ANDREW & CO., Cincinnati, Ohio, are erecting a two-story brick and stone building at the corner of Colerain avenue and Alabama street, which will be ready for occupancy about the middle of May. The company is in the market for a grinder, gear-cutter, planer, radial drill, automatic screw machine and engine lathes.

EDGEMONT MACHINE COMPANY, Dayton, Ohio, manufacturer of friction clutch pulleys for countershafts and extended sleeve clutches for line-shaft duty, has recently added a number of new and specially designed machines to its already fine equipment, and is now in position to take care of its rapidly increasing clutch business.

H. W. JOHNS-MANVILLE CO., 100 William St., New York, because of rapidly increasing business, has moved its Chicago branch now at Randolph St. to the four-story and basement building at Nos. 27-29 Michigan Ave., with 32,500 square feet of floor space. Office, store and warehouse are all under one roof. Its Baltimore, Md., office, store and warehouse has been located at 30 Light St.

CHARLES T. MAIN, formerly 201 Devenshire street, Boston, Mass., has moved into more commodious offices in 817-833 of the new Boston Safe Deposit and Trust Company building. He will be better prepared than ever to conduct the work in engineering of textile mills and other industrial plants, water power and steam power development, examination and reports on plants with reference to their value, reorganization and development.

LODGE & SHIPLEY MACHINE TOOL COMPANY, Cincinnati, Ohio, has recently added an excellent dining hall to its factory. The dining hall building was formerly a large residence, which has been handsomely and tastefully decorated, and furnished appropriately for the purpose. Many beautiful pictures hang on its walls, which Mr. Shipley imported from Germany. The entire executive and selling force and heads of various operating departments take their meals here with all the conveniences of a first-class café.

TERMINAL ENGINEERING COMPANY, 30 Church street, New York, is the American office, in charge of Mr. E. C. Johnstone, agent for the James Hendry laminated leather products manufactured in Bridgeton, Glasgow, and Birmingham, Great Britain. An American factory has been completed near Newark, N. J., for the manufacture of these products, which comprise Hendry's laminated leather belting for dynamos, motors, and all classes of main drive also Hendry's helically laminated round leather belting to displace rope in rope drives.

JOHN B. MORRIS MACHINE TOOL COMPANY, Court, Harriet and Vogt streets, Cincinnati, Ohio, has been incorporated under the laws of Ohio with a capital stock of $125,000, and has purchased the machine tool trade formerly conducted by the J. B. Morris Foundry Company. Plans are being completed for a new factory building with a floor space of over 30,000 square feet, to be used in the manufacture of machine tools formerly built by the J. B. Morris Foundry Company. Additional machine equipment will be installed and the new company expects to increase its line of machine tools.

GREEN FUEL ECONOMIZER CO., Mattewan, N. J., in connection with the Rhode Island Construction Engineering Co., worked out a heating system for the Waterbury Castings Co., Waterbury, Conn., which is giving satisfactory results. The new foundry of the Waterbury Casting Co. has a capacity of 515,000 cubic feet. The walls are nearly all glass and the problem was difficult to handle, but by the arrangement of heater mains and discharge pipes, the heated air is discharged, in such a manner as to make working conditions uniformly comfortable and to displace the smoke, causing it to rise to the roof.

INTER-OCEAN STEEL COMPANY, 217 Railway Exchange, Chicago, Ill., expects to have its new plant at Chicago Heights ready to produce locomotive and car wheel tires, tire rings and ore crushing machinery, forged and rolled weldless steel flanges for use on high pressure steam and water pipe boilers, and other rolled rings, about April 1. The machinery was designed by Mr. Julian Kennedy, who enjoys a world-wide reputation as a designer, and tire mill expert. The mills have an unusual capacity; they will roll tires of considerably larger diameter and of greater width and section than any other in existence.

GOLDSCHMIDT-THERMIT CO., 90 West St., New York, publishes a quarterly periodical called *Reactions*, devoted to the science of aluminothermics. The fourth quarterly issue for 1909 contains an interesting description of the repair of a 48-ton pulley in the wilds of North Carolina for the Consolidated Nickel Co., under conditions of great difficulty. The repair was successfully made with thermit, and the pulley is shown before and after the repair was made. Views of Sylva and its inhabitants give the reader a good idea of the limited resources of the region for making the heavy repairs that were very simply performed with thermit.

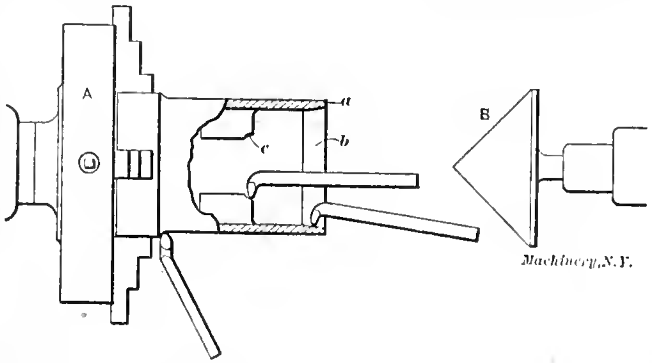
INGERSOLL-RAND COMPANY, 11 Broadway, New York, held its annual convention of managers and agents in New York, February 1 to 5. Mr. W. L. Saunders, president, presided at the meetings. The party left New York by private car February 1 for Easton, Pa., and passed en route through the Musconetcong Tunnel, the first railway tunnel in America driven entirely by machine drills. The rock drills used in this work were built by one of the pioneer companies now comprising the Ingersoll-Rand Company. The first day was spent at the Easton, Pa., plant examining the line of compressors, stone channelers, hammer drills, core drills, and pneumatic tools built in these shops. The second day was devoted to the Phillipsburg, N. J., works, inspecting the rock drills, electric-air drills, coal cutters and large compressors, which are the products of this plant. The party then went to the Painted Post, N. Y., shops by special train, where, on February 3, the compressors, rock drills, hammer drills, pneumatic tools and pneumatic hoists produced at this plant and at the Athens, Pa., shops were examined. The party returned to New York by special train and devoted February 4 and 5 to business meetings at the Hotel Astor. A social feature of the convention was a banquet and theatre party on Friday evening, February 4. Forty-two representatives of the company were in attendance.

Supplement to MACHINERY, April, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Turning Gas Engine Pistons in the Turret Lathe"

SHOP OPERATION SHEET NO. 130

Stanley Gould MACHINERY, April, 1910



Machining a Gas Engine Piston—1

NOTE.—The method of turning a gas engine piston here described is not given as one to be followed where pistons are being made in quantity, but rather as a good method for a jobbing or other shop where there is not sufficient work of this kind to warrant making expensive special tools and appliances. The machine used is a standard engine lathe.

1. First chuck the casting in a four-jawed independent chuck *A*, placing the solid end of the piston next to the chuck. Set the casting true by the inner surface, so that when it is turned on the outside the walls will be of uniform thickness. Face the edge *a* of the open end of the piston to the proper length, making allowance for truing up the top or solid end of the casting.

2. Bore out the open end for, say an inch, to a taper of about 1 or 2 inches to the foot as at *b*. When machining this surface, the compound rest should be swung around until it is within, say 8 degrees, of the right angle position, which will give about the right taper. The tool is, of course, fed by the feed-screw of the compound rest. This tapered surface is used in a subsequent operation for driving the piston while taking the finishing cut. If the work is held by chuck jaws it is likely to be sprung.

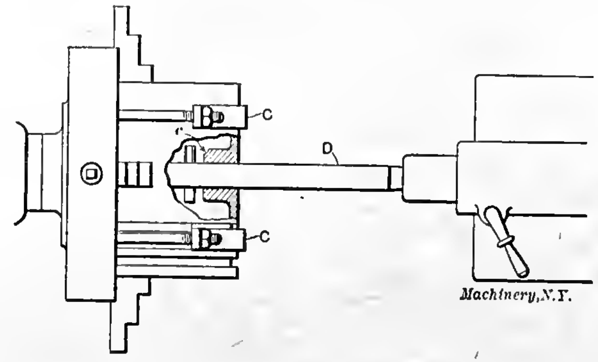
3. With the boring tool bore out the wrist-pin bosses on the ends to the finished width between them for a short distance, as at *c*, so that when they are being faced off in another operation there will be a surface to work to.

4. Next bring up the cone-center *B* and adjust it to the open end of the piston. This center is to support the work during the rough turning operation. Turn the casting, as far as the chuck jaws will permit, to within 1/16 inch of the finished size; then reverse the piston in the chuck and set it so that the rough turned surface runs true. Next center the solid end and support the piston by the tail-stock center. Then face the end until the piston is the correct length; also turn the outside surface previously held by the chuck jaws until it is reduced to the same size, or if anything a little smaller than the previously turned part.

5. Cut the grooves for the packing rings to the finished depth, but allow about 1/32 inch at the sides for finishing later. The depth should be obtained by calipering the diameter at the bottom of the groove, rather than by measuring from the rough outside surface.

SHOP OPERATION SHEET NO. 131

Stanley Gould MACHINERY, April, 1910



Machining a Gas Engine Piston—2

1. A hole is next bored through the piston for the wrist-pin. Before placing the work in the machine the center of the hole should first be located on the outside of the piston, the correct distance from the solid end and in line with the bosses on the inside.

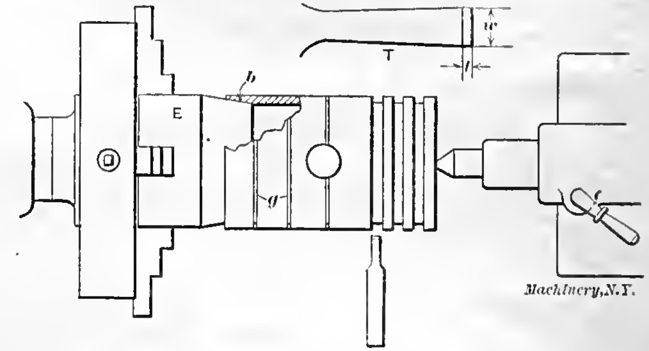
2. Hold the piston against the slot in the chuck with the tailstock and clamp it with a strap *C* across each end. As the engraving indicates, these straps are curved to fit the curved surface of the piston, which gives them a better grip. Set a chuck jaw against each side of the piston, and, if the swing of the lathe will permit, set a jaw against each end, as shown in the illustration. Before the clamps *C* are tightened, adjust the casting by turning it and by moving the chuck jaws until the center of the wrist-pin hole is in line with the point of the tailcenter, which should be set for straight turning. When the clamps are tightened withdraw the tailcenter and test the accuracy of the setting by bringing a pointer held in the toolpost close to the punch center while the work is revolving rapidly. If the punch mark moves in a circle, the work should be adjusted to bring it exactly in line with the axis of the lathe spindle.

3. With a centering tool cut a center for starting a twist drill and then, feeding the drill by the tailstock, drill a hole through both sides of the piston. This hole should be large enough to be followed by a boring tool, which is next used for boring the wrist-pin bosses to a running fit for facing-bar *D*, which should be smaller than the finished bore of the bosses.

4. With a double-ended cutter which is ground on both sides, face off the end of each wrist-pin boss. As the faces of these bosses should be central with the piston as well as the correct distance apart, the advantages of boring them, as described in the preceding sheet, will be understood. Just enough should be faced from each boss to barely remove the marks left by the boring tool. When facing the outer boss, the boring-bar may be held against the tailstock by a tool in the toolpost bearing against a lathe dog on the bar. A better method, however, is to use a bar that is turned taper on the end to fit the tailstock spindle. After both bosses have been faced, the bar should be removed and each boss finished to the required size with a boring tool.

SHOP OPERATION SHEET NO. 132

Stanley Gould MACHINERY, April, 1910



Machining a Gas Engine Piston—3

1. An old casting *E*, or other piece, is next turned to fit the tapered surface *b* in the open end of the piston. This is done by swinging the compound rest around to the same angle to which it was set when boring the part *b*, as previously explained. The piston is then forced tightly on this turned piece, and the outer end is supported by the tailcenter as shown. Evidently the work will now run, at least approximately true, and the method of driving by the tapered plug makes it possible to take a continuous finishing cut throughout its length. When taking this cut, allowance should be made for finishing either by grinding or filing. If oil grooves *g* are required, they are now cut with a small round-nosed tool. These annular grooves serve as a reservoir for the lubricant. It is the practice in some shops to finish a part of the upper surface of the piston, tapering to allow for the greater expansion which occurs at the upper end, owing to its proximity to the heat generated in the combustion chamber.

NOTE.—There is a difference of opinion among automobile and gas engine manufacturers in regard to the necessity of grinding pistons. Some makers claim that inasmuch as the packing rings prevent leakage, it is not necessary to grind the piston.

2. The packing ring grooves, which were previously roughed out, are now finished to the correct width. If a number of pistons are being turned the grooves may be quickly machined to a standard width by using a square-nosed tool, ground as at *T*. As shown, the sides, as viewed from the top, are ground straight back or without clearance for a distance *l* of about 1/16 inch, and the width *w* is made equal to the groove width. By having the straight part *l*, the tool may be ground without changing its width. If this straight part, however, extended clear back, the grooves in different pistons would be less likely to have a uniform width, as a slight change in the position of the tool would result in a tapering groove.

NOTE.—The following dimensions for gas engine piston ring grooves represent good average practice: For diameters between 3¼ and 4 inches, width 7/32 inch, depth 5/32; between 4¼ and 5, width 5/16, depth 3/16; between 5¼ and 6, width ⅜, depth 7/32; between 6¼ and 7, width ½, depth ¼; between 7¼ and 8, width 9/16, depth 9/32 inch.

COMMERCIAL RATINGS FOR INTERNAL COMBUSTION ENGINES*

By WILLIAM D. ENNIS†

VARIOUS empirical ratings have been proposed for automobile and other engines, based on the cylinder dimensions and the speed. These are founded either on tests of a large number of types, or on an analysis, such as follows, of the factors limiting the output of an engine running under stated conditions.

The Indicator Diagram

The power exerted by an engine during a working stroke is shown by such a diagram as that given by the indicator. The

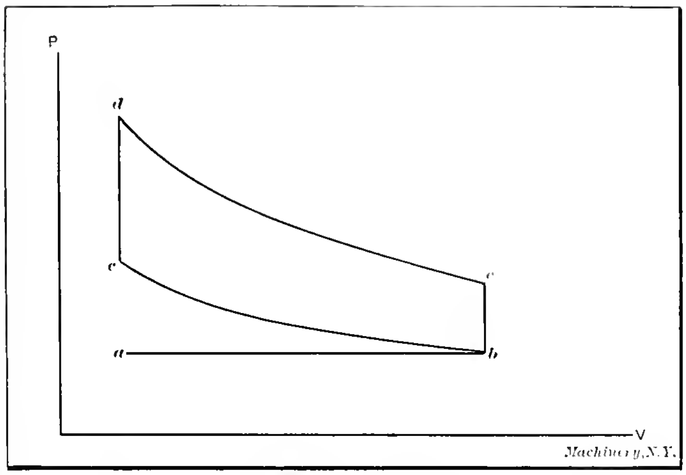

Fig. 1. Ideal Gas Engine Diagram

factors which would influence this diagram in an internal-combustion engine may be listed as follows:

a. The diameter of the cylinder and the stroke of the piston.

b. The type of the engine, whether 2-cycle or 4-cycle.

c. The mechanical design, including the questions of port areas, jacketing, and gas velocities.

d. The fuel used, the nature of the fuel limiting the temperature allowable during compression.

e. The clearance, which is determined by reference to factors *b*, *c* and *d*.

The ideal diagram of a gas engine is shown in Fig. 1. Gas enters the cylinder along *ab*, without friction, at constant pressure. It is compressed along *bc*, without gaining or losing heat, until the piston has reached the end of its stroke at *c*. Ignition then occurs. The spread of flame is instantaneous, so that the line *cd*, representing a rise of temperature and pressure, is straight and vertical. The piston immediately moves forward, the gas expanding behind it along *de*, again without gaining or losing heat. At *e*, the piston has reached the outer end of its stroke, the exhaust valve opens, and the gas passes out without friction. The pressure falls instantaneously to that at *b*, the remaining low-pressure gases leaving the cylinder (also without friction) during the return stroke of the piston along *ba*.

The actual indicator diagram of the 4-cycle type of engine is shown in Fig. 2. Gas enters as before during the outstroke of the piston along *ab*, but port friction wire draws the charge so that the pressure gradually decreases. The pressure at *b* in a 4 cycle engine may be about 12 pounds absolute (2.7 pounds less than atmospheric pressure) and in a 2-cycle engine about 20 pounds absolute. Compression occurs along *bc*, but the curve does not rise as rapidly as the corresponding curve in Fig. 1. This is to be explained on the ground that heat is being given up to the cylinder walls, so that the temperature and pressure of the gas at any point are less than they would otherwise be. It has been found that the curve *bc* follows approximately the law

$$PV^n = \text{constant},$$

in which P and V are corresponding pressures and volumes and the value of n may be taken at 1.3. Then

$$P_b V_b^{1.3} = P_c V_c^{1.3}, \text{ for example.}$$

An important principle in gas engine design may here be suggested. The temperature due to the compression reached at c must not exceed that at which the gases will ignite of themselves. Suppose this temperature, for the fuel in question to be 600 degrees F. Then by a fundamental formula for gases,

$$\frac{P_c V_c}{T_c} = \frac{P_b V_b}{T_b} \text{ and } \frac{V_c}{V_b} = \frac{P_b T_c}{P_c T_b} \qquad (1)$$

in which the symbol T refers to the absolute temperature, equal to the Fahrenheit temperature plus 460.

We have, moreover, as already stated

$$P_c V_c^{1.3} = P_b V_b^{1.3} \text{ and } P_c = P_b \left(\frac{V_b}{V_c}\right)^{1.3} \qquad (2)$$

Combining Equations (1) and (2), we find

$$\frac{V_c}{V_b} = \left(\frac{T_c}{T_b}\right)^{-3.33}$$

The value of T_b depends upon the temperature of the gases when admitted to the cylinder, and the warming which they undergo by transfer of heat from the walls during the suction stroke. Suppose it to be 200 degrees F. We then find $T_c = 600 + 460 = 1060$, $T_b = 200 + 460 = 660$, and $\frac{V_c}{V_b} = \left(\frac{1,060}{660}\right)^{-3.33} = 0.206$, whence $\frac{V_c}{V_b - V_c} = 0.26$ the clearance, expressed as a fraction of the stroke.

Ignition occurs at c; but as the spread of the flame is not

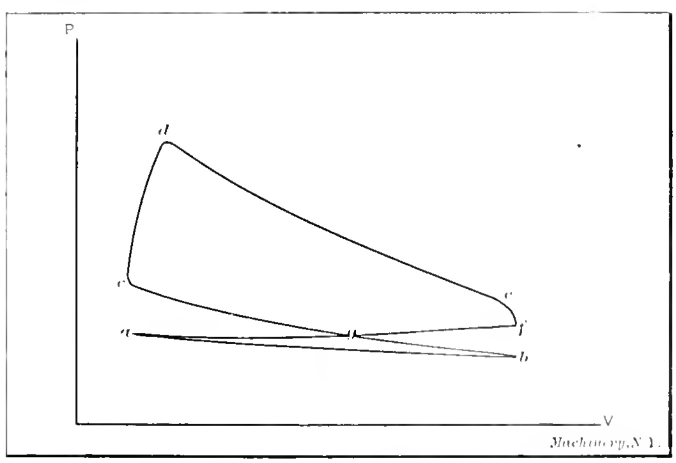

Fig. 2. Actual Diagram, Four-cycle Type Engine

instantaneous, the ignition path *cd* is swerved to the right by the movement of the piston. Further, the resulting rise of temperature attained at *d* is only a fraction of that which might be expected from a computation based on the composition of the gas. This fact is due to the increase of volume during ignition, the transfer of heat to the cylinder walls, and the slow burning, by reason of which some of the

* See also MACHINERY, November, 1909, "Approximate Horsepower Formulas for Gasoline Engines."

† Professor of Mechanical Engineering, Polytechnic Institute of Brooklyn, N. Y.

combustion occurs along the expansion path de. The temperature attained at d seldom exceeds 3,000 degrees F. = 3460 degrees absolute, and the corresponding pressure, assuming no important change of volume to occur between c and d, is given by the formula,

$$\frac{P_d}{P_c} = \frac{T_d}{T_c}.$$

Along the expansion path de some heat is given up by the gas to the cylinder walls. Any "after-burning" due to incomplete ignition along cd will also affect the shape of de. In most cases, the curve in question may be approximately represented by the same sort of formula as that given for the compression curve,

$$PV^n = \text{a constant},$$

in which the value of n, for our present purpose, may be taken at 1.33. When the value of n is the same for the expansion curve as for the compression curve, we have the simple relation:

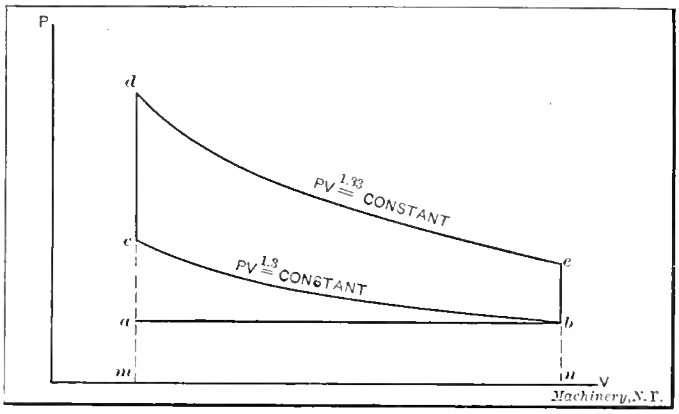

Fig. 3. Designer's Diagram

$$\frac{P_d}{P_c} = \frac{P_e}{P_b}.$$

The exhaust valve opens at e, and the gas is forced out of the cylinder against an appreciable resistance along efa. The indicated work is $cdefg - agb$.

The Designer's Diagram

We may now simplify the indicator diagram as in Fig. 3, eliminating the negative loop agb and the rounded corners of the diagram in Fig. 2, and treating the ignition line cd as straight and vertical. The indicated work of such a diagram would be represented by the enclosed area, or, we may say, by

$$mden - mcbn.$$

For an area like $mden$, subtended by a curve like de, we have the formula

$$\frac{P_d V_d - P_e V_e}{0.33},$$

the 0.33 being the quantity $n - 1$, where n is the exponent of the equation representing the curve. Similarly,

$$mcbn = \frac{P_c V_c - P_b V_b}{0.3}, \text{ and}$$

$$cdeb = mden - mcbn = \frac{P_d V_d - P_e V_e}{0.33} - \frac{P_c V_c - P_b V_b}{0.3}.$$

Computation of Pressures and Work

For a 4-cycle engine, $P_b = 12 \times 144 = 1{,}728$ pounds per square foot. To find P_c, we write

$$\frac{P_c V_c}{T_c} = \frac{P_b V_b}{T_b}, \text{ or } P_c = \frac{P_b V_b T_c}{V_c T_b},$$

and substituting values already given, we obtain:

$$P_c = \frac{1728 \times 1060}{0.206 \times 660} = 13{,}400 \text{ pounds per square foot, about.}$$

For P_d, we have, approximately,

$$\frac{P_d}{P_c} = \frac{T_d}{T_c};\ P_d = P_c\frac{T_d}{T_c} = 13{,}400\ \frac{3000 + 460}{1060} = 44{,}000 \text{ pounds per}$$

square foot.

For P_e, we write

$$P_e V_e^{1.33} = P_d V_d^{1.33};\ P_e = P_d\left(\frac{V_d}{V_e}\right)^{1.33} = 44{,}000 \times 0.206^{1.33} = 5380$$

pounds per square foot, about.

Let $V_b - V_c = V_e - V_d = D$, the displacement of the piston per stroke.

But $V_c = 0.206\ V_b$, whence $0.794\ V_b = D$; $V_b = V_e = 1.26\ D$; and $V_c = V_d = 0.26\ D$. Then,

$$cdeb = D\left(\frac{(44{,}000 \times 0.26) - (5380 \times 1.26)}{0.33} - \frac{(13{,}400 \times 0.26) - (1728 \times 1.26)}{0.3}\right) =$$

$$D\left(\frac{11{,}440 - 6780}{0.33} - \frac{3490 - 2180}{0.3}\right) = 9750\ D.$$

Under the assumed conditions, *viz.*, a pre-compression pressure of 12 pounds per square inch and a temperature of 200 degrees F., a compression curve $PV^{1.3}$ = a constant, a temperature after compression of 600 degrees F. and after ignition of 3,000 degrees F., with an expansion curve $PV^{1.33}$ = a constant, with a piston displacement of D cubic feet, the work per active stroke, measured in foot-pounds, is 9,750 D. This must be somewhat reduced to allow for the rounding of corners of the actual diagram, the negative loop agb, Fig. 2, etc., say to 9,000 D, which then represents the indicated work to be expected from the engine.

Engine Capacity

Let S be the piston speed in feet per minute, s the piston speed in inches, A the area of the piston in square feet, a its area in square inches, and N the number of revolutions per minute. The displacement of the piston in cubic feet per stroke is then $AS \div 2N$. The number of active strokes per minute depends upon the form of engine. Thus, for 4-cycle engines, we have the following ratio of active strokes to total strokes:

Single-acting,	1-cylinder,	1 to 4;
	2-cylinder,	2 to 4;
	4-cylinder,	4 to 4;
	6-cylinder,	6 to 4;
Double-acting,	2-cylinder,	4 to 4;
	4-cylinder,	8 to 4.

Since there are $2N$ total strokes per minute, the number of active strokes in a single-acting engine, if 4-cylinder, is $2N$; and if 6-cylinder, $\frac{6}{4} \times 2N = 3N$. The indicated horsepowers of the two forms of engine are then $\frac{9{,}000 \times 2ND}{33{,}000}$ and $\frac{9{,}000 \times 3ND}{33{,}000}$; and since $D = AS \div 2N$, these horsepowers may also be written:

$$\frac{9{,}000 \times 2ANS}{33{,}000 \times 2N} = 0.273AS, \text{ and } \frac{9{,}000 \times 3ANS}{33{,}000 \times 2N} = 0.409AS.$$

Empirical Ratings

Since $S = \frac{s}{12}$ and $A = \frac{a}{144}$, we have for the 4-cylinder engine:

$$\text{I.H.P.} = 0.273 \times \frac{s}{12} \times \frac{a}{144} = 0.000158sa.$$

If d be the cylinder diameter in inches, $a = 0.7854d^2$, and

$$\text{I.H.P.} = 0.000158 \times 0.7854sd^2 = 0.000124sd^2.$$

If the piston speed be taken in feet as in standard nomenclature, then,

$$\text{I.H.P.} = 0.00149\ Sd^2 = \frac{Sd^2}{670}.$$

From this we may formulate the following rule: The indicated horsepower of a single-acting four-cylinder four-cycle

engine is equal to the piston speed in feet per minute, multiplied by the square of the cylinder diameter in inches, and divided by 670. A $4\frac{3}{4}$-inch engine at 800 feet piston speed would then be rated at 28 H. P.

Ratings are sometimes based on the cylinder dimensions only, the number of revolutions per minute being regarded as standard. If L be the length of the stroke in inches,

$$S = 2LN \div 12 = \frac{LN}{6}, \text{ and, for a four-cylinder engine,}$$

$$\text{I.H.P.} = \frac{LNd^2}{4{,}020} = \frac{LNa}{4{,}020 \times 0.7854} = \frac{LNa}{3155}$$

$$\text{I.H.P. per cylinder} = \frac{LNa}{3155 \times 4} = \frac{LNa}{12{,}620}$$

At 1,000 R.P.M. the indicated horsepower per cylinder is then equal to the product of the length of stroke in inches, piston area in square inches, and number of revolutions per minute, divided by 12.62.

Another method of rating at 1,000 R.P.M. may be derived as follows:

$$\text{I.H.P.} = \frac{LNd^2}{4{,}020} = \frac{Ld^2}{4.02}, \text{ or}$$

$$\text{I.H.P.} = \frac{Ld^2}{16.08} \text{ per cylinder.}$$

If the diameter of the cylinder equals the stroke, we have:

$$\text{I.H.P.} = \frac{d^3}{16.08} \text{ per cylinder, or approximately } \frac{d^3}{16}.$$

For m cylinders this becomes:

$$\text{I.H.P.} = \frac{md^3}{16}.$$

Effective Horsepower

The effective horsepower may be assumed to be 85 per cent of the indicated horsepower. By inserting this value in the formulas for the indicated horsepower per cylinder we find the actual horsepower:

$$\text{H.P.} = \frac{Sd^2}{3{,}150} = \frac{LNa}{14{,}900} = \frac{LNd^2}{19{,}000} = \frac{Nd^3}{19{,}000}.$$

The denominators are given in round numbers to facilitate calculations. They are, however, very close to the exact values.

Rules Based on Formulas Given

Under the stated conditions of pressure, temperature, etc., which are approximately correct for four-cycle gasoline automobile engines, the effective horsepower per cylinder may be estimated by any of the following rules:

1. The product of the piston speed in feet per minute times the square of the diameter in inches, divided by 3150.

2. The product of the stroke in inches, the area of the piston in square inches, and the number of revolutions per minute, divided by 14,900.

3. The product of the stroke in inches, the square of the diameter in inches, and the number of revolutions per minute, divided by 19,000.

4. The product of the cube of the diameter in inches times the number of revolutions per minute, divided by 19,000. This last rule holds good only when the stroke equals the diameter.

Rule 1 appears to be the simplest and most direct. The rule sometimes quoted, giving the horsepower of the whole engine as equal to the diameter squared multiplied by the number of cylinders and divided by 2.5, can be justified only on assumptions of a constant piston speed and fixed length of stroke for all engines. Rules in any one of the four forms given are, however, satisfactory and scientific as long as their application is limited to a specific fuel and specific type of engine. The constants will vary if the rules are extended to cover such cases as, for example:

a. A double-acting four-cycle engine using producer gas.
b. The same engine using natural gas.
c. The same engine using blast furnace gas.
d. A single-acting four-cycle engine using kerosene.
e. A single-acting two-cycle engine using kerosene.

The following data will permit of establishing rules for the kinds of engines suggested, as well as for some other forms.

The value of P_b, Fig. 3, in two-cycle engines equals 18 to 21 pounds; in four-cycle engines, 12 to 14 pounds, absolute. The value of T_b will range from 140 to 300 degrees F.

The values of n (the exponent for the expansion curve) vary from 1.2 to 1.38, being lower in larger engines. T_c should not exceed 450 degrees F. if the gas contains more than 10 per cent, by volume, of hydrogen. In no case should it exceed 600 degrees F.

The value of P_c will usually be kept within the following ranges:

In automobile engines, 45 to 100 pounds.
In ordinary gasoline engines, 60 to 85 pounds.
In kerosene engines, 30 to 85 pounds.
In natural gas engines, 75 to 130 pounds.
In producer gas engines, 100 to 160 pounds.
In blast furnace gas engines, 120 to 190 pounds.

The value of T_d will seldom or never exceed 3,000 degrees F., and may, without serious error, be taken at this value for all the fuels mentioned. The percentages of deduction to be made for the rounding of the corners of the diagram, etc., and losses between cylinder and crankshaft will aggregate from 15 to 25 per cent in four-cycle engines, and from 30 to 40 per cent in two-cycle engines, being greatest in small engines.

* * *

NEW METHOD OF ELECTRO-PLATING—THE "GALVANIT" PROCESS

In a paper read before the Royal Society of Arts in Great Britain, Mr. A. Rosenberg described a novel process whereby metals of various kinds may be coated with nickel, silver, zinc or other metals with no more difficulty or exertion than that of using an ordinary polishing powder. The new method consists in the use of a mixture of pulverized materials in which the metal of which the coating is to be made is the main constituent; the deposition process consists simply in applying the powder by means of a rag or brush, and rubbing the object to be treated in the presence of moisture. The process depends upon the action between one ingredient (the electro-positive metal) and the other ingredient (the metallic salt) as soon as the addition of moisture to the mixture converts the latter into an electrolyte. The electro-positive metal constitutes the anode and the object treated the cathode. The action is explained on the principle that the finely powdered electro-positive metal makes innumerable contacts with the cathode surface and acts as so many minute anodes. These innumerable minute anodes gradually dissolve, and in dissolving set up in the liquid small local electric currents. In this way the metallic salt in solution forms a thick film on the cathode, which thus becomes plated all over with a deposit. The decomposition of liquid electrolyte is generally increased by heat, and this is found also to be the case with the application of powder for coating in the process just described. Although a rise in temperature is not necessary in the use of "galvanit," as these powders are called, a quicker and thicker deposit of metal can be obtained, in some cases, with the aid of heat. It is, therefore, an advantage to heat the article before applying the powder, to select ingredients in the mixture which will evolve heat while decomposing, and to use magnesium as the electro-positive ingredient.

As an example of a practical mixture, the following is given for depositing zinc, all parts being by weight: Zinc, 15 parts, ammonium sulphate, 5 parts; magnesium, 1 part; chalk, 10 parts; and talc, $2\frac{1}{2}$ parts. For depositing other metals, the zinc may be merely replaced by the metal which it is desired to deposit. The talc serves the purpose of preventing the mixture from absorbing moisture while being stored. The chalk used acts as a filling, and as a polishing agent. A powder for depositing nickel may be composed of 20 parts by weight of nickel ammonium sulphate, and 2 parts of magnesium powder.

METAL SPINNING—2

By WILLIAM A. PAINIER

A twenty-four-inch metal spinning lathe that is rigged up in a modern way, is shown in Fig. 17. The hand wheel of the tailstock has been discarded for the lever *A*, which is more rapid and can be manipulated without stopping the lathe. This lathe has a roller bearing for the center *B* which is a practical improvement over types previously used. The pin *C*, which is used in the rest as a fulcrum for the spinning tools is also an improvement, being larger than those ordinarily used. It is ¾ inch in diameter, 6 inches long, and

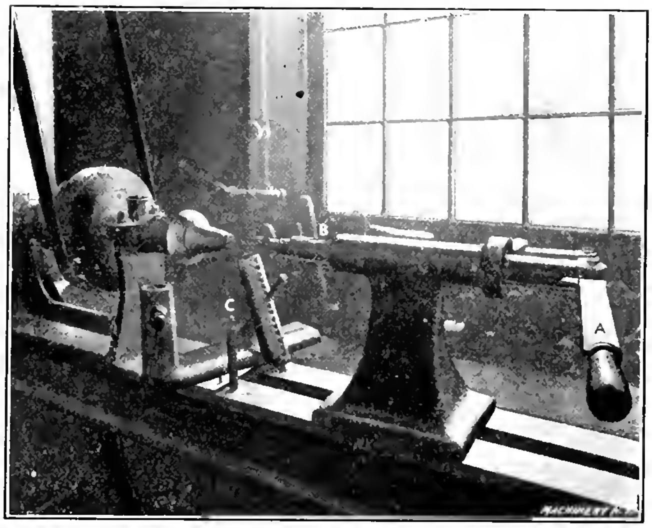

Fig. 17. A Modern Spinning Lathe

it has a reduced end for the holes in the rest, ⅜-inch in diameter by 1 inch long. This pin is large enough so that the spinner can conveniently hold it with his left hand when necessary, and it can also be rapidly changed to different holes. The pins ordinarily used, because of their small size, do not have these advantages. The speed of a spinning lathe having a five-step cone should be about 2,250 to 2,300 revolutions per minute with the belt on the smallest step, and from 600 to 700 revolutions per minute with the belt on the largest step. The fastest speed given is suitable for all work under

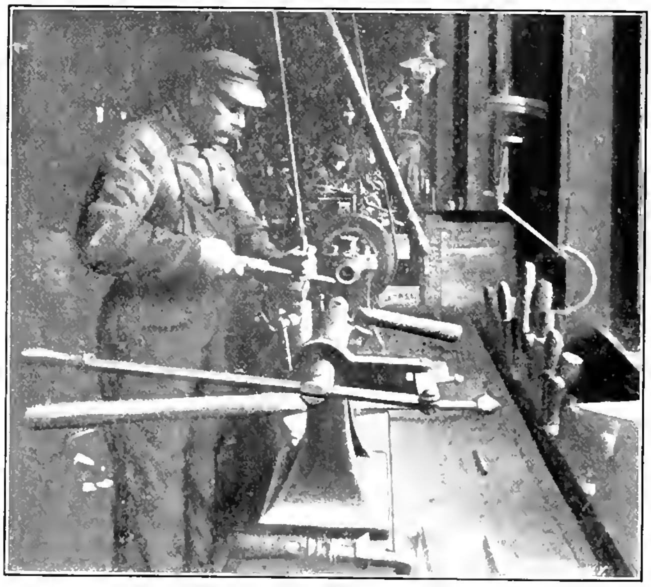

Fig 18. View showing how the Tool is held when spinning

5 inches in diameter, and the slowest for work within the capacity of the lathe. On large shells it is sometimes necessary to change from one speed to another as the work progresses.

Figs. 18 and 19 show the spinner at work, and illustrate how the tool should be held, and also the proper position of the left hand. This spinner, Alfred Danielson, learned his trade in Stockholm, Sweden, and he has worked in Europe, Canada and in several cities in the United States as a foreman. He learned his trade from German and French mechanics, of which countries both claim the origin of the art.

Address: 1515 Franklin St., N. S., Pittsburg, Pa.

Construction of the Tailstock and Back-center

Fig. 20 shows a spinning-lathe tailstock, which has been changed from the hand-wheel-and-screw type to one having a lever and a roller bearing. The spindle *A* which is withdrawn from the lever and turned one-quarter of a revolution to give a better view of the rollers, is made from 1¾-inch cold rolled steel. The rollers against which the center bears do not project beyond the spindle, so that the latter can be withdrawn through the tailstock. This eliminates the excessive overhang caused by ball bearings and other centers. When the center projects too far, the tailstock cannot be set close to the work, owing to the necessity of withdrawing the center when removing the spun part. The application of this principle to a spinning lathe is original and the type of center illustrated was used only after all other kinds had failed, including all the types of ball bearings and revolving pins. The best forms of ball bearing centers do not last over a year, if in constant use, and they will not always revolve on small work. Two other spindles are shown in this engraving, which were taken from other lathes in order to show different views of the parts. The cylindrical pieces *B* are the hardened friction rollers which belong in the slot of the spindle *F*, and *C* is the hardened pin upon which they

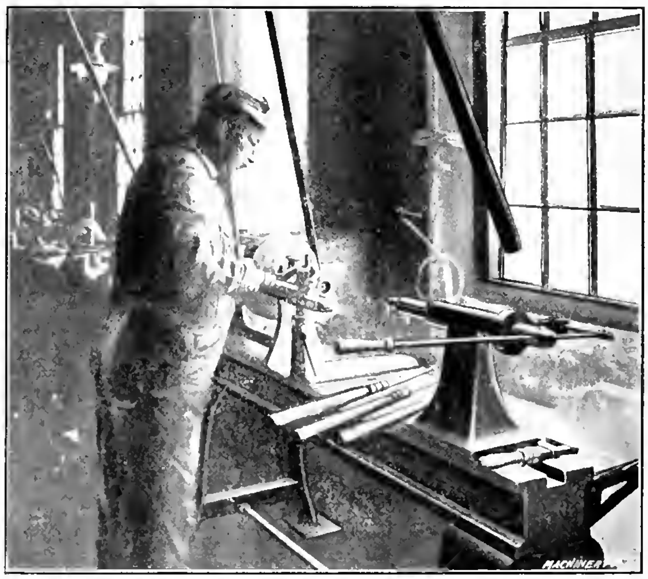

Fig. 19. Another View showing the Position of the Spinner and the Way the Tool is held when forming the Metal

revolve. The hardened center *D* has a threaded end on which the back-centers *E* of different lengths and shapes are screwed. The friction rollers should always be in a vertical position, and care should be taken to have them exactly central with the spindle.

Fig. 21 is a sketch which shows the construction of a back-center and also gives the principal dimensions of a roller bearing for a 1¾-inch spindle. *A* is a hardened steel bushing, which is driven into the machine steel spindle. The parts *B* are the hardened steel rollers which travel in opposite directions. These rollers have a small amount of friction, and this is distributed over a large area. A spindle revolving at 2,300 revolutions per minute will not cause these rollers to rotate very rapidly, while a ball bearing with balls traveling in a channel 1½ inch or 2 inches in diameter would be traveling at the same speed as the driving spindle. They also wear out rapidly as the end strain is very great, it being necessary to force the center against the metal with considerable pressure to keep it from slipping. *C* is the hardened pin upon which the rolls revolve, and *D* is the hardened spindle on which the various back-centers are screwed. The collar *E* should either be flattened for a wrench, or a 5-16-inch hole, in which a wire can be inserted, should be drilled through the spindle, so that it can be kept from rotating when screwing on the back-centers. Some spinners prefer the spindle loose, so that it can be withdrawn when changing the centers, while others prefer one with considerable lateral

motion, but not enough to permit of withdrawal. By inserting a screw-point in the recess *F*, the center has considerable lateral motion, but not enough to allow it to be withdrawn. This recess is useful in that it helps to distribute the oil. All parts should be hardened and drawn to a light straw color; they should also be ground or lapped to a true fit after hardening.

I started to replace ball bearing centers with this design over five years ago, and now have it on nine spinning lathes. Most of these have been in constant use now for over three years, and it has not been necessary to replace a single part.

Tools Used in Metal Spinning

Fig. 22 shows an attachment which is used to roll any bead or form. This tool, when in use, is inserted in the tail-stock spindle in place of the regular center. It is adjustable for any diameter. The roll illustrated is for making a sharp turn, but rounds and other forms are used. The shell being spun by this tool should be held on a hollow chuck. The roll is set at a point where the metal is to be turned over, and by its use the curve may be governed and made uniform with less skill than when the work is done by "air spinning." In addition, the spinning may be done in less time. This attachment, for some shapes, makes the use of sectional chucks unnecessary.

Fig. 23 shows several spinning tools, the heads of which were turned in the lathe instead of being forged. This method of making spinning tools is, as far as I know, original. The spinners prefer them to the tools which are forged in one piece, because the heads which are screwed to the shanks, are made of the best quality of steel, such as the high speed or

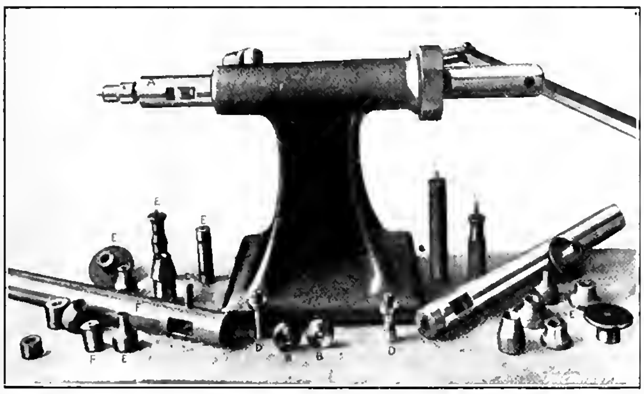

Fig. 20 Detailed View of a Spinning-lathe Tailstock

self-hardening steel. The shapes are also better and the surfaces more true. The heads of these tools are all threaded with standard 1/4-inch, 3/8-inch and 1/2-inch pipe taps, according to the size. Obviously, a spinner can have as many different shaped heads as may be required, and only one handle, of each of the sizes given. The tapering threads in these heads insure that they will always screw on the shanks tightly no matter how often they may be replaced. The 1/4-inch size takes a 1/2-inch cold rolled holder; the 3/8-inch, a 5/8-inch holder, and the 1/2-inch, a 3/4-inch holder. These will be found large enough for the heaviest work. The egg-shaped tool *A* is a good form for roughing or breaking down, as it has plenty of clearance on the heel, and a blunt point that will not tear the metal. This tool is shown in four sizes. The ball or spherical tool *B* is a good one to use on curves and large sweeps. The tool *C* is a double cone, and is slightly different from *A*, as it has a blunter point. One of these heads is shown at *D* screwed onto a reducer by which it is held in the lathe chuck while being turned. These heads or points can also be turned while on the handle by using a steady rest.

A group of trimmers, skimmers and edgers is shown in Fig. 24. Three skimmers of the built-up type are illustrated, the shanks being of machine steel and the blades being riveted to the holders. These blades are made of either high speed or regular steel. Skimmers which are forged in the regular way from one piece of steel, are shown at *B*. A number of edgers *C*, which are made of high-speed or self-hardening steel, are also illustrated. These tools are used without handles until they are worn down short, after which tangs are forged on their ends and they are used in handles. Edgers are utilized on all kinds of work for trimming the ends of the shells. The skimmer is seldom used on metal chucks, but mostly in connection with wooden chucks, where the metal cannot be smoothed down with a planisher. The skimmer is run over the metal lightly, taking a thin shaving and smoothing the uneven surfaces. It requires considerable skill to use this tool without wasting the metal. The surface of the work is finished with emery cloth after skimming.

Figs. 27 and 28 show a number of spinning tools of various shapes. The letters *A* indicate the breaking-down or round-nosed tools of different sizes. This type of tool, which is finished smooth and has a blunt point, is used for forming corners and sharp angles, and it is the tool most commonly

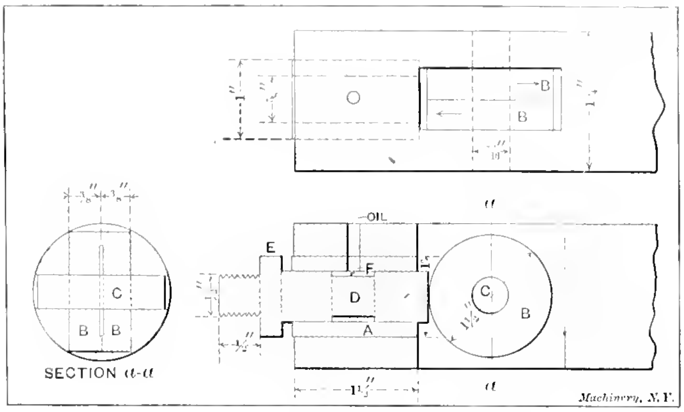

Fig. 21. Sectional View showing the Back-center and its Double Roller Bearing

used by spinners. The planishers and burnishers *B* are used on all convex surfaces and for finishing on metal chucks where there is to be no skimming done. The tools *C* are known as hook or poker tools, and they are used to turn up beads or curves from the inside of the shell. The holders having rollers are used for turning over beads, the metal first being trimmed and turned to a vertical position. The other shapes shown are irregular tools for special work and they are not in daily use.

Two pairs of spinners' pliers for turning over the edge of the metal when making large curves are shown in Fig. 29. The wedge-shaped pieces shown in this illustration are used when breaking down or roughing shells to give a bear-

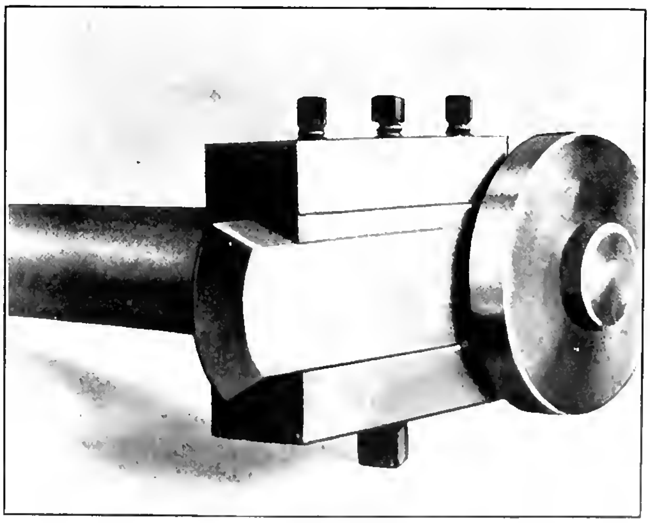

Fig. 22. Attachment used for Rolling Sharp Turns and Beads

ing to the metal in order to prevent it from wrinkling or buckling when changing its formation. These pieces are made of hard wood with the exception of the one to the right, which is of steel. When one of these pieces is in use it is held in the left hand at a point directly opposite the spinning tool, the metal being between the two. Wood is preferable in most cases, as it does not harden the metal blank.

The tools shown in Fig. 25 are used in spinning steel. The round tools are of drawn brass, and they can be used where the steel tools cannot, for while a steel tool is perfection on

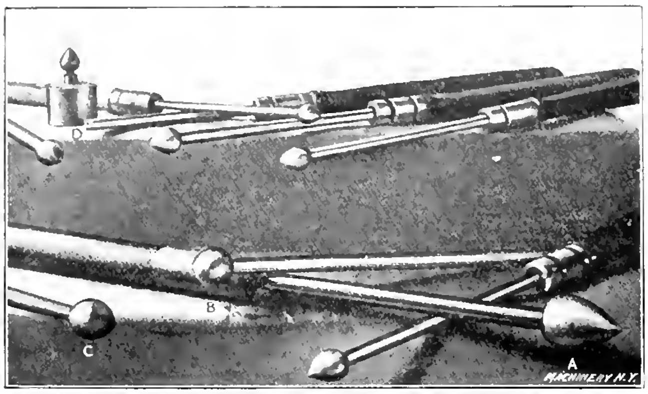

Fig. 23. Metal Spinning Tools with High-speed Steel Removable Heads

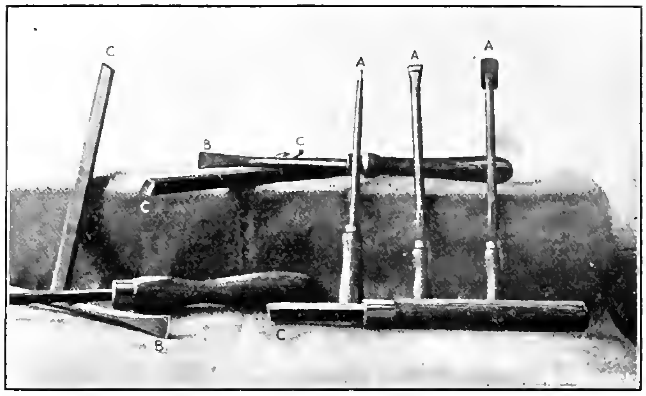

Fig. 24. Tools used for trimming and skimming Spun Work

brass, a brass tool is the only thing on steel. It wears out, however, much more rapidly than one of steel. The rolls shown in the center are used for breaking down steel shells. These tools are hardened and have hardened roller bearings. The handles are made of one-inch iron pipe, which is filled with lead to give weight and strength.

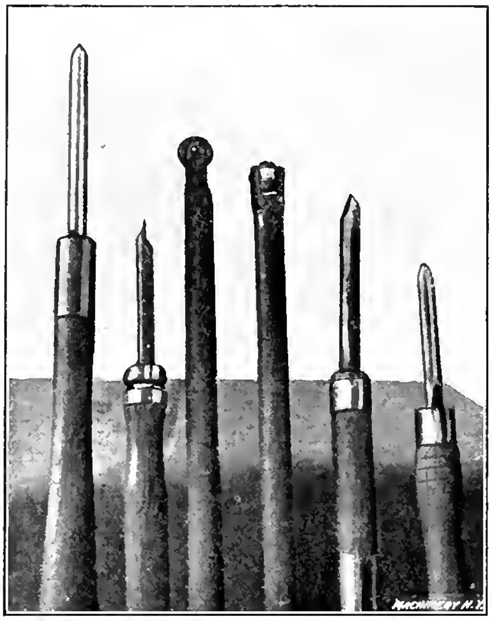

Fig. 25. Some Spinning Tools used in working Steel

Hard wood tools that are used for breaking down large thin copper blanks ranging from 2 to 5 feet in diameter are shown in Fig. 26. These tools are also used where the surface that the tool will cover without hardening the metal is important. Blanks which are broken down with these tools are finished with the regular types.

The handles of spinning tools vary in diameter from $1\frac{1}{4}$ to $1\frac{3}{4}$ inch, and in length from 16 inches to 20 inches. The tools should project from the handles from 9 to 18 inches, and the total length of the tool and handle should average from 30 to 34 inches.

A group of wood-working tools is shown in Fig. 30. These tools are of the type commonly used by spinners for turning the various shapes of wooden spinning chucks. As the tools illustrated are the kind regularly used for wood turning by patternmakers and other wood-workers generally, they will need no description.

Preparation of the Metal

Brass, copper, and German silver should be pickled after annealing in order to get the scale or oxide from the surface. There are furnaces that anneal without scaling by excluding the air when heating, but they are not in general use. A pickling bath may be made by using one part of oil of vitrol (sulphuric acid) and five parts of water. The shells can be put in hot, or the bath can be heated by a coil of lead or copper pipe running through it. Steam in no case should enter the bath, as the iron in the feed pipe will spoil the pickle. Any basket or box that may be used to hold the shells in the pickle should not contain any iron. If a box is used it should be held together with copper nails. The pickle can be used cold, but it will take a little longer time to remove the scale. As soon as the scale is free, which will be in about half an hour, the shells should be removed or washed thoroughly in running water. The shells should

be allowed to dry before the next operation, which is that of spinning. A lead-lined wooden tank or an earthen jar may be used for holding the pickle. The pickle which is used for steel should be about half as strong as that employed for brass. After the work is in this pickle, the latter should be brought to the boiling point, after which the pieces should be taken out and washed. They are then replaced in the fire for a short time to evaporate any acid that may remain after washing.

Finished brass articles may be given different shades by dipping them in a solution consisting of one part aqua fortis (nitric acid) and two parts oil of vitrol. This solution should

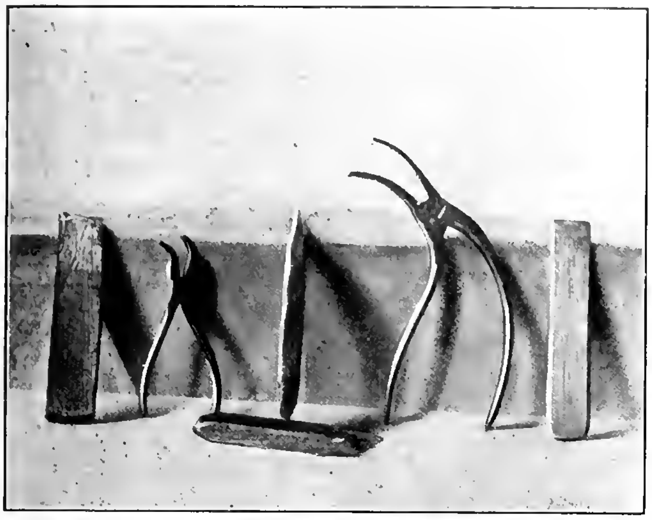

Fig. 29. Spinners' Pliers which are used for turning the Edge of the Metal when making a Large Bend

stand seven or eight hours after mixing to cool, and be kept in a crock immersed in a water bath.

* * *

"A New Departure in Photography," by Robert W. Wood in the February *Century*, describes some interesting experiments conducted by the author. He conceived the idea, or at least applied it, of photographing common objects with the ultra-violet and infra-red rays which are invisible to the human eye, lying beyond the visible violet and red section respectively of the spectrum. The results of his investigations may be valuable, as they indicate a means of analysis of non-luminous bodies shining by reflected light. A new conception of light and vision is given. "Painting a thing as it is" takes

Fig. 30. Wood-turning Tools which are used in turning Spinning Chucks

on a new meaning. Chinese white, for example, which is the whitest pigment known, when photographed with the ultra-violet rays only, reproduces jet black in the photograph. The light rays, of course, are passed through a ray filter which shuts off all but the rays desired. Zinc oxide, deposited on a snow-covered hill, for example, would be quite indistinguishable to the eye as compared with the snow, but its presence would be clearly shown with a camera fitted with a ray filter shutting off all but the ultra-violet light. In the same way deposits of sulphur on the moon, or what are believed to be sulphur, are shown clearly on photographs made through a telescope which is fitted with a filter that passes only ultra-violet rays.

THE CHOICE OF A FACTOR OF SAFETY FOR HIGH-CLASS MOTOR SPRINGS*

By F. E. WHITTLESEY†

In designing motors for automobiles, aeroplanes, etc., it is of the utmost importance to choose the proper factor of safety for every part. If this is true of the parts which are not deflected appreciably by the strains to which they are subjected, how much more important is it in the case of the springs, many of which deflect hundreds of times every minute. The risk of injury and loss of life which may be caused by a broken engine or clutch spring is so great, especially in an aeroplane, that none but the most carefully designed and manufactured springs should be used.

It is an easy matter to determine the fiber stress that a spring will stand without taking permanent set. This can be determined by testing the material in a torsional testing machine or more easily during manufacture of the springs by direct testing of the deflection for a given weight. The ultimate torsional fiber stress for wire springs is usually taken at about 150,000 pounds per square inch for the smaller sizes of music wire, down to 80,000 pounds per square inch for ½-inch wire. It is much more difficult to determine the proper factor of safety for a spring in order to give reliable service. This is a matter of the greatest importance and calls for the exercise of good judgment by the designer, who should also know the conditions under which the spring will operate.

The conditions entering into the matter are: 1. The physical conditions under which the springs operate. 2. The number of compressions per minute.

The Physical Conditions

The spring should have its ends squared and ground at right angles to its axis; the outside diameter should be at least one-third of the length, and it should be supported its entire length unless it is very short, these conditions being necessary to prevent buckling, which introduces bending and twisting strains. High-class valve springs when placed on end on a flat plate should not vary more than ½ degree from the perpendicular to the plate. Of course, this accuracy is expensive, but it pays when reliability, not cheapness, is desired. The spring should be protected from rusting by a good coat of Japan, baked on, or by electro-galvanizing, and should not be subjected to heat from the motor sufficient to affect the temper.

The Rate of Compression

A spring which acts only occasionally can be safely designed to carry a load which will cause a fiber stress nearly up to the elastic limit of the spring, but when compressions or extensions are at all frequent, a much larger factor of safety must be used. A valve spring operating, say, 200 times per minute should have a factor of safety of at least 4. In other words, a spring made of ¼-inch wire, having an ultimate torsional fiber stress of 100,000 pounds per square inch should be designed to work at a stress of not over 25,000 pounds per square inch. If the material is free from flaws, such a spring should give good results in practice.

The builder of high-class motors will be well repaid for giving careful attention to the design of their springs, instead of following the practice formerly more prevalent than now, of first designing all other parts of the machine and then accommodating the springs to the space that happened to remain for them.

PRIZE FOR INVENTION OF REVERSING MECHANISM FOR COMBUSTION ENGINES

A prize of 5,000 marks ($1,250) has been offered by a German association for the advancement of the industries for the best design and description of a direct reversing mechanism for combustion engines, the mechanism being especially adapted for the use on combustion engines on board ship. Detailed information on the subject and the conditions of the competition may be obtained from *Der Verein zur Beförderung des Gewerbfleisses*, Charlottenburg, Berliner Strasse 171.

THE CALCULATION OF CRANKSHAFTS FOR INTERNAL COMBUSTION ENGINES*

By D. O. BARRETT†

The crankshaft may rightly be termed the "backbone of the engine," and the designer should use his best judgment and skill in designing this most important member. In the following, the formulas are given for crankshafts for determining the diameter, and the breadth and thickness of cheeks, of single-acting, single-cylinder, four cycle engines of medium speed with over-hanging flywheels and two bearings, of the ordinary type up to 75 horsepower. The formulas have been actually applied to engines up to 60 horsepower, and as far as known, no crankshaft has ever failed. The data on which the formulas are based have been obtained from a complete line of engines built by one of the largest manufacturers, and from a few sizes from some other concerns.

Diameter of Crankshaft

The strength of a shaft as regards twisting, is proportional to the cube of the diameter, while the torque exerted upon the shaft by the force of the explosion is proportional to the square of the bore of the cylinder and to the throw of the crank, which is half the stroke. Expressing this as a formula we may write:

$$\frac{B^2 \cdot \frac{1}{2} S}{D^3} = c \qquad (1)$$

in which B = bore of cylinder in inches,
S = stroke of piston in inches,
D = diameter of crankshaft in inches,
c = constant determined by good practice.

The usual value of constant c for existing successful engines varies between 10 and 19, the average value being about 15, which, in the following formulas is assumed as good average practice.

The stroke S may be expressed as a function of the bore B. Assume, for example,

$$S = a\,B$$

Substituting in Equation (1) we have:

$$\frac{B^2 \times \frac{1}{2}\, a\, B}{D^3} = 15$$

Solving for D we have:

$$D = \sqrt[3]{\frac{a}{30}} \times B \qquad (2)$$

The average engine has a stroke of about $1\frac{1}{2}$ times the bore, but this factor varies from $1\frac{1}{4}$ to 2. For $a = 1\frac{1}{4}$, $D = 0.347\,B$, and for $a = 2$, $D = 0.405\,B$.

Fig. 1 is a diagram for determining diameters of crankshafts for gas engines, according to the formula given. To use the diagram, find the intersection of the bore-and stroke-lines at the right-hand side, and determine the corresponding value of a on the diagonal lines. Then follow the horizontal line from the intersection to the left-hand side of the chart to the same value of a on the diagonal lines, and then follow the vertical line down to the proper diameter of shaft. The heavy dotted line in the diagram shows the procedure for a 12-inch bore, 18-inch stroke engine, the diameter of crankshaft obtained being $4\frac{3}{8}$ inches.

Sizes of Bearings

For best results the mean pressure on the crank-pin should not exceed 400 pounds per square inch of projected area. In the following, 390 pounds per square inch has been assumed. The total pressure on the crank-pin bearing is the area of the piston multiplied by the mean effective pressure (M. E. P.).

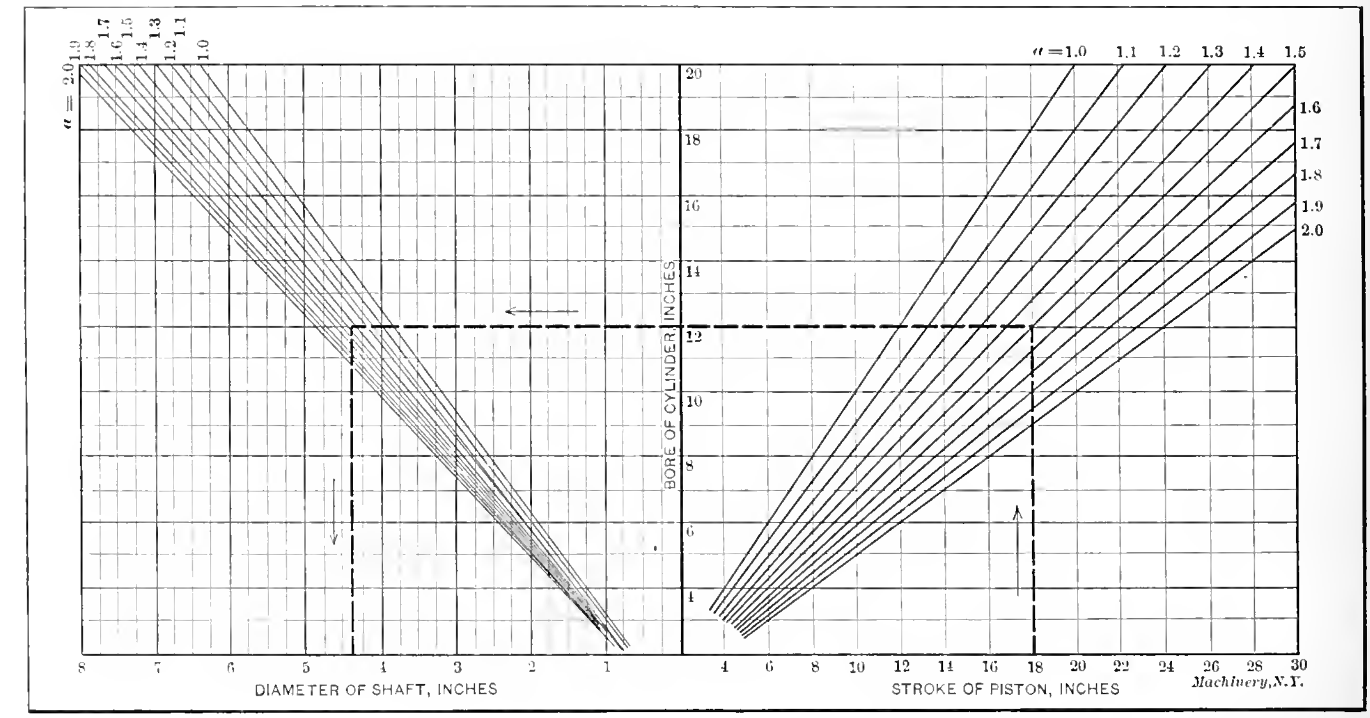

Fig. 1. Diagram for obtaining the Diameters of Crankshafts for Gas Engines

Hence, if P_1 = unit pressure on pin (390 pounds per square inch of projected area),
B = bore of cylinder,
l = length of crank-pin bearing,
d = diameter of crank-pin bearing,

then:

$$P_1 = \frac{0.7854\,B^2 \times \text{M.E.P.}}{l\,d}$$

and if the mean effective pressure is assumed as 75 pounds per square inch, then,

$$l\,d = \frac{0.7854\,B^2 \times 75}{390} = 0.151\,B^2$$

As in these bearings, length and diameter are usually equal ($l = d$), we have:

$$d^2 = 0.151\,B^2, \text{ or } d = 0.39\,B \qquad (3)$$

When this formula gives d smaller than D, the value of d should be increased, because in practice the diameter of the crank-pin is never made smaller than that of the shaft. They are usually made of the same size, and it is even better practice to make the crank-pin at least $1\frac{1}{4}$ times the diameter of the shaft.

The diameter of the shaft in the main bearings is usually about 1.1 times the diameter of the shaft, or

* For previous articles on gas engine design see: "Formulas and Constants for Gas Engine Practice," by Sanford A. Moss, February, 1906; "Current Practice in Petrol Engine Design," by G. W. Rice, October, 1906; "Formulas for Gas Engine Flywheels," by R. E. Mathot, August, 1907; "Formulas for Gas Engine Crankshafts," January, 1908; "The Design of Springs for Gas Engine Valves," by F. E. Whittlesey, May, 1908.

† Address: 87 Lincoln Ave., Freeport, Ill.

$$d_1 = 1.1\, D \qquad (4)$$

Making the shaft in this manner slightly increases the cost, but this style is used in the best designs.

The length of the main bearings varies from 1.75 to 2 times the diameter of the shaft, or

$$l_1 = (1.75 \text{ to } 2) \times D. \qquad (5)$$

Dimensions of Cheeks

Having now obtained the various diameters of the shaft and the lengths of the bearings, we will determine the formulas for the cheeks. The crank cheeks in horizontal and in the larger vertical engines are machined and rectangular in section. They act as a beam supported at one end. The strength of such a beam is directly proportional to its breadth b and to the square of its thickness t, and inversely proportional to the length (which, in turn, is proportional to the stroke S). The load acting at the end of the beam is proportional to the square of the bore B. Hence,

$$\frac{b\, t^2}{B^2 S} = c.$$

The average value of the constant c is 0.045, which has been found by plotting the constant for existing engines and assuming an average value. The thickness t is usually made about 2.2 b, and as $S = a\, B$, as mentioned before, we have:

$$\frac{t^3}{2.2\, a\, B} = 0.045, \text{ or } t = \sqrt[3]{0.099\, a} \times B \qquad (6)$$

All dimensions have now been reduced to some term containing B, so that, having decided upon the bore and stroke of the proposed engine, it is an easy matter to proportion the crankshaft.

In Fig. 2 is shown a diagram for determining the breadth and thickness of the cheeks for crankshafts for gas engines. To use the diagram, find the intersection of the bore- and stroke-lines at the right, and determine the corresponding value of a on the diagonal lines. Then follow the horizontal line from the intersection to the left-hand part of the diagram, to the same diagonal line a. Then follow the vertical line down to the bottom of the diagram where the breadth and thickness of cheek are given. The heavy dotted line in the diagram shows the procedure for a 12-inch bore, 18-inch stroke engine. The breadth and thickness found are 2 7/8 inches and 6 3/8 inches, respectively.

The ends of the cheeks are made concentric with the pin or shaft opposite, that is, the pin end of the cheek is turned when revolving about the shaft center and *vice versa*. The length of the crankshaft depends upon whether the driving pulley is to be bolted to the arms of the flywheel or keyed to the shaft. The latter method is preferable although slightly more expensive. The shaft, however, should only be long enough to engage the pulley hub, thus keeping the driving pulley close to the flywheel. A longer shaft gives an inexperienced operator an opportunity to set the pulley out far enough to seriously strain the unsupported end of the shaft.

* * *

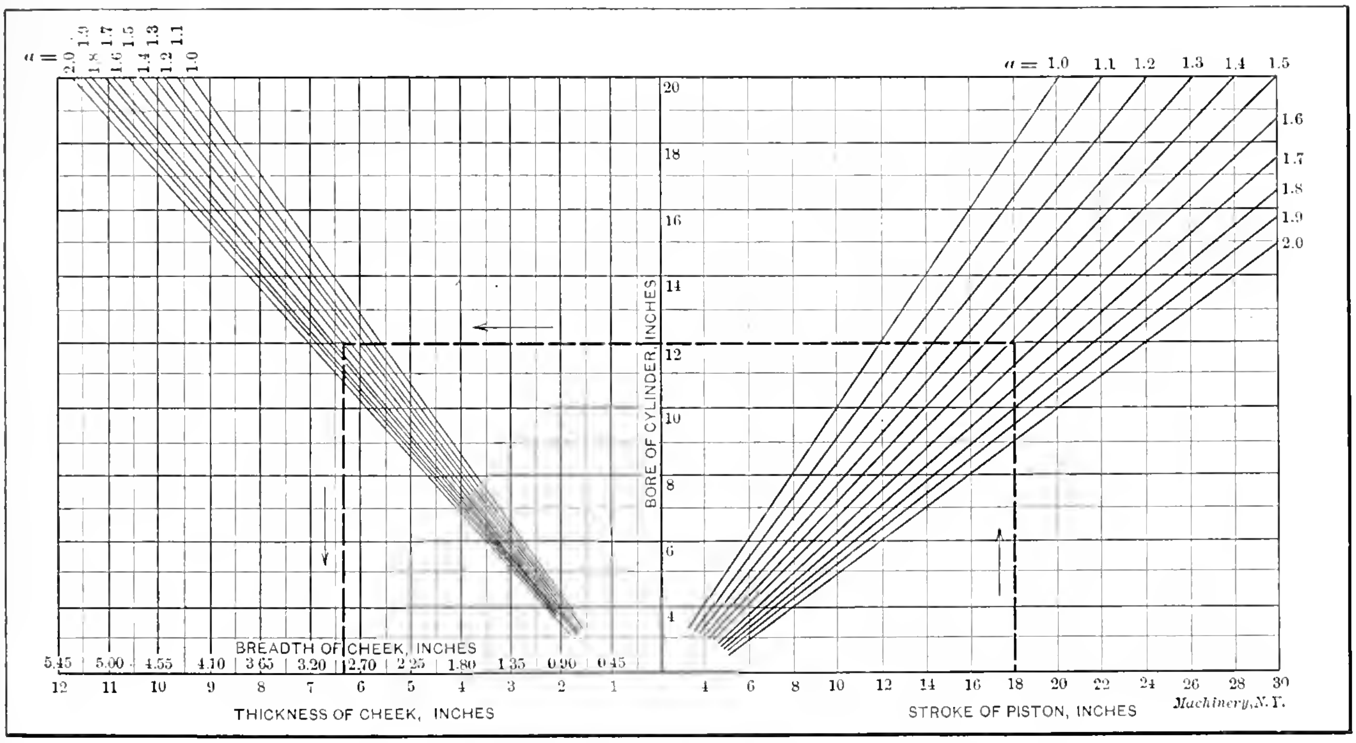

Fig. 2. Diagram for the Cheek Dimensions of Gas Engine Crankshafts

MAKING LEAKY GAS ENGINE PISTONS TIGHT

By GEORGE CORMACK, JR.*

There is no doubt that one of the most difficult tasks that the gas engine repair man encounters is a worn and leaky piston and cylinder. If the engine has been used for any length of time the putting in of new rings on the piston will not greatly improve matters, and many times will only make the leak at compression and explosion pressure worse. There is only one real way of overcoming this difficulty, and that is to rebore the cylinder and fit a new piston and rings. The following, however, is an easily applied makeshift which often proves satisfactory when the engine is an old one and the other parts are in a condition which would hardly justify the expense of reboring the cylinder and fitting a new piston. Gas engine pistons usually leak because the rings become too narrow for the grooves in the piston, allowing the gases to escape by getting under and around the rings.

The method is, briefly, as follows: Take out the piston and take off the rings. Clean the piston rings and grooves thoroughly. Get a piece of soft asbestos rope and before putting the rings back into place, wind some of the rope in the bottom of the ring grooves in the piston. Then soak the asbestos thoroughly with gas engine cylinder oil, and put the ring back in the grooves. Put in enough of the asbestos rope so that the rings will have to squeeze it down fairly tight when the piston is pushed into the cylinder. This method may not be considered as a very mechanical job, but an old leaky piston when so treated will, after running a few minutes, be very tight, and may run for months before the operation needs to be repeated.

* * *

What is said to be the largest belt in the world has recently been completed by a prominent belt-making firm. It is 210 feet long by 6 feet wide; 540 hides were used in its construction and the cost of it is stated to be $5,800.

* Address: Rockford, Ill.

LIGHT, VENTILATION AND DRAINAGE IN ONE-STORY SHOP DESIGN

We present herewith drawings showing the general construction of two types of one-story shop buildings, both particularly designed for climatic conditions as met with in the North, and both eminently successful in actual use. The controlling features in the design in each case were the obtaining of proper light, ventilation and drainage, together, of course, with adaptability to manufacturing purposes.

The shop illustrated in Fig. 1 may be said to have been designed along ideal lines. While it was not by any means built in a mood of reckless expenditure, it was the intention of the owners to spare no reasonable profit-returning expense in its construction. The details of the resulting design are shown in Fig. 2, where it will be seen to be of the single-story, saw-tooth construction. The building is intended primarily for erecting, and medium heavy machining operations. It is provided with aisles down the sides for the passage of stock, machine parts and finished work. The cross bays are provided with crane runways as shown in Fig. 2, which shows at the left a cross section of one of these bays.

In the matter of light, the advantages of the saw-toothed construction are well recognized. After deciding that this type would be employed, the designer in charge visited a number of similar shops for the sake of obtaining points as to the relative merits of various details of design. One difficulty met with, in some otherwise very satisfactory roofs, was that of an unexpected flood of heat reflected down upon the workman from under the side of the long slope of the saw tooth. This heat comes, by radiation, from the top of the following slope, in an upward direction through the windows, and then down again into the shop. In some places this reflected heat was so objectionable that the workmen formed the habit of standing behind posts or other shelter to get away from it. No difficulty on this score has been met with in the design here illustrated, owing, perhaps, to the particular roof proportions adopted.

Another difficulty which was investigated is that of excluding the direct rays of the sun during the long days of the year, when it rises and sets considerably to the north of the due east and west direction. It was at first attempted to settle, by calculation, on the proper angles for excluding these rays, and several expert investigators tried their hand at the problem. The results were unsatisfactory, however, so the roof angle of 27 degrees was arbitrarily selected. If the sun's rays became troublesome in the morning or evening, it was planned to put up vertical steel curtains at the sides of the windows, which would exclude this direct light, though leaving a free passage for the desired lighting from the north. This screen arrangement has been found unnecessary. It may be mentioned in connection with the roof proportions here given, that the latitude is about 43 degrees.

In the matter of ventilation the saw-toothed roof has often been found unsatisfactory, from having been built in too great a width. The attempt is made, especially in textile work, to cover enormous areas and still insure proper air circulation by the provision of ventilators in the roof. While these help, and should be provided, the constant flow and change of air necessary to preserve the comfort (and consequent productivity) of the workman, can only be obtained in summer by the natural sweep of the outside air through the building, or by the more expensive alternative of forced ventilation. This sweep of outside air is not effective in buildings of this kind of more than 100 feet width; consequently that is the dimension adopted for this particular structure. Additions to the area can be made by lengthening the building, or by erecting other units of the same width. The building is, of course, plentifully provided with side windows, which are opened in the summer to permit the desired sweep of air. Many of the textile mills have been made with blank walls.

Roof drainage is an important point to be considered in high latitudes. Travelers in northern New England have, doubtless, noticed the distinctive appearance given to the towns by the steep pitch of the house roofs. This steep pitch is necessary to make the roofs clean themselves of snow; otherwise the tendency is for the snow to melt at the warm ridge and run down to the cold eaves where it freezes, clog-

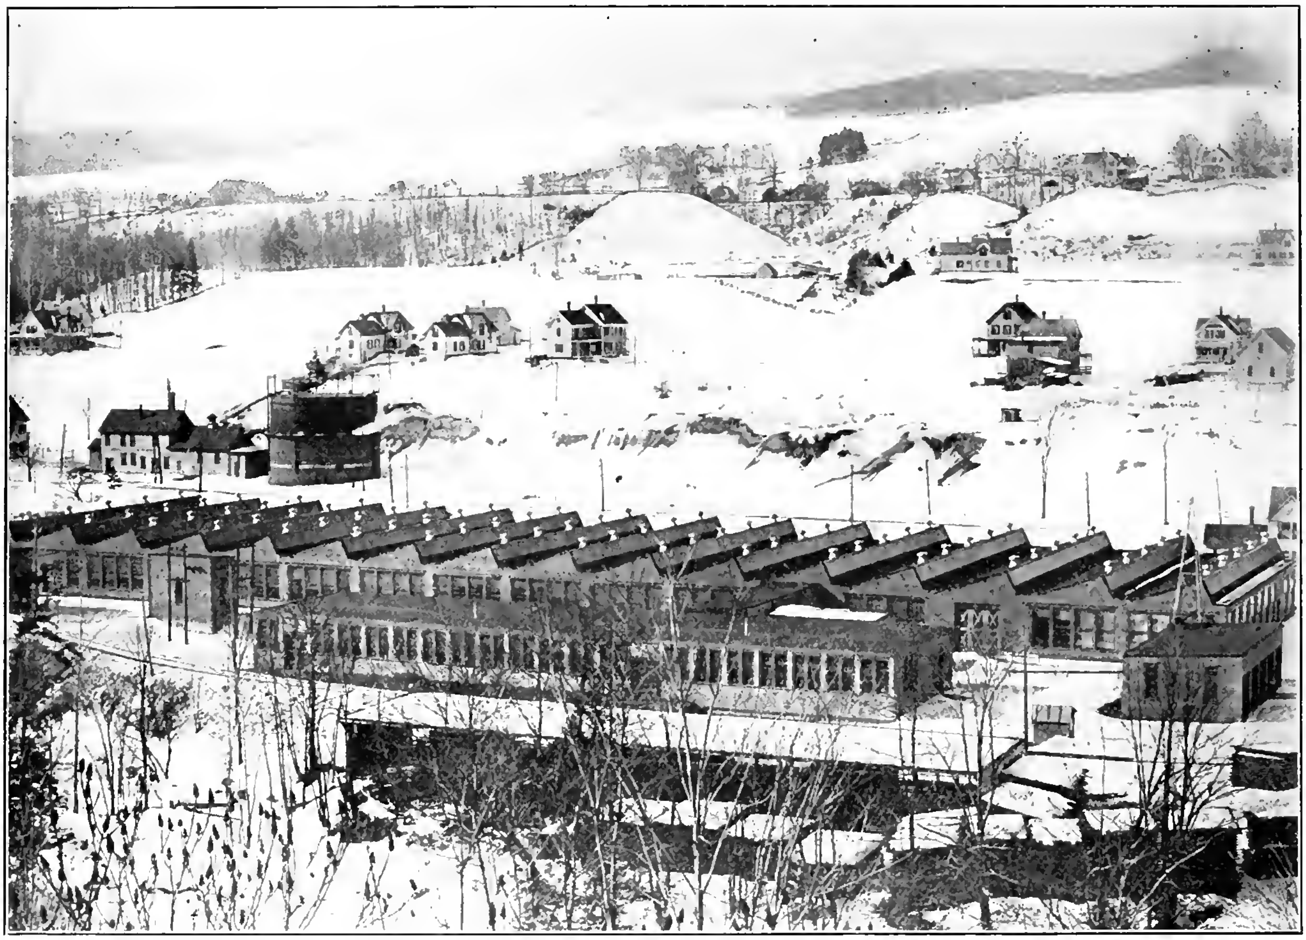

Fig. 1. A Successful One-story, Saw-tooth, Shop Design, for Northern Latitudes

ging up the drain pipes, and forming a dam of solid ice, which causes the water to work back in under the shingles. If the roof is self-cleaning, these troubles are avoided.

No attempt is made of course to build the roofs of manufacturing plants on the self-cleaning principle, nowadays. What should be done is to locate the drainage pipe at the warmest point in the whole area, so that when any melting is going on, it will be at this point, leaving a free, unobstructed flow for the water. The saw-toothed roof lends itself readily to drainage in this way. Each valley is provided with three drain pipes, one in the center and the other two, twenty

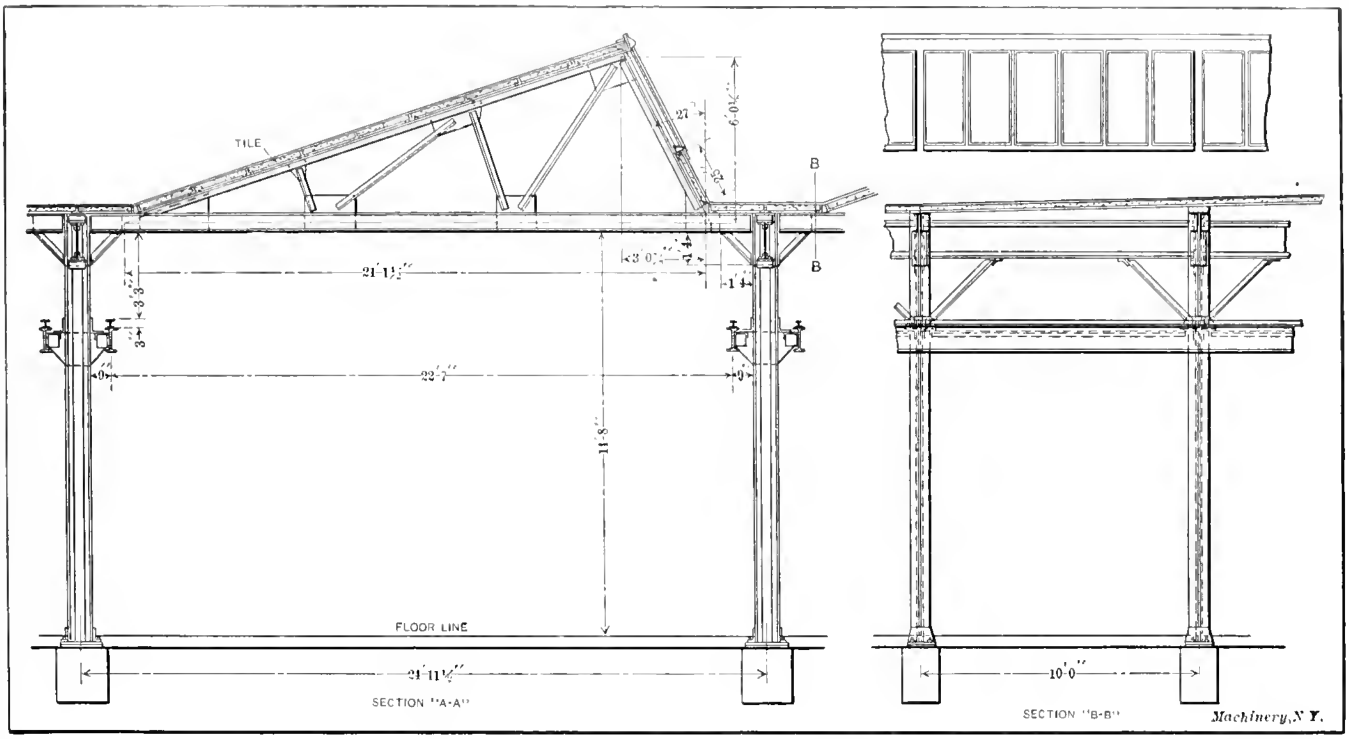

Fig. 2. Structural Details of the Building shown in Fig. 1

feet from either wall of the building. These pipes pass down alongside the rows of posts in the shop. If any freezing is done, it will be at the ends of the valleys next to the outside walls, and as the water is not expected to drain from there in any case, there is no danger of forming ice which will dam up the melting snow.

It will be seen that the valleys have a flat door, which permits free passage for workmen in repairing the roof, reglazing the windows, etc. The roof is covered with book tiling, supported by small T's as shown, and cemented. The whole is then covered with roofing. It was expected that it would be possible to drive roofing nails into the tiling, but when the latter was delivered this was found to be impossible, so the roofing is held on by laying it on heated asphaltum. This has been found successful and no creeping has been noticed.

As shown in Fig. 2, the bottom of the window sashes is 25 inches above the floor of the valley. This gives an ample reservoir capacity for snow and ice. The roofing is carried in an unbroken sheet down the side slope, over the valley and up under the window casing. At the ends of the valleys the roofing is lapped over the wall, which has the exact form of the saw tooth, instead of being a trifle higher as it is sometimes made. This construction avoids the extensive use of flashing, and gives a watertight construction at a minimum of expense. There are no trap doors in the roof. Everything is sealed up snug and warm, excepting that a large number of ventilators is provided, as shown in Fig. 1. This building belongs to the plant of the Jones & Lamson Machine Co., of Springfield, Vt.

The building shown in Fig. 3 is of a less expensive construction, but of a design which secures a maximum of serviceability for each dollar expended in its construction. It is one story high, of slow-burning construction, with a roof of the hopper type. The slow-burning construction is entirely practicable for a one-story building, though for two or more stories the advisability of using even very heavy wooden framing might be questioned. The advantages of the building from the standpoint of light, ventilation and drainage will be readily understood.

In regard to the light, it should be noted that the building is comparatively narrow (40 feet wide) with windows reaching to the ceiling. The useful light for machine shop operations, coming from the sides of the building, is that which

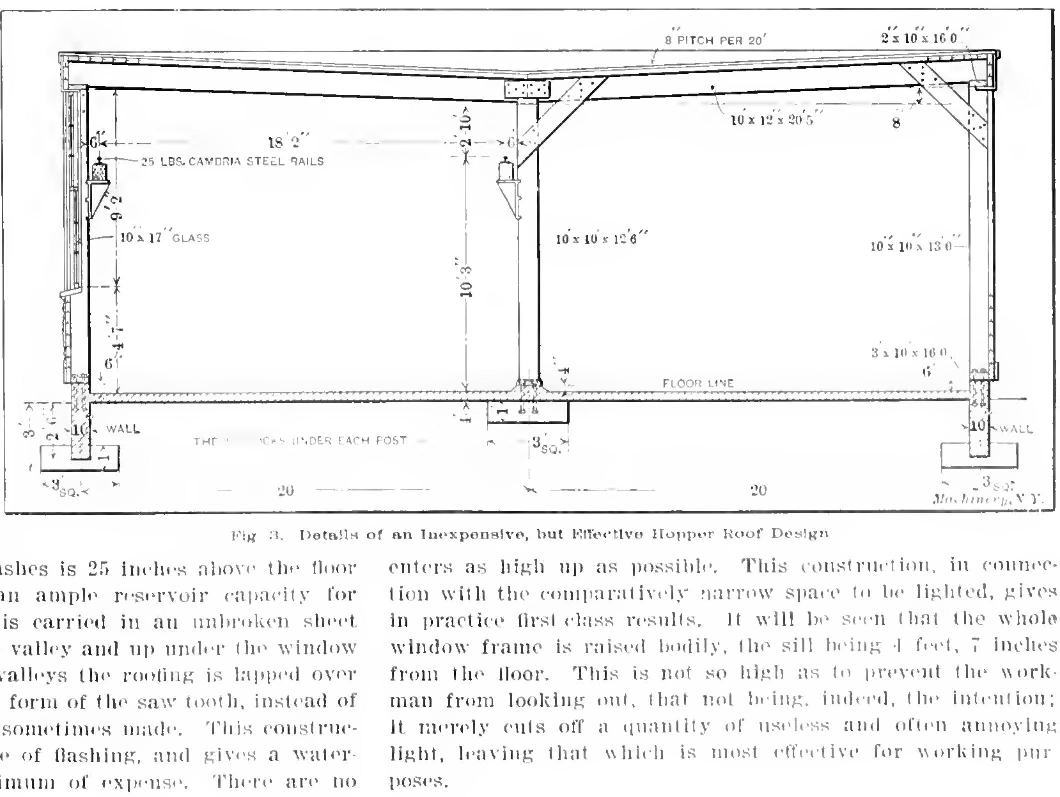

Fig. 3. Details of an Inexpensive, but Effective Hopper Roof Design

enters as high up as possible. This construction, in connection with the comparatively narrow space to be lighted, gives in practice first class results. It will be seen that the whole window frame is raised bodily, the sill being 4 feet, 7 inches from the floor. This is not so high as to prevent the workman from looking out, that not being, indeed, the intention; it merely cuts off a quantity of useless and often annoying light, leaving that which is most effective for working purposes.

This building is narrower than that shown in Figs. 1 and 2, and consequently easily ventilated and cooled in summer. The shipping doors at that time are also thrown open on each side, this serving to keep in motion the body of air near the floor of the shop. With this design, in the part of the building devoted to the offices the windows are brought down to the normal level. The shop windows only are located high in the wall.

The hopper roof, drained from the center, meets the requirements for northern climates as already described. As fast as the snow melts, the water runs off without requiring the thawing of drain pipes or the clearing of the gutters of ice. The roof, in fact, takes care of itself entirely. Owing to the manner in which the roofing is applied, no flashing is required over the windows, and projecting eaves are avoided as unnecessary. The roofing is carried over the edge of the building and laps onto the outside of the woodwork. This, in turn, laps over the outside of the window casings, effectually sealing the building from the entrance of water at these points.

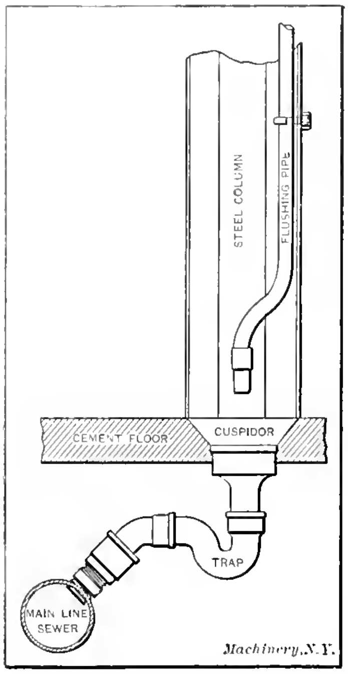

Fig. 4. An Automatic and Efficient Substitute for the Saw-dust Box

Another building of identical construction with this last is shown in front of the saw-toothed roof in Fig. 1. This smaller building is used for painting, snagging, carpenter work, etc. Enlargement in this case, as in the previous one, would be done by lengthening the old building, or by erecting other units of the same width, rather than by adding to the width of the original.

While we are on the subject of drainage, it will not be inappropriate, perhaps, to call attention to an interesting provision in the design of the Jones & Lamson shop shown in Fig. 1. This provision, shown in detail in Fig. 4, may be called an "automatic cuspidor." It consists simply of a series of drains in the concrete floor, placed at every other column across the width of the shop. These are connected, through traps, with sewer pipes embedded in the soil beneath the building, and are flushed at regular intervals of eight or ten minutes with a stream of water, controlled by the regular apparatus for such work.

A more sanitary arrangement could not easily be conceived of. It is certainly an attractive improvement over the practice of indiscriminate expectoration on the floors, machines and work; and even over the more advanced practice of providing individual boxes filled with saw-dust, cleaned and refilled at more or less regular intervals by the individual workman, or by some one especially appointed to the position.

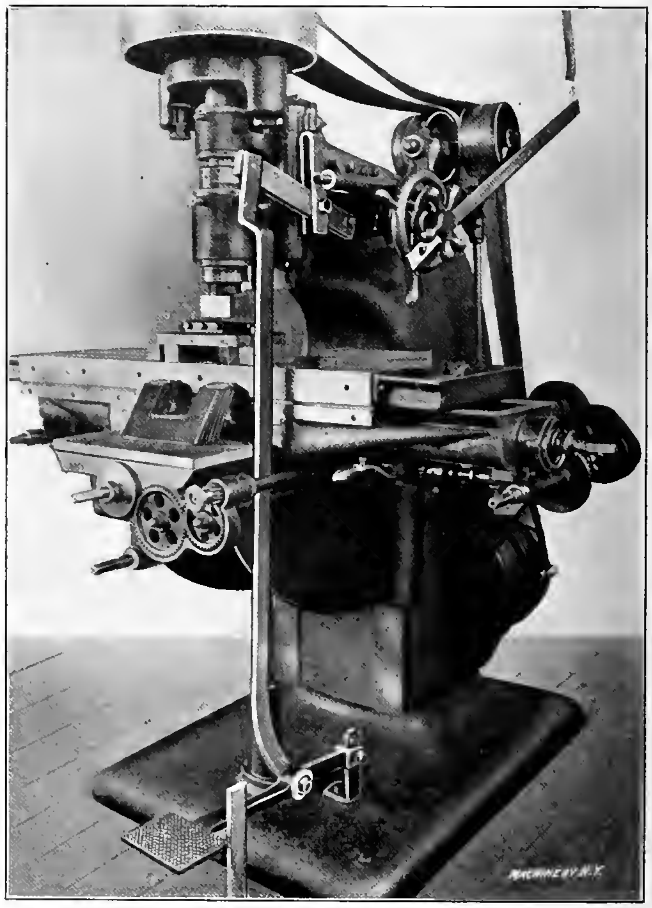
* * *

Fly-wheel repairs in a mountain town in North Carolina were recently made in an unusual manner by the Goldschmidt-Thermit Co., as related by the *Engineering News*. The fly-wheel was twenty-four feet in diameter, cast in two segments, each weighing ten tons. During transportation the rim was broken clear across, and two breaks took place in the spoke between the rim and the hub. Difficulties were experienced in supporting the wheel parts while making repairs, but finally this was successfully accomplished, and each weld in the spoke was made with a mixture of 250 pounds of thermit, 62 pounds of punchings, 5 pounds of ferro silicon and 2½ pounds of pure manganese. The rim was afterwards welded by using 500 pounds of thermit, 125 pounds of punchings, 10 pounds ferro silicon and 5 pounds of pure manganese.

A VERTICAL MILLER USED FOR A PUNCH PRESS ON EMERGENCY WORK

The Colburn Machine Tool Co., of Franklin, Pa., has built for some time past a line of welding machinery for the Toledo Electrical Welding Co. Included in the construction of an electrical welder is a transformer, whose coils are wound on cores built up of thin iron laminations. In making these laminated cores, this firm suddenly found itself in need of a punch press, when there was none available in the establishment. In this emergency, a few hours' tinkering on the part of the superintendent, Mr. Weller, produced the arrangement shown in the accompanying engraving, which worked well and gave first class satisfaction.

The die is mounted on parallels on the table of the vertical milling machine, as shown; this leaves a space underneath for the scrap to drop through, whence it is easily removed. The punch is mounted in a holder having a taper shank, fitting the regular taper of the spindle which is blocked from turning by suitable means. For working the spindle head and the spindle up and down for the operation of the punch, a foot-power movement was given by the connections as shown.



Converting a Miller into a Punch Press, with the Aid of a Few Pieces of Strap Iron

The treadle at the base was once used for another line of machinery. To it was bolted a long link, as shown, bent up out of scrap iron, and connecting with a lever pivoted to the upper overhanging frame of the machine. This, by means of the short double link shown, operates the vertical spindle slide, which could thus be brought down by foot pressure. For returning it, a long arm of strap iron is used, bolted to the quick-adjusting handwheel of the spindle slide as shown. The outer end of this lever is attached to a spring hung from the ceiling. When the treadle is pressed, the spindle is forced down against the pressure of this spring, returning again when released. The action of the foot-power connection is free enough so that the workman has no difficulty in keeping it going the greater part of the day on thin machine steel.

While an arrangement of this kind must be considered in the light of a temporary rigging, yet the ability in a few hours to rig up such a device is a valuable one, and one that will be very necessary in machine shop work so long as emergencies arise.

NEW ROTARY GAS ENGINE FOR AERIAL NAVIGATION*

By CHESTER L. LUCAS† and JOHN J. ROSS‡

The gas engine has long since passed the experimental stage, and its usefulness as a prime mover for automobiles and marine craft, as well as its superiority in generating power for the many industries into which it has been introduced, has been proven by actual practice. The principal reasons why the gas engine has forged to the front are: 1. The economy of its fuel and maintenance. 2. Low first cost and cost of installing. 3. Light weight and small space required. 4. It may be operated by comparatively unskilled labor.

On account of its light weight the gas engine has been adopted, almost without an exception, for use in aeroplane work. Generally speaking, there are but three forms of power that could be considered: steam, electricity and gas. As the excessive weight of fuel and water for steam, and the weight of the storage battery for electricity, are prohibitive, gas power has been adopted. The ideal towards which the aeroplane experimenters have been striving is an engine or motor that will be light, powerful, positive in its ignition, and reasonably simple in its mechanism so as to require little adjustment or attention from the aviator.

The L. A. W. Rotary Internal Combustion Gas Motor

To meet these requirements has been the aim of the designers of the new L. A. W. rotary internal combustion motor, recently exhibited at the First National Exhibit of Aerial Craft, Boston, Mass. This motor, which is of the six-cylinder, two-cycle type, is the result of seven and a half years' experimenting on the part of the inventors, Oliver A. Light, James O. Light, Edward Keeler (who was recently killed in an automobile race), and Victor W. Page. The latter has been associated with Messrs. Light for the last two years and he is largely responsible for the Page-Light aeroplane in which the new motor is to be used.

The Page-Light Bi-plane

The Page-Light aeroplane is of bi-plane type; its general design is shown in Fig. 1. The frame is light yet very strong, being composed of ash and aluminum. Steel wire is employed for bracing. The four wings are each 10 feet in length and $6\frac{1}{2}$ feet wide and are designed so that they may be detached for convenience in transportation. The motor, as shown in Fig. 4 is mounted on trunnions so that it may be tilted to any desired angle in the horizontal plane, thus helping the rudders to elevate or lower the aeroplane. The propeller, made of laminated ash and mahogany, is 6 feet 6 inches in diameter and located at the extreme front of the machine. The overall length is 22 feet and the width is 27 feet. The weight of the machine including the aviator is about 750 pounds, and it has a supporting surface of 300 square feet. It is the intention of the designers to materially reduce this weight in future machines.

The Motor and Its Parts

The first impression one gets of the L. A. W. 30 H.P. gas motor is the novel form; it resembles a flat disk, 22 inches in diameter and 7 inches thick, and weighs 150 pounds. Upon disassembling the motor it is found to be composed of but four principal members: the cylinder casting, the pistons, the outer case and the supply chamber.

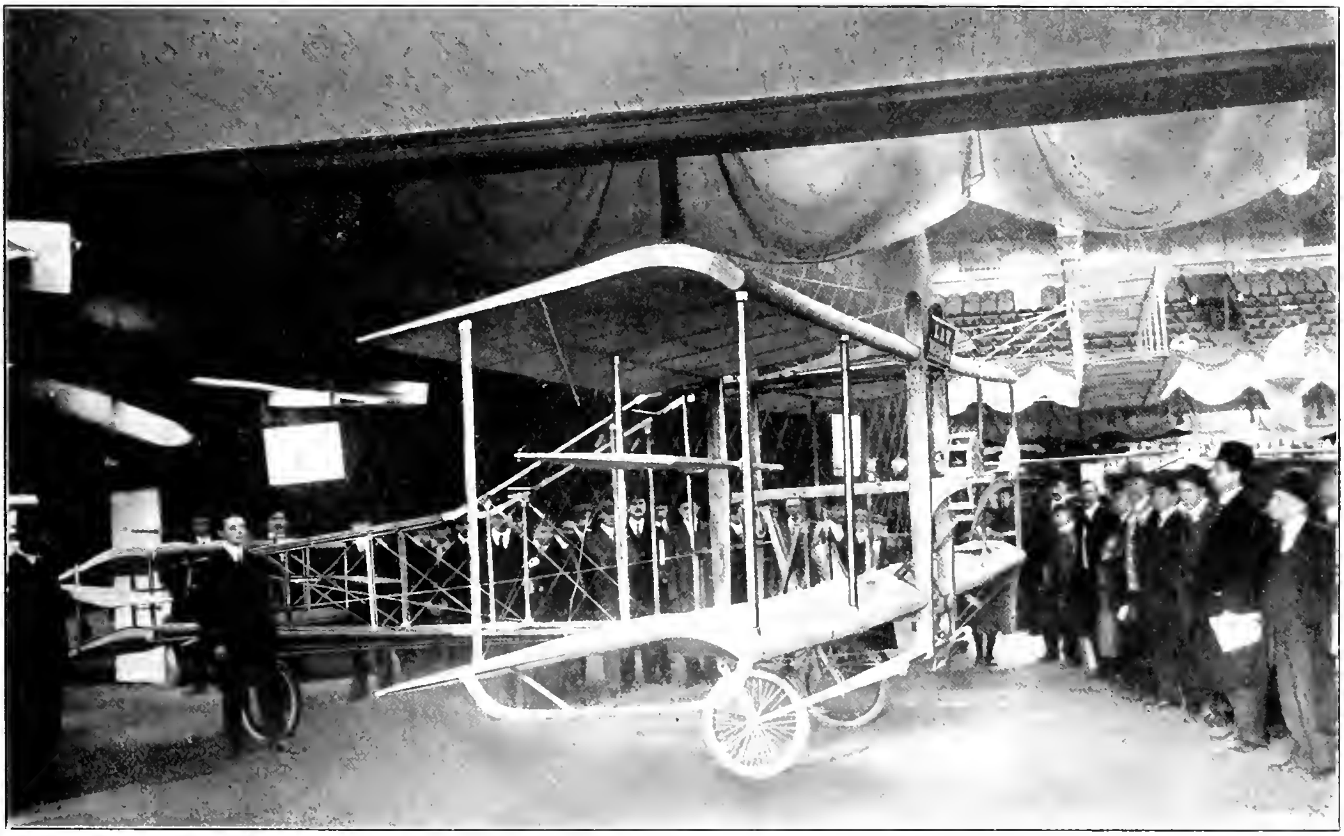


Fig. 1. The Page-Light Aeroplane, which uses the L. A. W. Gas Motor

The cylinder casting, which forms the larger part of the motor, weighs approximately 90 pounds, and has the six cylinders cast integral. These cylinders as shown in Fig. 3 are spaced equidistant around the casting, 60 degrees apart. The cylinders are not located radially, but are thrown off center. At their outer ends they are connected by a band of metal, a part of the casting itself. This band strengthens the cylinders and stiffens the casting in general and on it are located the fan blades for cooling the motor while in operation. The center of the casting is bored to receive the supply chamber and is mounted in the outer case, one and one-quarter inch off center. This casting is of gray iron and over all it measures $17\frac{1}{4}$ inches diameter and 13 inches thick.

The Cylinders and Pistons

The cylinders proper are covered with cooling spines [illegible] inch long of which there are 75 to each cylinder. The cylinders are bored $2\frac{1}{2}$ inches in diameter and have $2\frac{1}{2}$ inches of piston travel. For about half their length the cylinder walls are slotted to receive the guide-shoes that reciprocate in them. At the heads of the cylinders are the inlet ports E, and midway of the length of the cylinders are the exhaust ports J, of which there are eight to each cylinder, four on each side. The pistons P are of gray iron, turned and ground to size

* See MACHINERY, July, 1908; "Adams-Farwell Aeronautic Gasoline Motor."

† Address: 1 Bailey Ave., E. Saugus, Mass.

‡ Address: 522 Western Ave., Lynn, Mass.

Two eccentric piston rings are fitted to each piston. At the end of each piston, on opposite sides of its walls are fitted square brass shoes *M* which run in the slots in the cylinder walls. These shoes take up the larger part of the wear on cylinder and piston and steady their action as well. At the extreme ends of these shoes are mounted annular ball bearings *H*, the balls in which are 5/16 inch in diameter. Both pistons and cylinders are very light, mere shells in fact. This is made possible by the system of guide-slots and shoes that relieve these parts of most of the strain.

The Outer Casing

The outer casing *L* is made of aluminum and consists of the front and back plates and the cylindrical part that encloses portions of the sides. Upon the sides of the casing are attached the lugs for the trunnion mounting. The front and back casings have numerous ventilation holes drilled near the center to supply fresh air for cooling.

The casing is held together by eight 3/8-inch bolts. Set into the casing are steel tracks *I* in which the annular ball bearings *H* attached to the pistons *F* run. These steel tracks are hardened and ground so as to give a perfect bearing.

The Supply Chamber and Blower

The supply chamber *A* is a cylindrical gray iron casting turned and ground on its outside surface. The interior is left as cast on account of the heat regulating spines *O* that project into the chamber. About this part the cylinder casting revolves. A large percentage of friction is eliminated by the use of a double row of annular ball bearings *P*. On the outer surface of the supply chamber are spiral oil grooves leading from each end toward the supply port hole. The blower *B* with its metal casing is located at the mouth of the supply chamber. The power for its operation, which by the way is but 1/8 horsepower, is obtained by means of a friction drive *N* connected to the cylinder casting. The blower, which has a 3-inch fan, runs at a high speed to insure an abundance of pressure, and will give good results at high or low speeds. This is the smallest size made by the American Blower Co., the fan, case and gearing weighing but one pound.

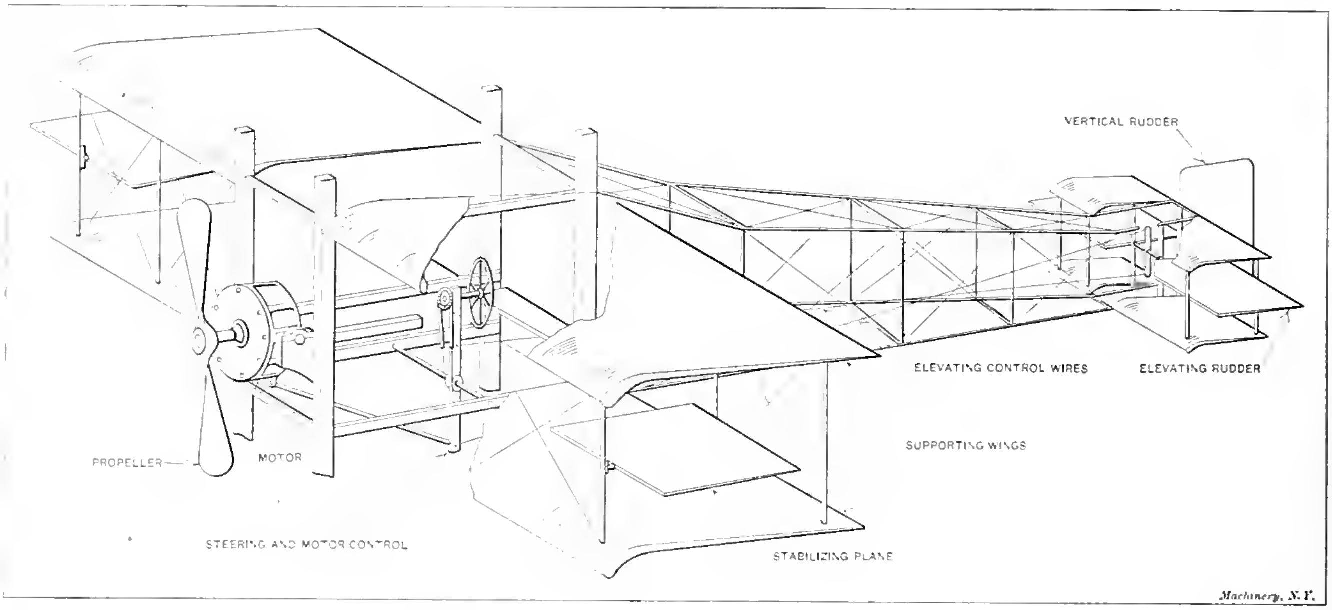

Fig. 2. Details of the Aeroplane, showing Control System

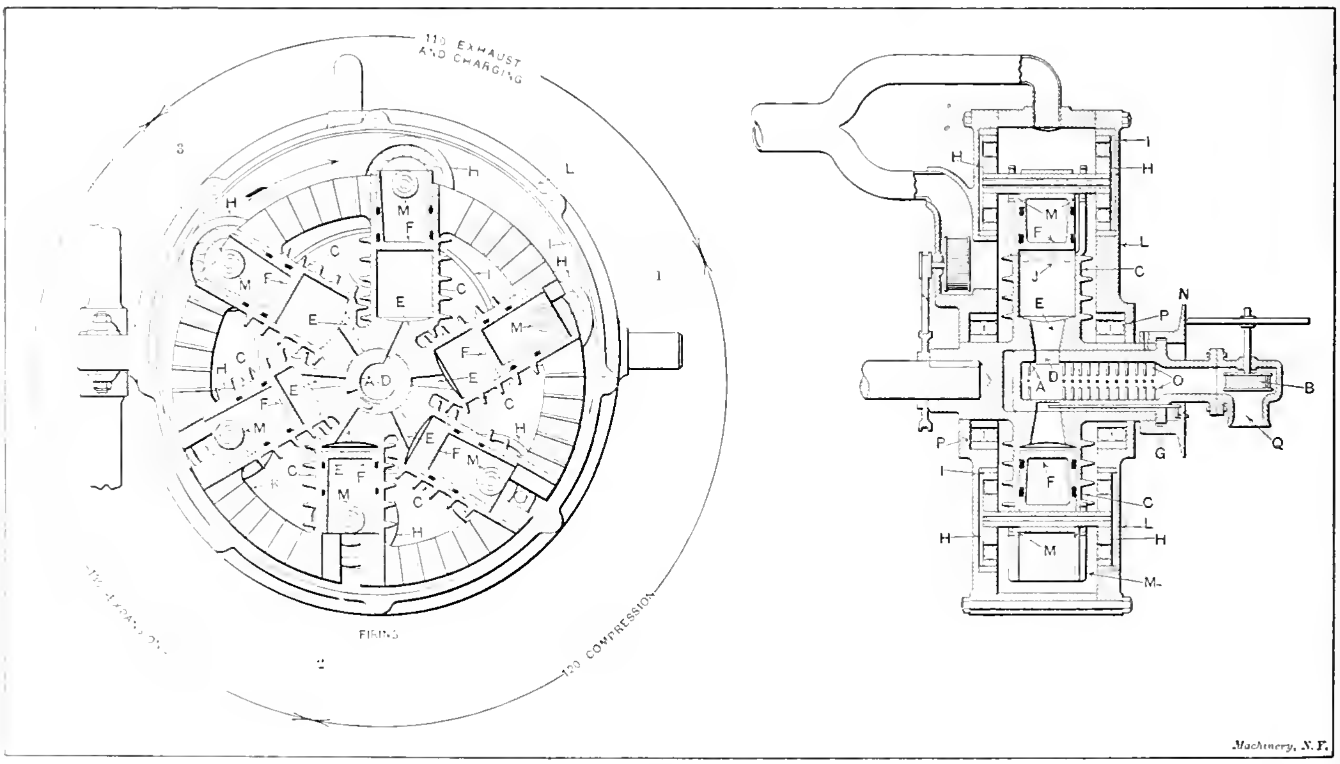

Fig. 3. Sectional Views of the Motor

Spark Plug and Wiring

One would think that a confusing network of wiring would be necessary for firing the six cylinders, but in reality but one spark plug and one set of wiring are required. This spark

plug, located in the supply chamber close to the end and near the entrance port to the cylinder, can be fired by means of any standard make of coil; the inventor of this motor has found the Splitdorf to give good results.

Operation of the Motor

The operation of this novel type of motor is quite distinctive from the working of other types of gas motors. The mixture is taken through a Schebler carburetor and thence to the intake and into the supply chamber *A*. The blower *B*, at its location at the mouth of the supply chamber, accelerates the flow of the mixture. From the supply chamber the mixture enters the cylinder *C* when the cylinder is between positions 3 and 1. At this position entrance port *D* of the supply chamber is in line with the cylinder port *E*. The rotation of the cylinder casting causes piston *F* to commence its inward stroke, thus compressing the charge. This inward stroke is actuated by the pressure exerted upon the ball-bearing end of the piston, caused by the cylinder casting being mounted eccentrically with reference to the track in the outer casing. As the charge in this cylinder is compressed, succeeding cylinders are filling in their regular order. At position 2, 120 degrees from position 1, the charge is compressed ready for

Fig. 4. The L. A. W. Motor and its Mounting

firing. At this point contact is formed by the timer *G* and the charge is fired. The pressure exerted on the piston *F* by the expanding gas is transmitted by the annular bearings *H* to the outer flange of track *I* in the casing and hence causes a rotation of the cylinders.

Ths expansion of the gas starts the piston on its outward stroke and at the end of the stroke the exhaust ports are disclosed, allowing the gas to escape. At this position, 3, the cylinder has traversed 130 degrees from the firing position 2, or 250 degrees from the time it starts to compress the charge. From position 3, to position 1, a distance of 110 degrees, the gas is exhausted; immediately a new charge rushes in. Thus it is obvious that the motor works on the two-cycle principle. The burned gas rushing out through the four holes *J* at each side of the cylinder keeps the cylinder from becoming unevenly heated, and thus all danger of warping cylinder walls and the resulting binding of the piston is eliminated. Best results have been reached by running the motor at the speed of 1,200 revolutions per minute though higher speeds have been employed.

The outside walls of the cylinders being covered with cooling spines, and the 84 fan blades mounted on the band that connects the cylinders are the principal factors in the air-cooling of the motor. The fact that the cylinders are in rapid motion through the air greatly aids the cooling process.

The system employed for lubricating the working parts of this motor is simple. The lubricating oil is fed into the supply chamber along with the mixture. The centrifugal force does the rest, by spreading it to every part of the motor, cylinder walls, ball bearings, and track. Restricted by the outer casing, the lubricant is drained to the base of the motor, filtered and again started on its journey.

One of the strongest points of this gas motor is its light weight in proportion to the horsepower. The machine has been perfected but a short time, and the inventor believes that further developments will bring the weight down to less than two and one-half pounds per horsepower.

Cooling System

Most of the efficient types of gas engines or motors are water-cooled. This means that a heavy water-jacket must be employed, which added to the weight of the water for cooling proves a serious drawback in aeroplane use. The fan-blades on the cylinder casting together with the cooling spines on the cylinders themselves and the fact that the

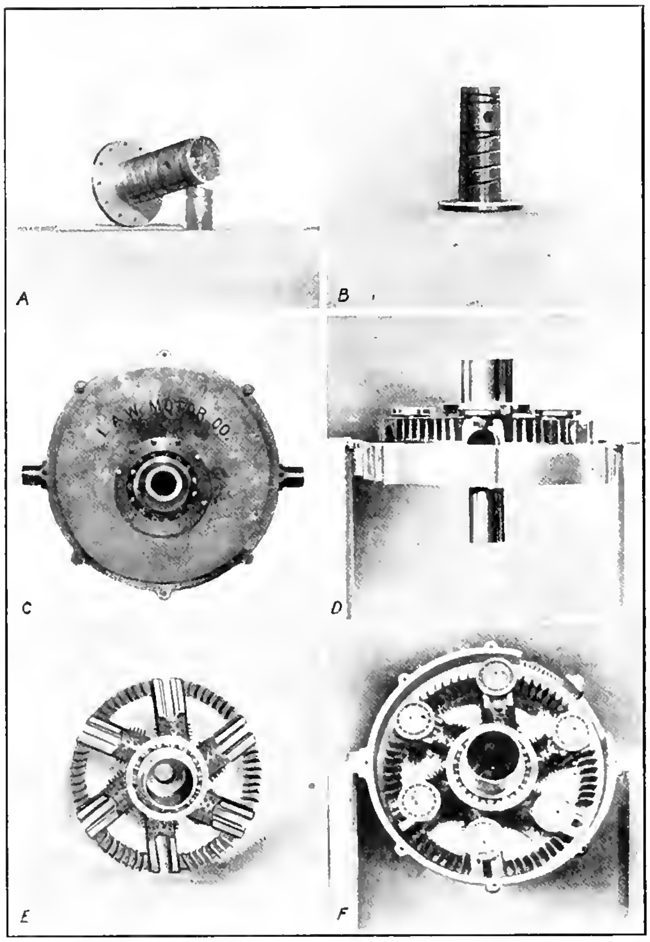

Fig. 5. A. Supply Chamber. End View showing Heat-regulating Spines. B. Supply Chamber, seen from the Side. C. Motor Assembled. D. Side View of Motor with Part of Casing Removed. E. Cylinder Casting. F. Motor with Front Casing Removed

ample exhaust ports let out the burned gas so quickly and evenly are the points that make the cooling system a pronounced success. In this connection, though not a part of the cooling system, it is well to note that the internal spines are for regulating the temperature of the mixture as it passes through the supply chamber.

Ignition

The simple method of firing is superior to the usual system and must not be overlooked. A six-cylinder gas engine with but one spark plug and one set of wires is novel. In addition, the inventors claim that the motor is self-firing after the first two revolutions. This is brought about by means of a small drilled hole through the supply chamber, off-set enough to prevent penetrating the inner wall of the supply chamber. This hole connects the two adjoining cylinders but is not open except at the very end of each explosion. The opening, barely an eighth of an inch in diameter, allows a little of the flaming charge to shoot into the next cylinder, whose charge is ready for firing. This operation repeats itself in the next cylinder and so on, doing all of the firing and dispensing with the use or need of any electrical appliances. The comparatively few

parts of the L. A. W. motor make its care very easy. Fewer adjustments are necessary and there is less danger of breakdowns—a point sought for by aviators. One example of this feature is shown by the absence of the fly-wheel, the entire cylinder casting taking its place and satisfactorily doing the work.

The fact that this motor will run in any position is advantageous to aeroplane use. As shown mounted on trunnions at the front of the Page-Light aeroplane, it illustrates the value of this point, which is made use of in manipulating the machine. Referring to Fig. 2 which illustrates the system used in elevating or lowering the bi-plane, if the aviator wishes to rise to a higher level, he pushes the steering wheel from him; this tilts the propeller upwards and at the same time throws the elevating rudder down in front. For lowering the biplane the process is *vice versa*.

It is claimed that the motor will run on alcohol, kerosene, benzol or crude oil as well as on gas or gasoline, or in fact any combustible mixture. The elimination of most of the packing required on the ordinary gas engine at cylinder heads, intake and exhaust fittings, etc., is commendable. The annular ball bearings used at all of the principal working points keep down the friction and lessen the wear and tear on the motor.

The makers of this new gas motor are L. A. W. Motors Company, 539 Howard Building, Providence, Rhode Island. At Providence this company has the first aeroplane factory in New England and the third one to be established in America. The company is prepared to give positive dates for delivery of rotary gas motors of 30, 40, 50, 70 and 100 horsepower to be used for any purpose.

HERSCHEL FALL INCREASER FOR HYDRAULIC TURBINES*

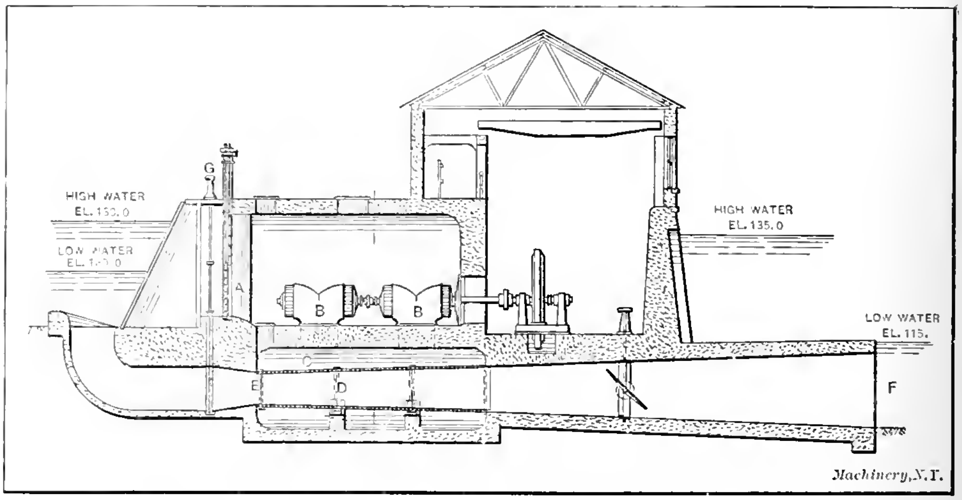
One of the difficulties which have to be reckoned with in installing turbines is that of the loss of head during high water. This condition always seems paradoxical to any one who is not familiar with the conditions, but it is easily explained. When a stream arises during a flood, the height of the water over the crest of the dam increases as a rule considerably less than the rise in height of the back water below the dam, so that the difference in levels is less than during the normal flow. This more rapid rise of the back water is due, of course, to the fact that the lower channel is almost invariably restricted, while the discharge of the dam itself is purposely made ample in area, so that a large increase in the volume of water makes comparatively little change in level.

The loss of head during high water has been at times so serious as to render the plant practically useless. It has usually been avoided by installing additional waterwheel units; or sometimes, in the case of hydro-electric plants, by furnishing an extra wheel on each generator shaft. These additional turbines make up for the loss of power due to the loss of head by employing more of the water going to waste over the dam. The disadvantage of the construction is, of course, the increased cost of wheels, gates, governors, water passages, generators, etc., required.

Mr. Clemens Herschel, the designer of the Venturi tube water meter, has devised a very simple and inexpensive method of overcoming the back water difficulty. This method employs a principle parallel with that on which the Venturi meter operates. It consists in effect of an apparatus similar to the well-known steam ejector for lifting liquids, but built on a large scale, and operated by water instead of by steam. It is applied to the discharge chamber to lower the head in the chamber below the level of the back water in the tail race. An application of this device is shown in the accompanying engraving.

In this particular installation the high and low water elevations above the datum line, give, as may be seen, a head of 15 feet for low water, and of 3 feet only for high water. The intake is shown at *A*. Two double turbines of the submerged type are used for each generator, discharging into chamber *C* and out through the perforations in pipe *D* into the tail race at *F*. During low water the gate in tube *D*, operated by handwheel *G*, is closed.

When, however, the head is so much increased as to lower the capacity of the station below that required, gate *G* is opened, permitting the water to flow through into tube *D*, and



Water Power Station Fitted with a Hydraulic Ejector for Lowering Head in Discharge Chamber below Back-water, during High Water

out into *F*. This tube, it will be seen, has a constricted throat at *E*, which increases the velocity of the water at this point above that due to the head. This velocity the water retains in passing through the enlarging sections at *D* and beyond. This condition results in lowering the pressure in *D* below that due to the height of the back water, and as this tube is perforated all around, this lower pressure draws in the water from *C*, whose head is also lowered, increasing the effective head under which the wheels work. The whole discharge of both ejector and wheels is, of course, through tube *D* into the tail race at *F*.

In the case of a plant on which Mr. Herschel recently made estimates, it was concluded that with the usual arrangement of surplus turbines an expenditure of $200,500 would have been required. By the use of the fall increaser this could have been reduced to $150,000 or $175,000 depending on whether the submerged, or the siphon type arrangement was used for the wheel.

* * *

In the March, 1909, issue of MACHINERY, engineering edition, the profit-sharing scheme of Sir Christopher Furness of the Middletown Ship Building Yard, England, was mentioned. The first dividends under the new system have now been declared, and it appears that the method employed is very profitable both to the employers and employes. The employes pay for their stock at regular par value, so that their participation is in the form of actual dividends rather than profit-sharing in the ordinary sense of that term. For the first year the regular stockholders, according to the rules of the agreement, received ten per cent on their invested capital, while the employes received nine per cent on their investment. It is a little difficult to see the justice in making the employes receive less on their investment than the stockholders, except that this method of declaring dividends was made part of the agreement under which the employes were permitted to acquire stock. Nevertheless, it must be admitted that the scheme has proved highly beneficial both to employes and employers and that the waste incident to strikes and lock-outs has been avoided. The idea of making the workers partners in the business also deserves commendation.

MACHINING GAS ENGINE FLYWHEELS, CYLINDERS AND BEDS*

PRACTICE OF THE FOOS GAS ENGINE CO.

By ETHAN VIALL†

Like many of the big manufacturing concerns, there is nothing very startling about the shop practice of the Foos Gas Engine Co., Springfield, Ohio, yet it is far in advance of the majority of similar shops in quantity, finish and economical production of its output. This firm builds all sizes of engines from 2 to 500 horsepower, and the methods used in handling the larger and less-called-for castings are necessarily different from those employed on the class of engines which are built in lots of one hundred or more at a time. As it is the usual shop practice that interests us the most, but a glance will be given toward the large sizes, while the medium sizes will be considered in detail. Taking up in order the parts as enumerated in the title, we first turn our attention to the flywheels.

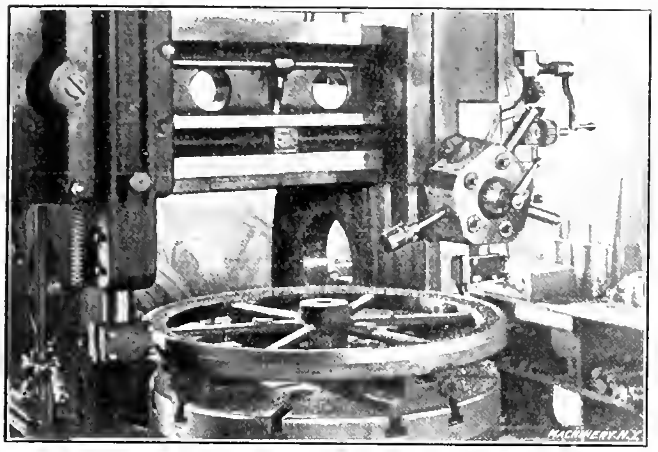

Fig. 1. First Operation on a Flywheel—Turning the Rim in a Vertical Boring Mill

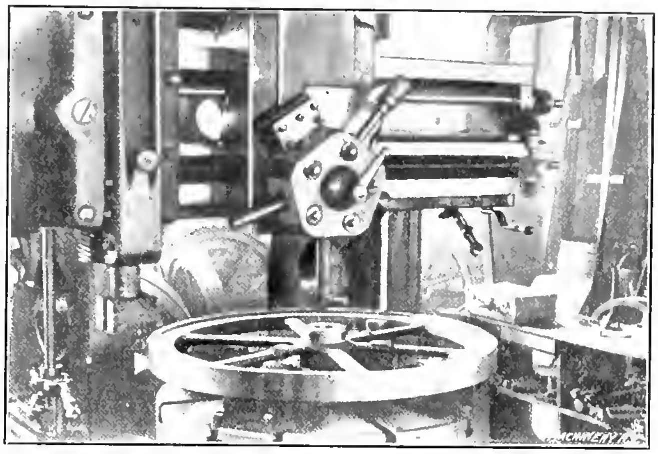

Fig. 2. The Hub Machined on the Outside end the Center Hole Bored and Reamed

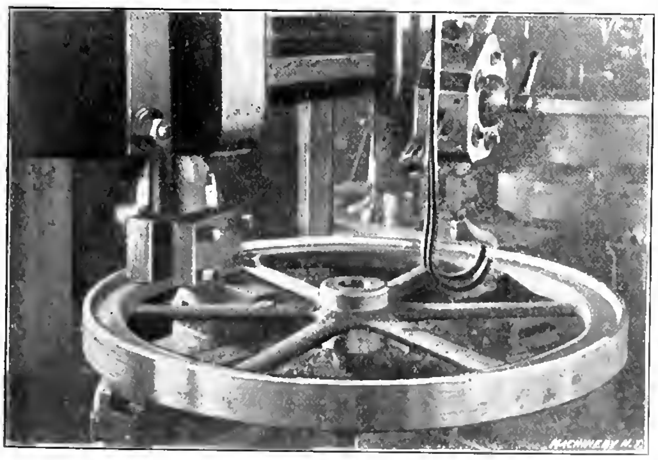

Fig. 3. Finishing the Opposite Side of the Wheel, which is centered by a Plug in the Table

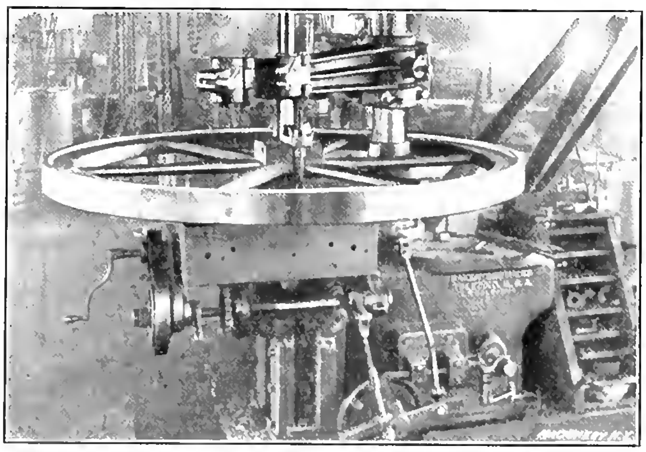

Fig. 4. Cutting the Keyway in a Flywheel of the Split-hub Type

Machining Flywheels

After coming from the foundry, the solid flywheels are cleaned of sand and carefully looked over for cracks or flaws, and any unsightly or unusual lumps of metal are carefully removed. The casting is then placed on a Bullard turret-head boring mill, the table of which is fitted with four independent chuck jaws, and chucked central, the jaws coming in contact with the inside of the rim. Two of the jaws are in contact with two of the spokes, to prevent slippage while taking the rim cut. The first operation is to true the outside of the rim as shown in Fig. 1, and the next to surface off the edge and side; the hub is then finished on the outside and the hole bored and reamed as in Fig. 2. After all of one lot of flywheels have been finished in this way, a plug which exactly fits the reamed center hole, is placed in the center of the table, the flywheels are placed over this plug and the other side is surfaced off as shown in Fig. 3. This engraving also shows the hooks used on the air hoist to handle the wheels. From the boring mill the flywheels go to a Baker Bros. keyseating machine, Fig. 4, and the keyways are worked out. The flywheels having split hubs are worked up in practically the same way, except that only the ends, and not the barrel of the hub, are finished.

Various Operations on the Cylinders

The first thing done with a cylinder by a machinist, is to insert pieces of wood like A, Fig. 5, in each end and mark approximate centers on them to line up by. The cylinder is then placed on the adjustable V's, B and C, on a Pratt & Whitney double spindle mill, with one end braced against the angle plate D, and strapped down as shown. A surface gage is used on the centers just described, to get the cylinders in the proper position. The cylinder ways E, on each side of the casting are now milled on the edges and bottoms. After the entire lot has been milled in this way, the special vise A, Fig. 6, is placed on the same machine, the small milling cutters are removed and the cylinder is turned end for end and is clamped in the jaws of the vise by the ways just milled; the inlet and exhaust box pads B are then surfaced off. Next the cylinders are placed in a Barrett horizontal boring mill, Fig. 7, on the supports A, being located by the cylinder ways, as in the last operation; they are then rough bored, faced on each end, counterbored and the head end grooved for the packing.

The machine shown in the engraving, has been fitted with an alarm bell on the turning head so that the operator can run several machines without danger of smashing his tools, the bell being so set as to ring a minute or so previous to the end of the cut. The last three engravings also show the hoist hooks used to handle the cylinders, one hook being inserted in each end.

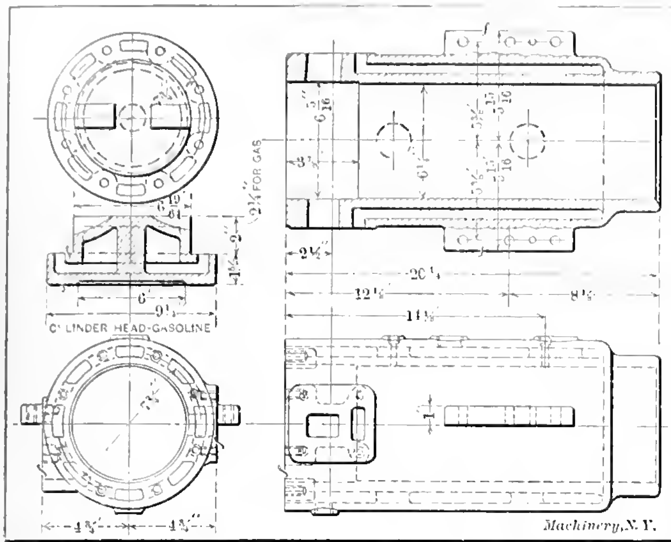

Fig. 13. Detail of a 6 1/4 by 8 Gas Engine Cylinder

As soon as the cylinders leave the horizontal boring mill, they are taken to the testing room where the water jackets are subjected to cold water pressure to detect flaws or leaks, the openings in the end of the cylinders being stopped up by rubber pads like *A* and *B*, Fig. 14, which are held down by a ring and clamp. The side opening is also covered up as at *C*, and water is admitted through the pipe *D* which runs down through one of the rubber pads and opens into the cylinder jacket. If the cylinders prove sound they are again placed in a Barrett horizontal mill and finish bored to exact size, as in Fig. 9, little time being needed for cylinders of this shape to "season," as the testing with cold water effectually cools them.

The holes in the cylinder-ways are drilled and the lower water pipe hole drilled and tapped, on a Bickford radial drill press, using the fixture shown in Fig. 10. Next the cylinder is indexed half a turn and the holes for the lubricator, water pipe and relief valve are drilled and tapped and the cylinder-way holes counterbored as at *A*, Fig. 11. Following this, the inlet and exhaust box pads are drilled and tapped as shown in Fig. 12, the drill bushings being placed in a "trap door" which is lifted up out of the way during the tapping opera-

tion; the scheme is more plainly shown at A, Fig. 10. After all the side holes are finished, the cylinder is strapped to an angle-plate as in Fig. 15, and, using the ring drilling jig A, the holes for the cylinder head are drilled; then by removing the jig the holes are easily tapped. Finally, after all the pads on the cylinder have been finished and all the holes have been drilled and tapped, it is given another cold water pressure test as in Fig 16. It is then ready for the assembling department.

In order to make the foregoing operations and tests clearer to those not familiar with the construction of this type of cylinder, it is shown in detail in Fig. 13, and the bed is similarly shown in Fig. 17.

Machining the Bed

Like the cylinder work, a number of the operations on the beds are milling operations, and in Fig. 8 is shown an Ingersoll mill at work on the bottom of a bed, one side and two surfacing mills being used. The side mill machines one edge which simplifies the subsequent setting of the bed for the various operations. The beds while being milled as shown, are held up and located by several angle-plate jacks and stops so that after one bed is correctly set, it is comparatively easy to set the others to be machined. When the beds have all been finished, the jacks and other fixtures are taken off and the bed is set on as shown in Fig. 18. The milling cutters are changed to two surfacing and two side mills which are

used to finish the outside and top of the cylinder pads as shown. Next the surfacing and large side mills are removed and an inserted tooth side-mill put in; the engine bed is then turned end for end, as in Fig. 19, and the pads *A*, *B*, *C*, *D*, and one which is back of the cutter, are surfaced off.

The next is a planing operation in which the beds are placed in gangs on an American Foundry and Machine Co. open-side planer, Fig. 20, and the surfaces for the main bearing caps, gear bracket and governor pads finished.

The drilling and tapping operations on beds that are not too heavy, are done with a Bickford radial drill, while the bed is clamped to the adjustable table of a special fixture, Fig. 21. In using the fixture, the table is set as shown, and the side holes drilled and reamed; next the jig-plate is removed and the table is turned, so that the top of the bed is uppermost, as in Fig. 22. The table is locked by the catch shown more clearly at *A* and *B*, in the preceding engraving.

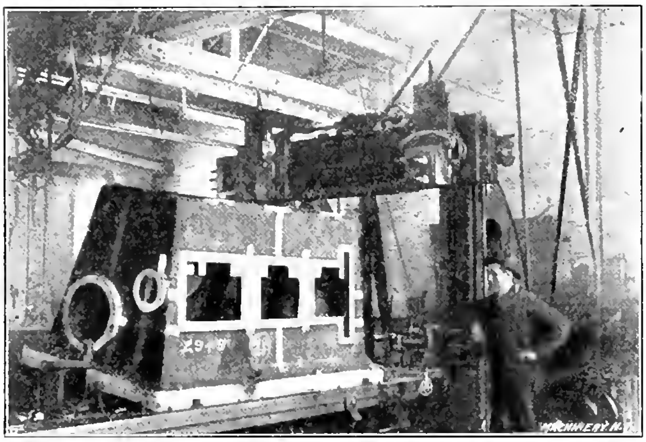

Fig. 33. Planing Side Plate Pads of Large Vertical Bed

While in this position, the governor, gear-bracket and cylinder-way pads are drilled and tapped, using the jig-plate as shown; now the table is tilted as in Fig. 23 and the main bearing cap holes are drilled and tapped. The jig-plate is then removed and the one shown in Fig. 24 is put in its place and the rocker shaft cap holes are drilled and tapped. The set-screw holes at *A* and *B* are also drilled at this setting, using the small jig shown at *C*. The bed is now removed from the drilling fixture, the bearing caps fitted on and bored out, faced, counterbored and reamed, on a horizontal boring mill as shown in Fig. 25. The main bearing reaming is done with the double adjustable-reamer *A*, and the floating driver

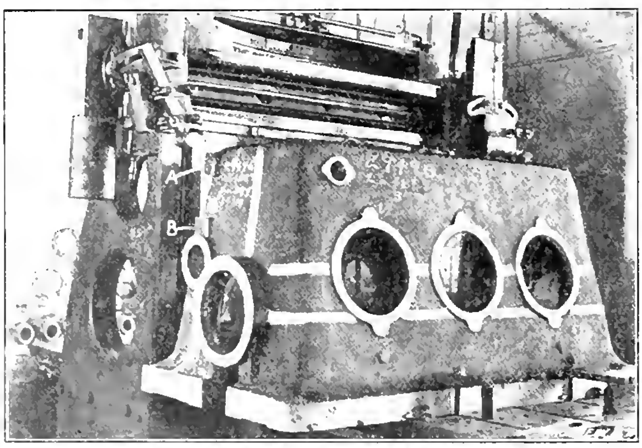

Fig. 34 Planing the End Pads on Vertical Bed

B. After this the brass bearing-bushings, which have been finished in the usual way, are fitted, and the beds are stacked up as in Fig. 26, ready for assembling.

In Fig. 27 is shown a bed with the cylinder in place and partly bolted down, the main bearing caps and bushings in place and the rocker shaft, arms and caps assembled, while in Fig. 31 is shown a complete engine ready for shipment.

Some of the two horsepower engines have the cylinders cast in one piece with the bed and are drilled, and the necessary reaming and tapping done in a universal fixture; all of this work is done, as in the previously described fixture, without removal, the various positions being obtained by means of index pins or stops. The first position of the casting is shown in Fig. 28, the second in Fig. 29 and a third in Fig. 30. There is one difference between this fixture and the one shown in Figs. 21 to 24, and that is that the drilling jig-

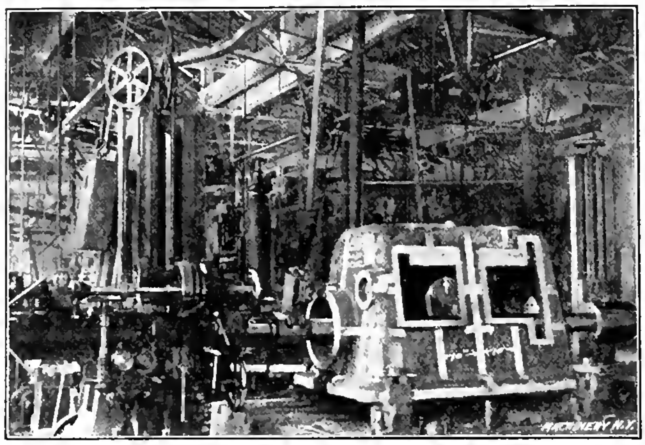

Fig. 35. Boring Crankshaft Bearing Holes in a Horizontal Boring Mill

plates are, for the most part, fastened to the fixture itself and so arranged, either by being hinged or otherwise, as to be shifted for tapping or the removal or replacing of the casting. This is possible owing to the comparative lightness of the casting, and the consequent lighter drilling-plates.

As stated at the beginning of this article, the large castings for engines above what might be classed as "commercial sizes," must be handled for the most part, as individual machining jobs, no "put in a hopper and grind 'em out" methods

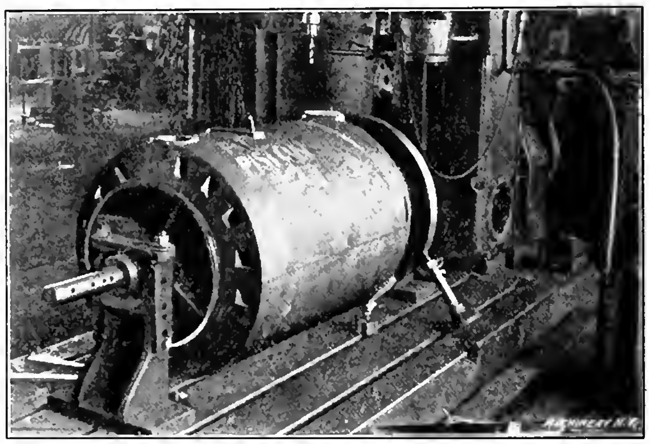

Fig. 36. Conical Centers used to hold Large Vertical Cylinders when Drilling and Tapping

being practical; so in order to make this point clearer, a few examples taken from the routing of a 150 H. P. vertical engine-bed will be given. Fig. 32 shows one of these beds placed on a huge surface-plate to be laid off. The surface-plate shown is one of the largest in use, being 8 by 12 feet, and it was made expressly for the Foos Gas Engine Company. The illustration also shows the surface gages, squares and angle-plates used in the work of laying off and marking the positions for the drilled holes and other work. From the surface-plate, the bed goes to the Cincinnati planer, Fig. 33, and the surfaces for the side-plates are finished as shown. The casting is then turned crosswise of the bed and the pads *A* and *B*, Fig. 34, finished. This engraving also shows the side of the bed opposite the one shown in Fig. 33. After planing, the holes for the crankshaft bearings are bored out on a Detrick & Harvey horizontal boring mill, Fig. 35.

Cylinders for the vertical type of engine have the side holes drilled and tapped while held in the fixture shown in Fig. 36, which consists of two large centers which fit into the ends of the cylinder and are adjustable for various lengths. The shaft on which the centers are placed, is supported on two V's across the top of which are clamping straps that make the setting of the cylinder easy. These locking straps are supplemented by small jacks used to keep the cylinder solidly in place while drilling or tapping large holes.

FIXTURES FOR MACHINING ECCENTRIC PISTON RINGS*

By C. T. SCHAEFER†

From time to time in the different technical papers there has been considerable comment on automobile engines and their manufacture, but none of the writers has solved the question of how to make perfect eccentric rings and it seems as though there are very few manufacturers of these engines who can turn out perfect rings at a minimum cost.

A piston ring is a very important part of a gasoline or gas engine, particularly on engines of the present day, as considerable compression is carried in the cylinders. We all know what a defective ring means—a loss of compression, which naturally means a loss of power—therefore it is essential to have the ring as nearly perfect as it can be made.

For a number of years it was the practice of many prominent manufacturers to put their rings through some fifteen operations; they even went as far as to grind the rings, which is a very expensive method. With the fixtures shown herewith, the grinding and quite a few other operations are eliminated and the cost of the rings reduced 50 per cent, which is more than the cost of these simple fixtures.

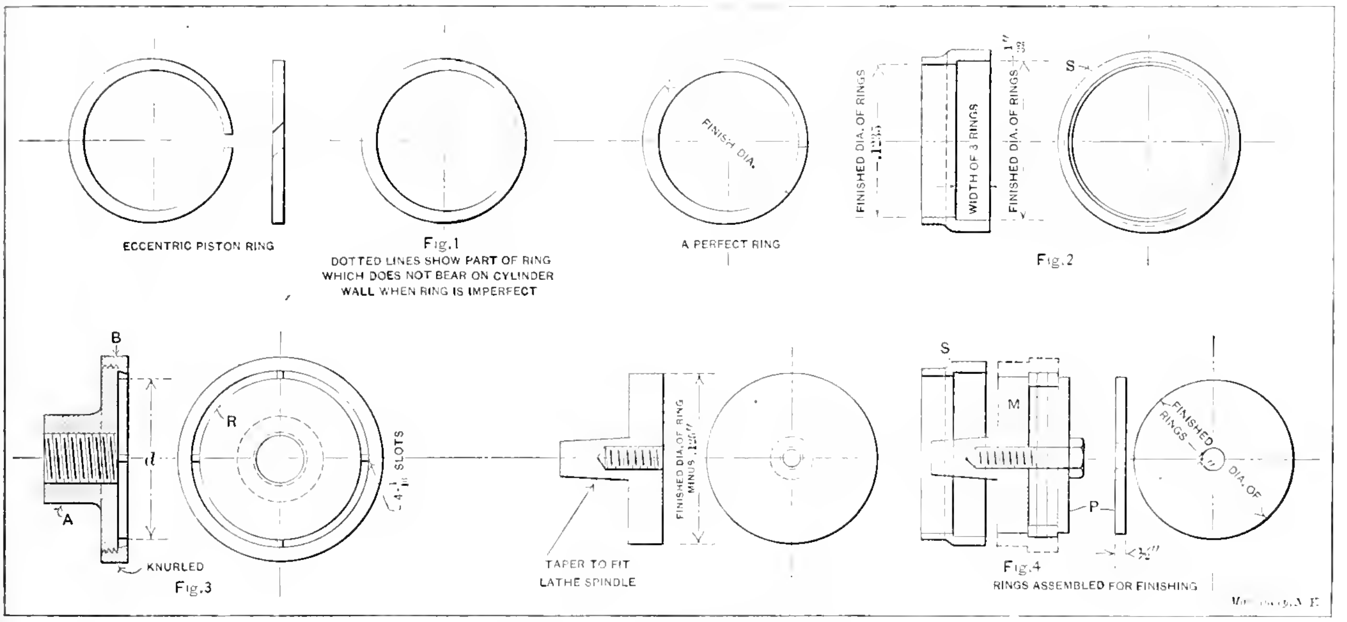
By referring to the fixtures shown it can be seen that they are not as elaborate as one might judge they ought to be, to produce an accurate ring. The secret of a perfect ring is to eliminate the hump, which presents itself at the slot when the ring is slotted and ready to put into the cylinder. A ring with this shape will only bear on two high spots, as shown in Fig. 1, where the dotted lines indicate the part of the ring which does not bear on the cylinder wall when the ring is imperfect.

It can easily be ascertained if the piston rings have a good bearing at all points by placing them in the piston and the piston in the cylinder and working it up and down, slightly revolving it at the same time. Before inserting the piston a little oil should be added to the cylinder wall. If a ring shows excessive wear on two points, it is evident that it is not perfect and should it be used in this shape, it would mean a loss of compression and consequently a loss of power, as previously stated.

Since the writer has been making rings with the fixtures described in this article, he has been getting considerable more power from engines on the test block, which shows the value of perfect rings.

The first operation on the rings is to turn the outside diameter of the blank eccentric, allowing 1/32 inch for finishing. When the inside diameter is finished, the rings are cut off 1/64 inch full of the required width, the sixty-fourth being allowed to true up the ring after it is slotted.

After the rings are cut off, they are clamped on a 6-inch faceplate, which is recessed to centralize the ring; they are then slotted in a hand miller, a spacing collar being used to space the saws. In slotting, a sixty-fourth should be allowed for filing the slots to the required opening. After this operation is completed, the rings are placed in the fixture shown in Fig. 3 and faced to the required width. By using this fixture, the rings will vary but a few thousandths in width. The hub *A* is made to fit the lathe spindle. The diameter *d* of ring *R* should be 0.001 inch larger than the outside diameter of the packing ring. Ring *R* should have four 1/16-inch slots cut into it to give it the necessary compression to grip the rings when the nut *B* is turned. The nut and ring *R* are tapered to get the action of a spring chuck. The nut is also knurled to permit the fixture to be used without the aid of any wrenches, making this operation quick and simple. The packing ring is placed in the fixture, the nut tightened and a very light cut taken off the ring—just enough to true it up; it is then reversed in the fixture and faced off flush with the side of the fixture. This should be done with a sharp-pointed tool and at high speed to get the best results. After this operation is completed, the rings are put in the sleeve *S* (shown in Fig. 2) which can be made to hold from one to five rings, but the writer has found it best to make the fixture take three rings. This sleeve is then placed over the mandrel *M* (Fig. 4), as indicated by the dotted lines, and the plate *P* is clamped against the rings as shown, with a one-inch bolt. The sleeve *S*, which served to set the rings concentric with the mandrel, is then removed. The taper shank of the mandrel is next inserted in the lathe spindle, and the rings are finished to the proper diameter.



Fixtures for Machining Eccentric Piston Rings

* * *

In a paper by Mr. W. H. A. Robertson read before the Institute of Metals, Great Britain, a formula for the power required to drive draw benches for the drawing of solid drawn tubes is given as follows:

$$H.P. = \frac{T \times A \times S \times \phi}{33,000}$$

in which T = breaking stress of material in pounds per square inch,

A = cross-sectional area of metal in tube in square inches,

S = speed of chain in feet per minute,

ϕ = efficiency of the draw bench.

This efficiency for a double-geared bench may be assumed to be approximately 65 per cent and for a single-geared bench 75 per cent. The formula, of course, is an approximation only, and it gives a result which is somewhat in excess of the actual requirements.

* For additional information on the manufacture of piston rings see the following articles previously published in MACHINERY: Making Piston Packing Rings; Faceplate for Eccentric Piston Rings, October, 1909; Making Piston Rings, November, 1908; The Manufacture of Piston Rings, June, 1909, and other articles there referred to.

EXPERIENCES OF A YOUNG TOOLMAKER*

By T. COVEY

"Jim," said Mr. Corbin, "here are about two hundred fillister head screws that we use for inserted tooth mills and other work, and I want the heads slotted; do them right away as we have a job waiting now that we are unable to complete until we get them." Jim took the box of screws out to the bench and in a half-hearted way looked around for a machine to slot them in. George was working at a vise near, and Jim said to him: "What do you think of that job for a lemon?"

"Why, that job is all right, especially for an apprentice boy," said George. "You don't expect to be given a job at making tools every time, do you?"

"I should think he would give me a job that gave me a chance to learn something instead of such work as that."

"You are too particular. If you had the grit to serve a couple of weeks' apprenticeship under the conditions as they were fifteen years ago you would think you were in Heaven here."

"Well, in my opinion this shop is a poor likeness to that place," said Jim rather shortly, as he walked away to find a machine. He found a small mill idle and putting on the vise clamped one of the screws in it, got a saw which he mounted on an arbor and started to work. In about an hour George came along and, joking, said, "What! Not done yet?"

"This job will be done in about a week," said Jim. "I've got eight slotted now."

"Pshaw! You can slot those screws in half a day and not sweat either. I thought you said that there was nothing for you to learn about that job. From the way you go about it I would say that you never slotted a screw before."

"Show me," said Jim.

"Go get a larger saw—one at least four inches in diameter, then put on the index head, screw the chuck onto the spindle, and set the knee so that the center of the index head is the same height as the center of the arbor. There is a line marked 'Center Line' here on the slide for the knee. Raise the knee to that line and you will be near enough. Then put one of your screws in the chuck, clamp it by the body with the head resting against the jaws; set the saddle so that the saw comes in the center of the screw, start the machine and bring the screw up until the saw just makes a mark on it, then back it away and turn the index half around, bring it up again and if the saw cuts in the same place it's central, and you can cut in deep enough to make the slot, and then set the stop for the table so that the saw can go no deeper. After the first one is right, all you have to do is to back the screw away from the saw for two or three inches, take it out, put in another, feed up against the stop and so forth. All your screws will be slotted alike, and if you feed by hand you can easily do one a minute."

"Yes, perhaps I can, but there will be no snap about it."

"If snaps are what you are looking for you will never make a toolmaker. Better go out in the shop and get a job on a big lathe or planer and stay there. Become a fixture at fixed pay." With which remark George went back to his work.

The finished screws fell into their box at a much more rapid rate after Jim had things going in the proper manner, and he became more satisfied with himself and his job. The remarks George had let fall had given him food for thought, and he wondered what George had meant when he mentioned the conditions fifteen years ago, and he stopped his machine and went over to where George was at work. "George," said he, "in what way were the conditions of apprenticeship fifteen years ago different from now?"

"Well, I am personally familiar only with those in the shop where I served at that time, and they were different in a great many ways."

"Tell me about it. Will you?"

"I have not the time now, neither have you, but if you care to eat your lunch with me I might tell you a few of the things that at that time I considered hardships but have since learned were benefits."

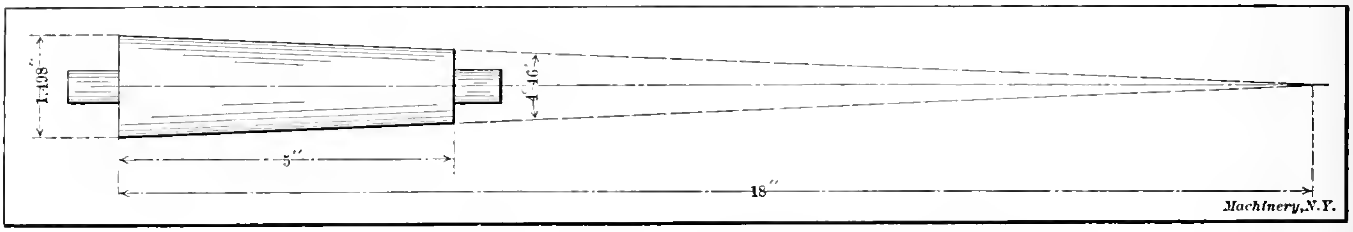
"Good," said Jim, "I'll be an interested listener," and he went back to his work.

When the whistle sounded for noon, Jim stopped his work, got his lunch basket and hunting up George remarked to him, "Well, here I am."

"I see," said George. "We will hunt up a nook by ourselves where we won't be interrupted. Here is a good place and a couple of seats."

"Now, as I told you, I can only speak of my own experiences, and while I am inclined to think that my lot was not as pleasant as some more fortunate, or unfortunate, apprentice boys of that period, I am quite sure that lots of other boys fared about the same. Generally speaking, a boy had to have more than an ordinary desire to become a machinist, and a good deal of stick-to-it-ive-ness to serve four years in those days.

"In the first place, I was raised on a farm, and my parents were poor. My capital when I started out for myself was their training and a district school education, the three 'R's' you might say. When I was 18 years old an old friend of my father visited him, and learning of my desire to become a machinist, agreed to give me work in his stave mill, and then do what he could to get me into a machine shop. I went with him to his home, a distance of 500 miles, and in a few days he took me to the machine shop where he got his repair work done, which was in another town about 15 miles away. Mr. Doring, the man that ran the shop, told us that there was no opportunity with him then as he had just put on a boy, and only had work for one. With this discouraging prospect we returned and I went to work in the stave mill at $1 per day. I stayed at this for a year, and saved about $75, which was pretty good considering that the mill only averaged half time. Then one day Mr. Doring sent for me to come down to his shop, which I did, and he agreed to start me in to learn the trade. His other boy had quit. He told me that for the first six months I would get three dollars per week, and could expect fifty cents a week raise every six months if I made good. Well, I considered it my opportunity and accepted it. He referred me to a boarding house where I was able to get my board for $3 per week."



Incomplete Sketch of Conical Roller Bearing, which made Necessary the Use of Elementary Geometry

"Say, you did not have much change left did you?" interrupted Jim.

"No; but I had the privilege of carrying my money once a week even if I could not spend any of it.

"Well, my hours were from 5.30 in the morning until 6 at night, and my work was first to care for the boiler and engine. I had to have steam up, the engine oiled, and everything in readiness to start up at 7 every morning. I had to oil all of the shafting twice a week; sweep out every other day; wheel out the chips and help the men, of which there were two, and clean all the castings, as my regular work.

"The shop did any kind of jobbing that Mr. Doring could get, and a great many of the jobs were taken for my benefit, among which were building a steel smokestack, cutting off an iron fence, sharpening lawn mowers, grinding plow points, and so forth. And among some of the odd jobs that I did about the shop was to paint the smokestack and roof; build a feed-water heater; pipe up a heating system; in fact, when work for outsiders was scarce I was likely to be put at any odd job about the place to keep me busy."

* Previous installments of this article have appeared in MACHINERY, August and December, 1909, and February, 1910.

"I don't see where you had much opportunity to learn anything about the trade at the class of work you got."

"Well, for the first year or so I did not learn much except what I could from observation, though I did get a simple job on a lathe or planer occasionally. I had more time than you think. We used natural gas under the boiler, so the firing was not much; and I generally did my sweeping and oiling in the morning before the shop started up, though this was not asked of me; all I was expected to do before 7 o'clock was to get steam up and the engine oiled. After I had been there about two years, Mr. Doring hired an old man to take care of the shop and help at such jobs as he was needed; then I was put on practically the same work as the men; and in my fourth year I was sent out on jobs by myself as occasion required."

"What kind of jobs were you sent out on?"

"Anything and everything. Sometimes to put some flues in a boiler or put on a patch, to set engine valves or install a pump or other work that in Mr. Doring's opinion did not require one of the men."

"Did you ever get stuck on any of them?"

"Yes, once in awhile, but not very often, because if a man came back and reported a failure, Mr. Doring made things uncomfortable for every one in the shop. He used to say when he sent a man out, 'Now take all the tools you want, and when you get there if you haven't the ones you need make them out of a fence rail.' He wanted the job done and seldom dictated how it was to be done—seemed to think that there was a way to do every job and he was paying his men for knowing it.

"The result of my apprenticeship with Mr. Doring has been very satisfactory to me, as I am confident that my training in that little jobbing shop was of more real benefit to me than ten years in a large manufacturing plant such as we are working in here. Now I don't want you to think that you do not stand a good show here; conditions in general have changed since then. In those days we had no toolmakers, at least in that part of the country, and a man that was classed as a machinist was considered competent to undertake and execute any job that came into the machine shop. Now it is different. A machinist may be a specialist; able to run but one machine properly, still he is a machinist. The majority of our old all-around machinists are in toolrooms now, classed as toolmakers. Even with toolmakers this specialization is growing, and we have our jigmakers, templet men, tool grinders, repair men, and so forth.

"You are having an excellent chance here, and though you may not learn anything about boiler work, tool forging and general repair work, you will, if you try, be able to hold a good job with good pay. Just remember that it is the men that can be depended on to do their best whether they are watched or not, and not the ones that work with one eye on the clock, the other on the boss, and their mind on pay-day, that will be found at the top of the list with a good job to carry them through hard times. Don't get the idea that the foreman don't know these men, for he does; nine times out of ten he has worked up from the bench himself and is wise to every play in the game. Remember that the foreman has troubles of his own, and enough things to see to without explaining every detail of a job he gives you; or why he gives it to you. I frequently get jobs that an apprentice boy could do if Mr. Corbin had the time to show him how; but the job has to be done, probably right away, and done right; what choice has he but to give it to a man that can do it without consuming his time in giving instructions. Don't be a kicker—be satisfied with your job at least until you are out of your time."

"Are you satisfied with your job?" asked Jim.

"As a means to something better, yes; but I am living in hopes of a better one some day."

"I thought you had about as good a job as any one in this shop, and your pay is what I would consider pretty good. Can you do better somewhere else?"

"Not as a toolmaker. You know that I told you that my capital when I started in was a district school education. That has been my handicap in this business, though I did not realize it until about three years ago. My climb has been more rapid since I located the trouble than it was before."

"I don't see what good it did you to find that out; as long as you did not have the education you didn't have it."

"I have got it; or rather, I am getting it. My day's work is not done at 5 o'clock. I go home, eat my supper, and then put in a couple of hours hard study; and considering the rate of pay I was able to draw when I started, this firm is paying me about double time for those two hours' work, too. It is a mystery to me how I was able to hold even as good a job as I had."

"What are you studying?"

"Well, so far I have gotten a fair knowledge of arithmetic, algebra, logarithms, geometry, trigonometry, mechanical drawing, hydraulics, and elementary mechanics. And I expect to study, steam, heat, applied mechanics, electricity, machine design, and so forth."

"Say! but you are going some. What good do you expect from such knowledge?"

"I've got some of the good, and I realize that it is a fact that a man can't expect to get and hold a good job on practical training alone; but combine practical training with technical knowledge and there is no limit to a man's possibilities. Hello! There is the whistle and we will have to stop this talk and get to work."

Jim got the screws finished and turned them in soon after lunch hour and Mr. Corbin gave him a job turning up some rolls for a conical roller bearing, and told him that Anderson had the sketch and he could use it with him. It was an experimental job and the draftsman had drawn a sketch full size but had not worked out the details completely. All the dimensions that were given for the rolls were the length, the size at the largest diameter, the included angle of the taper, and the length and diameter of the small bearings at the ends of the roll. Jim looked it over and then said to Anderson, "Mr. Corbin gave me the job of turning up those rolls but I don't know how I am to get them right from a sketch like that. Why couldn't they have given the taper per foot of that roll instead of the angle, or else the diameter of the small end?"

"I'll figure it out for you," said Anderson, "it is only a few minutes work."

"How do you do it?"

"Why, it is simple. You notice here that the distance from the apex of the angle to the large end of the roll is given as 18 inches, and the diameter of the large end is given as 1.498 inch. (See accompanying illustration.) By dividing this large diameter by 2 we get 0.749 inch. This gives us a right angle triangle whose side adjacent is 18 inches and whose side opposite is 0.749 inch. Subtract the length of the roll or 5 inches from 18 inches and we have another triangle whose side adjacent is 13 inches and whose side opposite we want to find as it represents half of the diameter of the small end of the roll. We know that since the angle is the same in both cases, the functions must be in direct proportion to each other; hence, 18 is to 0.749 as 13 is to x, or the required number. $0.749 \times 13 = 9.737$; $9.737 \div 18 = 0.5409$, or half the diameter of the small end; $0.5409 \times 2 = 1.0818$, or 1.082 inch as the diameter of the small end of the roll. Now to get the taper per foot, we subtract 1.082 from 1.498, which gives us 0.416 as the taper in five inches; using proportion again, $0.416 : 5 = x : 12$; $0.416 \times 12 = 4.992$; $4.992 \div 5 = 0.998$, or the taper is approximately one inch per foot."

"Well," said Jim, "to see you do it looks easy, and I suppose if one understands it it is easy, but I could not do it."

"Of course one should have some knowledge of the principles of geometry and trigonometry to understand why some of the operations are performed, but the actual figuring is generally pretty simple, especially in problems like this one."

"Did you get your knowledge of geometry and trigonometry before you started at this business?"

"No, when I started I had only a common school education, and when I realized that I had need of more I got it by studying at home. And I believe that is the case with the majority of mechanics. If a young man has a good education he usually starts in some other business than this—or at least that was the case in my time."

"Do all mechanics have to have this education in order to hold their jobs?"

"No. There are lots of mechanics holding comparatively good jobs without any other education than they obtained in a common school; they manage to worry along some way, and I suppose that as long as they know nothing of the advantages of an elementary knowledge of mathematics, they don't realize that they are working to a disadvantage."

"What is the reason that more men don't study and make themselves more able to do their work, if it is any great advantage?"

"There are numerous reasons; some men don't realize the intimate relationship which must necessarily exist between mathematics and mechanics; others, when the terms mathematics, algebra, geometry, trigonometery, and logarithms are mentioned become scared and make up their minds that these subjects are only comprehensible to men that have had a college education. In my own case I shied at logarithms until it was really forced upon me by circumstances which made it imperative for me to use certain formulas involving their use. I procured an elementary treatise on logarithms, and when I discovered the simplicity and time-saving qualities of the logarithmic method of figuring I kicked myself good and hard. It is safe to say that not more than two per cent of the machinists and toolmakers working at the trade could tell how to extract the square root of a number, and it is also safe to say that but a very few of them could learn how to do it by ordinary arithmetic methods, so as to remember the rule in less than a week's study. But if these same men would spend but a few hours in the study of logarithms they would find that by their use the extraction of the square, cube, or any root in fact, is reduced to a simple problem in division. It is surprising to me that many young men who pass up mathematics as beyond their powers of comprehension—as being too difficult for them to ever learn—are experts in other things requiring far more time and application to become proficient in. Take, for instance, billiards, pool, or bowling, at which many of our young men from the machine shops are able to put up a good game. Any man that will regularly devote a small portion of his spare time to the study of mathematics will find that it is an easy matter to absorb an elementary knowledge of them, and that they will help him far more than he ever anticipated."

"Well, I am pretty well satisfied that I want to know more about mathematics. What is the best way for me to go about it to get the knowledge? I am so situated that I cannot afford to go to a college to get it, and if I could I would not like to stop my work to do it."

"There are several methods open to you. You can take a course in some correspondence school; go to a night school; or, if you don't like either of these you can buy some books and study in your own way. The correspondence or night schools are better though, as you would have a systematic course of study mapped out for you, and some one to correct your work; but in any case you will have to put forth an effort to get an education, as it takes hard and diligent work to get knowledge in any of these ways; or any other way for that matter."

"In what way did you go about it?" asked Jim.

"I bought a few textbooks and studied them. I also subscribed to a couple of mechanical papers and read them very closely. It is hard for me to say which did the most good. There is lots of room for me to improve yet, and I still keep up my subscriptions to the papers, and when I come across a book that I think would benefit me I buy it. I don't study systematically now, I just read; in fact, I read practically all of my spare time and I find that it is a great help to me."

Jim went on with his job and did some thinking on what George and Anderson had said about the mathematics. He had made up his mind that he was going in for some study, but was still uncertain what action to take as he did not want to make a false start. "I'll just ask Mr. Corbin's opinion as soon as a good opportunity arrives," said he to himself. The opportunity came sooner than he expected, for in the course of an hour or so Mr. Corbin came along and noticed him turning the taper on the rolls and asked if he had got the taper off the sketch.

"No," said Jim, "Mr. Anderson figured it out and gave it to me. I have noticed a number of instances where figuring was necessary since I have been here, and if you have the time I would like to ask your opinion on a matter that has been on my mind lately."

"Go ahead," said Mr. Corbin.

"I have only a common school education, and by talking with some of the men here I have been led to believe that if I should study mathematics it would be of great benefit to me. I want to study at home, as I am not able to go to college, and if I were I would not like the idea of giving up my apprenticeship. Some of the fellows are in correspondence schools, and some are going to night schools, and I would like to ask you which you think the better way."

"Well, there is no doubt but what a knowledge of mathematics will be of use to you if you intend to continue in this business. Mathematics and mechanics are necessarily very closely associated, and a good practical man with a knowledge of mathematics has a decided advantage over a practical man without the mathematics, or over the technical man without the practical side. It takes the combination to fill the requirements of the responsible positions.

"As to the best method of getting an education along these lines a great deal depends on yourself. If you have a faculty of studying out a problem from printed instructions and similes, and the stability to keep steadily at it until you attain the desired results, you can do well by systematic home study; but if you can't get an understanding of a subject unless you have a personal instructor, and are unable to stay at a thing without someone to urge you on you will do better at a night school.

"Personally, I am an advocate of the methods of teaching followed by the leading correspondence schools; mind, I say methods of teaching; their indiscriminate methods of selling courses to persons regardless of their adaptability for the subject involved is greatly to be deplored, but it must be acknowledged that the larger ones are able to obtain a much more efficient corps of instructors, and map out and keep revised to the latest practice more systematic and complete courses of study than a school of small financial resources could hope to. Generally speaking, they give full value and good measure, but it's up to the student whether he gets the full benefit or not. You know the old saw, 'You may lead a horse to water, but you can't make him drink.' It's the same way with them, they will put the material before you and the remainder rests with you."

"Would you advise me to take the matter up now or wait until I have had more experience in a practical way?"

"Now! by all means; you can't get it too quick or too much of it, and when you do get it you will have a valuable asset that will be of use to you in practically any vocation. If you succeed in getting an education, and live long enough, you will realize that you have a good paying investment that no one can swindle you out of, and which will be all the more valuable to you because you worked hard to obtain it."

"If I decide to take up a course of study what do you think would be the most useful subject?"

"Mechanical drafting or mechanical engineering. In mechanical drafting you should get a good amount of the necessary mathematics, and in mechanical engineering you would get, without doubt, both the mathematics and the drawing with a good amount of other useful knowledge as well."

"Do you think I need to learn drawing? I thought that a trade by itself."

"In this business you will always be more or less closely associated with the work of draftsmen, and have to take your instructions from drawings made by them; hence a knowledge of the rules and methods followed in making these drawings will be of great assistance to you in enabling you to clearly and fully comprehend all the instructions and explanations represented on them; and if you should ever be placed in a responsible position where you would have the supervision of draftsmen, do you think you would be competent to direct in a matter of which you were ignorant?"

"You are right," said Jim.

"Of course I am. Well, I am glad to see you so much interested in this, and I hope you are rewarded with success."

That night Jim took the first step toward obtaining a suitable education to assist him in his climb to the top of his

chosen profession by beginning a course of home study, and soon became a student filled with the desire to absorb everything treated on in his course in a thorough and efficient manner; and though some may criticise the method by which he decided to obtain his knowledge, it must be conceded that so far as an elementary knowledge of a subject is concerned, it matters not so much *how* it is obtained as it does that it *is* obtained. The point is that it is desirable, needful, imperative, and that a young man desiring to become a progressive, successful mechanic, should have it.

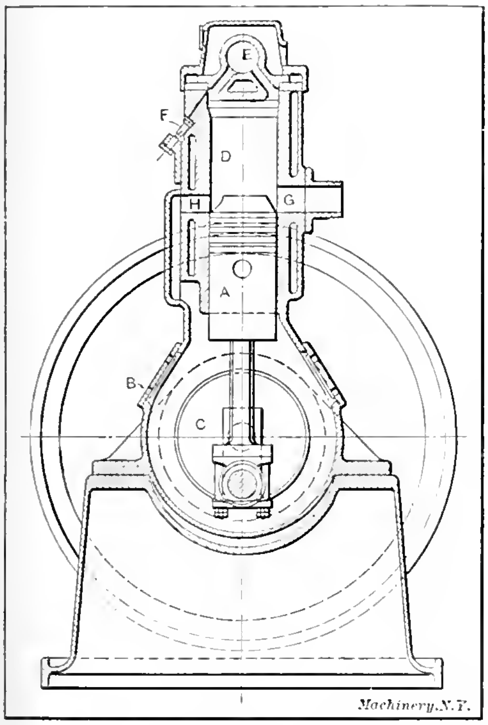
REVERSIBLE MARINE OIL ENGINE

As is well known, the two cycle petrol engine will run in either direction, according to which direction it is started, and it is possible to reverse it by first bringing it to a standstill and then pre-igniting the charge. Considerable efforts have been made to construct a two-cycle oil engine which would be capable of being reversed by means of a simple reversing lever in a manner similar to that used for steam engines. What appears to be a simple and practical solution of this problem has now been brought out by the J. & C. G. Bolinders Co., of Stockholm, Sweden. By adding certain devices to the engine, the reversing has been made both simple and certain, and an 80-H.P. engine of this design has been installed on board ship for testing purposes under actual working conditions. The accompanying illustration shows the general principles of the design of the engine. Near the end of its stroke the piston *A* uncovers the exhaust port *G* and the inlet *H* through which air previously compressed in the crank case *C* enters the cylinder *D*, sweeping out the products of combustion in the usual way. On the return stroke the air entrapped is compressed to 150 pounds pressure per square inch, and a small jet of fuel is pumped into the cylinder just at the end of the stroke. The charge enters through the jet shown at *F* and passes up into the vaporizer *E*, where it is automatically gasified and ignited. The pump which supplies the oil is actuated by an eccentric. The length of the stroke of the pump is adjustable, and by the ordinary hit-and-miss arrangement it can be thrown entirely out of action. Now, to reverse the engine, a clutch operating in connection with the pump and inlet valve is disconnected and a reverse lever moved over. The operation of the fuel pump is thus cut out, and the engine, accordingly slows down. When the speed has fallen to a certain limit, another pump comes into action which supplies a jet of oil to the cylinder, which is ignited at such a moment that the motion of the engine is reversed. As soon as this has taken place the regular pump immediately comes into play and the engine continues to run backwards. No skill whatever is required on the part of the attendant, who simply has to de-clutch and hold over the reversing lever until the engine changes its direction of motion.



Section through Cylinder and Crank Case of Bolinder's Reversible Marine Oil Engine

* Abstract of an article in *Engineering*, London, issue of December 20, 1909.

CIRCULAR FORM AND CUT-OFF TOOLS—2

By DOUGLAS T. HAMILTON

To provide for sufficient periphery clearance on circular tools, the center of the tool is located a certain amount above or below the cutting edge, as shown in Fig. 16. The hole *b* in the tool holders is raised or lowered depending on the position of the tools and the direction in which the spindle is rotating. The block *a* is provided for raising or lowering the hole in the tool holder. Raising or lowering the cutting edge of the tool relative to its center, changes the clearance angle *A* and also changes the form produced with the same tool. Clearance angles and the relation of the holes in the toolposts to the center of the spindle are, therefore, points which require careful consideration. With a given material, the larger the diameter of the work, the greater the clearance angle required. With the same dimension *C*, Fig. 16, a small tool diameter causes a greater clearance angle than a large diameter. The maximum diameters *D*, the cut-down below the center, *C*, the width of the cut-off tool *W* and the size of tapped hole *B*, as shown in Fig. 17, are tabulated in Table II, for the various sizes of Brown & Sharpe automatic screw machines.

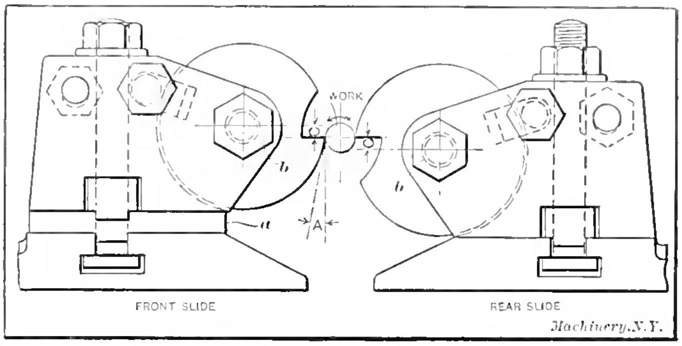


Fig. 16. Circular Form Tools and Holders showing Location of Center of Tool in Relation to Center of Piece being formed

Calculating the Diameter of Circular Tools

Locating the cutting edge of the tool below the center changes the form produced on the work. On account of this, the actual difference of diameters on the piece of work cannot be used for the measurements on the forming tool. If the dimension *A*, shown in Fig 17, on the piece to be formed, is transferred to the form tool and then the tool cut below the horizontal center line, as shown at *C*, it would make the dimension *A* on the piece greater than required. Therefore, it is evident that a certain amount must be subtracted from the dimension *A* on the work to find dimension *a* on the circular tool. A general formula may be deducted by the aid of geometry, by which the various diameters on the forming tool can be determined, when the largest or smallest diameters of the tool, the amount that the cutting edge is below the center, and the diameter on the piece to be formed, are known.

TABLE II. DIMENSIONS REQUIRED FOR DESIGNING FORMING TOOLS FOR B. & S. AUTOMATIC SCREW MACHINES (See Fig 17 for notation used

No. of Machine	D	C	B	W
00	$1\frac{3}{4}$	$\frac{1}{8}$	$\frac{3}{8}$–16	$\frac{1}{4}$
0	$2\frac{1}{4}$	$\frac{5}{32}$	$\frac{1}{2}$–11	$\frac{5}{16}$
2	3	$\frac{1}{4}$	$\frac{5}{8}$–12	[illegible]

Let R = largest radius of tool in inches,
A = difference in radii of steps on the work,
C = amount cutting edge is below the center in inches,
r = required radius in inches.

Then:

$$r = \sqrt{(\sqrt{R^2 - C^2} - A)^2 + C^2} \qquad (1)$$

If the small radius r is given and the larger radius R is required, the formula would be:

$$R = \sqrt{(\sqrt{r^2 - C^2} + A)^2 + C^2} \qquad (2)$$

Assume that it is required to make a circular form tool to

* Address: 169 Quarles St., Outremont, Montreal, Canada.

be used on the No. 0 Brown & Sharpe automatic screw machine for forming the piece shown in the lower view in Fig. 17, the diameters G and H to be formed by the tool. By referring to Table II it will be seen that the largest diameter should be 2¼ inches, and that the cutting edge is 5/32 inch below the horizontal center line. Half the diameter E, Fig. 17 (or radius r), is then found from Formula (1), by inserting the given values.

$R = 1\ 1/8$; $C = 5/32$; assume that $A = 1/8$.

Then

$$r = \sqrt{\left(\sqrt{(1\tfrac{1}{8})^2 - (\tfrac{5}{32})^2} - \tfrac{1}{8}\right)^2 + (\tfrac{5}{32})^2} =$$
$$\sqrt{\left(\sqrt{\tfrac{1271}{1024}} - \tfrac{1}{8}\right)^2 + \tfrac{25}{1024}} = 1.0014 \text{ inch.}$$

The value of r is thus found to be 1.0014 inch and diameter E will then be 2 times this or 2.0028 inches instead of 2 inches exactly, as would have been the case if the cutting edge had been on the center line. The formula may seem rather complicated, but when applied to circular tools used on the Brown & Sharpe automatic screw machines it can be simplified by inserting the values for R and C, these being constant for each size of machine. The formula would then take the following form:

No. 00 Brown & Sharpe automatic screw machine:

$$r = \sqrt{(0.866 - A)^2 + 0.0156} \qquad (3)$$

No. 0 Brown & Sharpe automatic screw machine:

$$r = \sqrt{(1.114 - A)^2 + 0.0244} \qquad (4)$$

No. 2 Brown & Sharpe automatic screw machine:

$$r = \sqrt{(1.479 - A)^2 + 0.0625} \qquad (5)$$

Top Rake

Most circular form tools are made without top rake, that is, they have the cutting edge in a horizontal plane when cutting, as shown in Fig. 17; tools made in this manner are best suited for cutting brass, but do not work entirely satisfactorily on tougher and harder metals, as the chip, instead of being cut away, is scraped off, this action destroying the cutting edge very fast. Form tools should, therefore, be provided with top rake, as shown in Fig. 18. The amount of top rake that should properly be used on circular tools for different materials varies from 0 to 18 degrees. Under general conditions the following angles are suggested as most suitable:

Material	Angle of Top Rake, Degrees
Rod brass	0
Drill rod and tool steel	8 to 10
Gun-screw iron	12
Machine steel	15
Norway iron	18

When top rake is ground on a circular form tool, as shown in Fig. 18, the calculations for the diameters must be accordingly changed. In Fig. 18 the case is shown exaggerated in order to be able to show clearly the various dimensions involved. To find the diameters of a form tool made in this manner, proceed as follows:

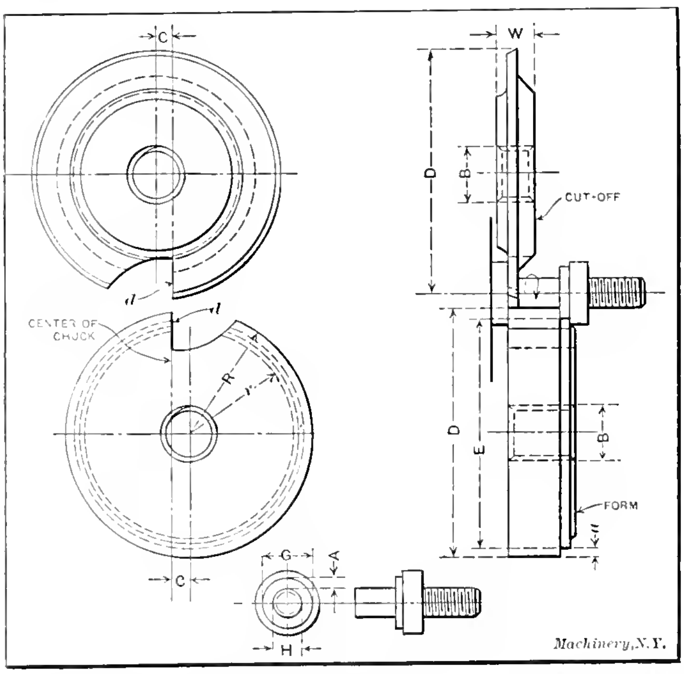

Fig. 17. Diagram showing Principal Dimensions of Circular Form Tools

First find radius R_1 which would be the actual radius if the tool were merely cut down the required amount C below the center of the tool, but had no top rake. Then the radius R_3 of the tool, required when top rake is given, must be found. In order to explain the procedure clearly we will assume a practical example. Let R = 1⅛ inch, C = 5/32 inch, D (see Fig. 18) = 9/16 inch, D_1 = 5/16 inch. Then A = 1/8 inch.

First find R_1 by means of Formula (1) or (4):

$$R_1 = \sqrt{(1.114 - 0.125)^2 + 0.0244} = 1.00126 \text{ inch.}$$

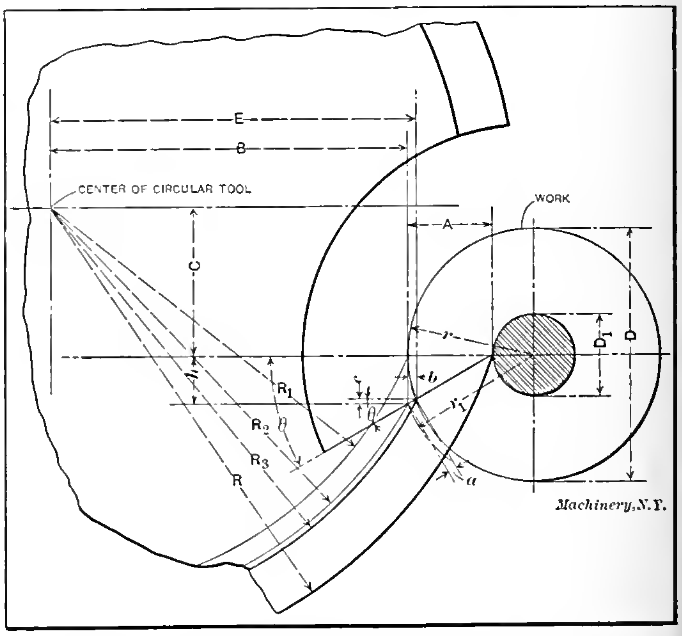

Fig. 18. Diagram for Calculating Form Tools having Top Rake

The next step will be to find dimension B:

$$B = \sqrt{R^2 - C^2} - A = 1.114 - 0.125 = 0.989 \text{ inch.}$$

The next step is to find dimension h and as the tool is to cut machine steel, angle θ is 15 degrees.

Then:

$$h = A \times \tan 15 \text{ deg.} = \tfrac{1}{8} \times 0.26794 = 0.03349.$$

This gives us the distance from the center of the work to the point where radius R_2 intersects the face of the cutting edge. Now R_2 may be found:

$$R_2 = \sqrt{B^2 + (C + h)^2} = \sqrt{0.989^2 + 0.18974^2} = 1.007 \text{ inch.}$$

Radius R_2 would be a fairly approximate dimension for the tool when the diameters of the tool and work are nearly of the same size, and when the angle θ is comparatively small. As the difference between the diameters of the tool and work increases, the diameter of the work being small in comparison with the diameter of the tool, it is necessary to find the theoretically correct radius R_3. To do this first find r_1:

$$r_1 = \sqrt{r^2 + h^2} = \sqrt{(9/32)^2 + 0.0335^2} = 0.2832 \text{ inch.}$$

We have further that $a = r_1 - r$, and $b = a \times \cos\theta$. Also $c = a \times \sin\theta$. Then $E = B + b$. Having obtained these dimensions we have:

$$R_3 = \sqrt{(C + h - c)^2 + E^2}.$$

Inserting the actual values in the formulas just given, we have:

$$a = \frac{9}{32} - 0.2832 = 0.00195,$$

$$b = 0.00195 \times \cos 15° = 0.00188,$$
$$c = 0.00195 \times \sin 15° = 0.00051,$$
$$E = 0.989 + 0.00188 = 0.99088,$$
$$R_3 = \sqrt{0.18923^2 + 0.99088^2} = 1.0088 \text{ inch.}$$

The found value of R_3 is the required radius of the tool. This radius is about 0.0075 inch greater than the radius R_1. The procedure may appear difficult at first sight, but a few examples in practice will make the user familiar with it.

While the angle of top rake as given is suitable for cutting the material specified, the distance C as given in Table II for the various machines is only suitable when cutting brass and drill rod and does not give sufficient peripheral clearance when cutting Norway iron and soft machine steel. The arrangement shown at C in Fig. 9 in the previous installment of this article should then be adopted, as the centers of both the form and cut-off tools would be raised as compared with the usual arrangement. This raising of the center is accomplished by putting packing strips of the required thickness under the tool-holder blocks.

Side Clearance on Circular Tools

The question of side clearance is a subject which few authorities seem to agree upon. Some advocate a great deal of side clearance, others only a slight amount, and still others, no clearance at all; in fact, some go as far as to say that a cut-off tool should be about 0.0015 inch narrower at the point than at the back. The greatest trouble with tools heating up and welding is not to be attributed to insufficient side clearance only, but to the quality of oil and other cooling lubricants used. It has been demonstrated that if a poor grade of oil is used and the tools made without side clearance, welding will surely occur; but take the same tools and use a good quality of lard oil, and the tools will run for days without welding. The writer admits that there are some cases in which side clearance is necessary, but the clearance should not be given as shown at *a*, Fig. 19, as this is not side clearance, but merely provision for pockets for the fine chips to lodge in, while the revolving stock forces the chips in and also tries to draw them out; and when a chip is drawn out, it leaves a rough finish on the end of the piece, and sometimes breaks the tool.

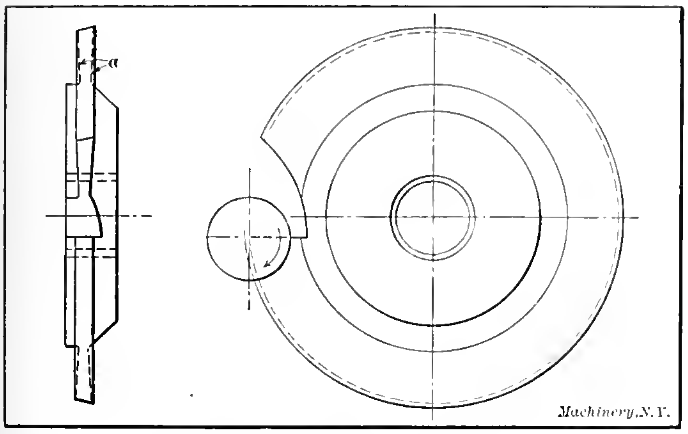

Fig. 19. Side Clearance on Circular Tools

When side clearance is necessary, and where the width of the slot is not important, a tool as shown in Fig. 20, where each section A of the tool is finished helically on each side, gives excellent clearance conditions. This tool is specially adapted for cutting vulcanite or fiber. It can also be used to advantage in cutting a very soft grade of iron. All the sections are ground, and when one becomes dull the following section is brought into position, and so on until the tool requires grinding again. When a tool is made without side clearance, it should be ground smooth on the sides, as any high spots on the face of the sides would cause heating and welding. A good grade of lard oil should also be used if good results are to be expected. When pieces as shown at A, Fig. 21, are being made the tools should be made without side clearance, and the faces ground and lapped as indicated. The form tool should be made in sections and straddle the thin portion of the piece; it should remain in position on the work until the angle on the edge of the cut-off tool is well into the stock as shown at *b*.

Speeds for Circular Tools

The conditions under which different work is made and the kinds of material used vary to such an extent that it is impossible to give any definite rules for the speed of the spindle or the feed of the tools, and whatever is said here is only by way of suggestion. The maximum speeds obtainable on the various Brown & Sharpe automatic screw machines are as follows: On the No. 00 machine the maximum spindle speed is 2100 R.P.M. and the maximum diameter of stock that can be turned is 5/16 inch; this gives a maximum surface speed of 197 surface feet per minute. On the No. 0 machine the maximum spindle speed is 1800 R.P.M. and the maximum diameter that can be turned is ⅝ inch, giving a maximum surface speed of 294 surface feet per minute. On the No. 2 machine, the maximum spindle speed is 1200 R.P.M. and the maximum diameter that can be turned is ⅞ inch, giving a maximum surface speed of 275 surface feet per minute. It can be easily seen that the greatest surface speed (294 feet per minute) is rather high for ordinary carbon steel tools even when working on brass rod. Then, if the highest speeds obtainable on the various machines mentioned are to be taken advantage of, a suitable grade of cutting steel must be used. This matter will be discussed later.

The following surface speeds can be used when the tools are made from Bohler's Styrian special steel:

Material	Surface Speed, Feet
Brass rod	200—300
Gun-screw iron	100—125
Norway iron and machine steel	80— 95
Drill rod and tool steel	60— 75

A good supply of lard oil should be provided, and the tools kept in good condition.

Feeds

In all cases, the feed is governed by the surface speed, the smallest diameter being formed and the width of the form tool. Feeds for forming tools are given in Table III. The widths covered here range from 1/16 to 1 inch, and the smallest diameters formed from 1/16 to 7/8 inch. It will be seen that a tool about ⅛ inch wide is, in general, adapted to take the coarsest feed. Tools from 3/32 to 3/16 inch (such as are commonly used for cutting-off purposes) admit of coarser feeds, as a rule, than either the wider or narrow tools. Thus the feed decreases as the tool decreases in thickness to 1/16 inch, except for small diameters, and increases from 3/32 to 3/16 inch. From 1/4 inch up, the feed must again be decreased to give satisfactory results. For cutting-off purposes the feed varies from 0.0008 to 0.0025 inch, depending on the nature of the material, the surface speed and the width of the tool. The feeds for machine steel, gun-screw iron and Norway iron should be less than the feed used for brass. The feed used in cutting off Shelby steel tubing should not exceed 0.001 inch per revolution; a surface speed as high as 125 feet per minute can be used with good results, when using tools made from Styrian special steel.

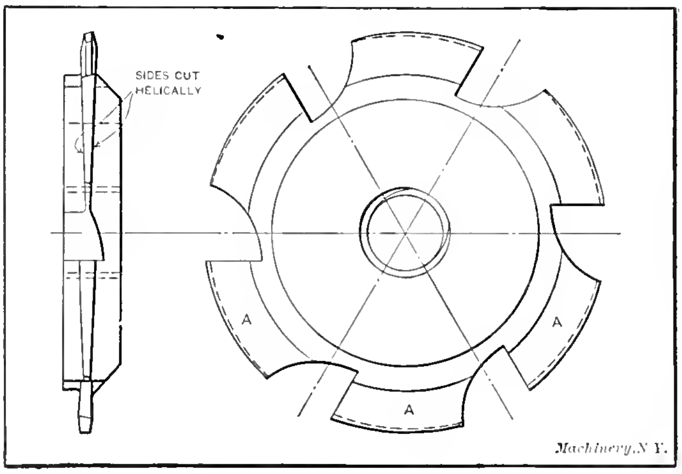

Fig. 20. Cut-off Tool with Side Clearance

Cooling and Lubricating Mediums

A proper cooling and lubricating medium is essential, if good results are to be expected. As previously stated, if a proper cooling and lubricating medium is not used, welding and excessive heating of the tools and work will result. There are various compounds on the market, some of them giving good results on certain classes of work, depending on the conditions under which they are used. Oil is used to advan-

tage in cutting internal and external threads where friction plays a very important part, but when cutting threads at high speeds, a cooling material largely composed of water is sometimes used. Oil will not conduct away the heat generated at high cutting speeds as rapidly as some of the special cooling compounds, because oil is more sluggish in penetrating to the point of the tool, where the chip is being cut or torn from the work. The writer would, however, advise that a good grade of lard oil be used on screw machines in preference to all other compounds or other poorer grades of screw cutting oil for the following reasons: 1. The speeds used are comparatively low. 2. A good supply can be furnished to the cutting edges of the tools. 3. Circular tools can be used without side clearance and yet give satisfactory results. 4. Good lard oil does not gum up the machines or cause rusting of the operating parts, as would be the case if cooling mediums composed of water and other compounds were used. The lard oil used should be thin and not sluggish, if good results are to be expected.

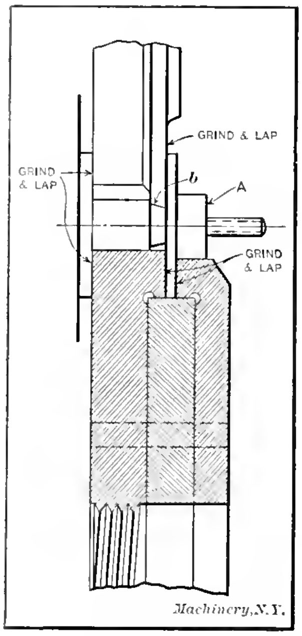

Fig. 21. Circular Form Tool without Side Clearance

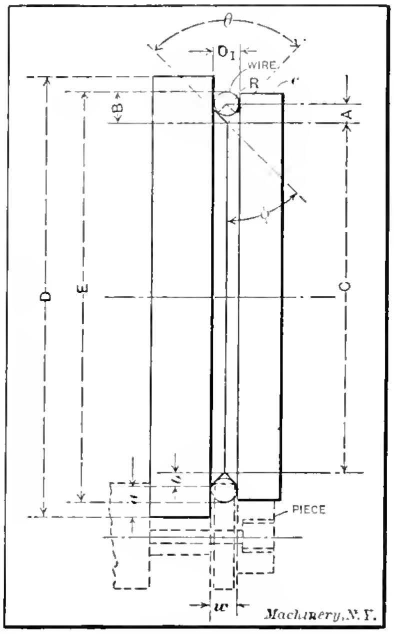

Fig. 22. Wire Method employed for Measuring Circular Form Tools

Selecting a Suitable Steel for Circular Tools

The conditions under which work is produced should determine the steel to be used in making the circular tools, *i. e.* if the piece to be made is of a very difficult shape, requiring sharp or thin projections on the tool, a grade of steel should be used which would not require a high heat to harden, as the thin projections are liable to become burnt or cracked while hardening. A brand of steel which has been found to give good satisfaction in such cases is Bohler's Gold Label special Styrian steel; this steel holds a fine edge satisfactorily and also gives a very smooth finish to the work; it is especially adapted for cutting brass. Care should be exercised in hardening this steel, as it hardens at a very low heat. Various other grades of special carbon and high-speed steel are used on screw machines, among which are the following: Jessops special steel, Novo high-speed steel, blue chip steel and Saben steel. Some of these kinds, especially Novo, give good results when high cutting speeds and feeds are used. Novo steel is frequently used for cutting machine steel and Norway iron, as it will stand a higher speed and a coarser feed than Styrian special steel; but where a high finish is required, Styrian steel should be used in preference.

Methods of Making Circular Tools

In designing circular tools, the question of making should be carefully considered, and where possible, the contour of the tool should be as simple as the requirements will permit. There are various methods employed in making circular tools of irregular shape, among them being the transfer scheme, templet system, master tools, and individual turning tools. For work requiring a fair amount of accuracy, the first two methods are not reliable. The master tool system is sometimes advisable when very difficult shapes are to be produced and when a large number of tools of the same shape are required. The writer considers that where a few tools are required, the individual turning tool method is the cheapest and best, and that direct measurements are more reliable than either the transfer scheme or templet system. The above-mentioned methods will be explained in the order in which they are given.

The Transfer Method

To illustrate what is meant by the transfer scheme, refer to Fig. 23; here a circular tool and setting gage are shown on the arbor *A*. The steps 1, 2, 3, 4, on the setting gage correspond with the various diameters required on the circular tool. The setting gage is turned to micrometer measurement and then copper plated with blue vitriol. To transfer the sizes from the setting gage to the circular tool, the master tools for the various shapes are brought in until they touch the setting gage, and the reading on the micrometer collar on the feed-screw is noted. The master tool is then brought into position on the circular tool and fed into the depth required, as indicated on the micrometer collar. The succeeding opera-

1	....	....	....	....	....	....	0.0002	0.0005	0.0008	0.00085	0.00095	0.001	0.0012

tions are continued in like manner until the desired shapes on the tool are completed. As previously stated, where a fair amount of accuracy is required, this scheme is not advisable, for the reason that if the feed-screw or slide has any lost motion, as is generally the case, the same pressure could not be brought to bear on the gage, when setting the master tool, as would be exerted on the circular tool when cutting to the indicated depth; then the circular tool would be larger in diameter than the setting gage.

Templets

Some authorities advocate making templets which conform to the contour of the piece to be made. Considerable skill is required to file complicated templets accurately, as any error which might occur would be doubled in the diameters of the product. It is just as easy to measure a circular tool, as it

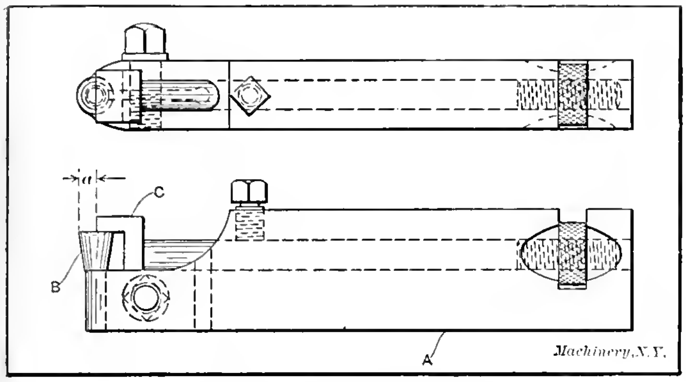

Fig. 24. Holder for Special Turning Tools

is to measure a templet, and in the first case the error would be less, as the measurement does not require to be transferred. The writer considers, that when accurate tools are required, templets should be avoided and direct measurements used instead.

Master Tools

Master tools are unnecessary, unless a large number of circular tools of the same shape are required. When master tools are being made, the differences in diameters due to the cutting down below center, should be calculated, and the tool made so that it can be set on the center of the work, when cutting the circular form tool, instead of setting the master tool below the center the required amount, as is advocated by some authorities. It is bad practice to set the edge of a tool much below the center of the work, as it tends to chattering, and the material is removed by a scraping action instead of being cut. In the majority of cases, it is prefer-

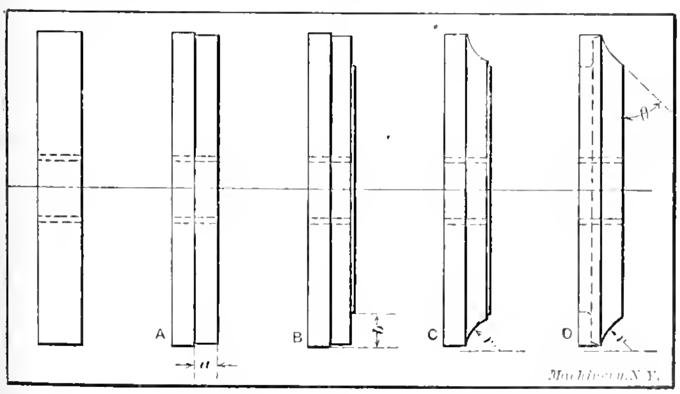

Fig. 25. Making Cut-off Tools for Spherical Work

able to make a circular master tool rather than a dove-tail tool, as the former is both easier measured and made.

Individual Turning Tools

The individual turning tool method, in conjunction with direct measurements, is preferable to all others, when only a small number of similar-shaped tools are required. In Fig. 24 is shown a tool holder A and tool B for forming the radii for oval head screws and other shapes of a similar character, special tools being inserted in the tool holder A, as required. When using this tool for forming circular cut-off tools, as shown in Fig. 11 in the previous installment of this article, the distance a is set equal to the radius of the tool B minus the amount that the center is ahead of the edge of the circular tool. The radius of the tool B is, of course, made equal to the radius required on the circular tool. The operating parts of this tool holder are clearly illustrated in Fig. 24.

The operations adopted in using this tool are shown at A, B, C, D, Fig. 25. The first operation A consists in taking a light cut (about 0.005 inch) across the circumference, making the distance a equal to the dimension D, shown in Fig. 11. Then a light cut is taken along the side as at B, making the distance b equal to the dimension X. Then the tool, shown in Fig. 24, is set square with the face-plate or at right angles to the centers, and the tool fed in, until the gage C touches the largest diameter of the tool, leaving the shape of the tool as shown at C, Fig. 25. A square nose tool is then set tangentially to the radius, forming the angle θ, as shown in Fig. 11. This square nose tool removes the material left after the operation at C, Fig. 25, and leaves the tool as shown at D. The individual turning tools used are concave tools, round or convex tools, square nose tools, and parting tools.

Measuring Difficult Shapes

When making circular tools of irregular contour, shapes difficult to measure are sometimes encountered. There are various tools and methods employed for this. An appliance to be used in connection with a micrometer for measuring deep slots and grooves is shown in Fig. 26. The special measuring pieces A are fitted to the anvil and spindle of the micrometer, and when the measurement is taken, the distances B are subtracted, giving the actual diameter of the tool. The pieces A can be made so that tools of very difficult shapes can be measured with accuracy. Where a form tool straddles a piece, the sharp corners produced by the tool rubbing against

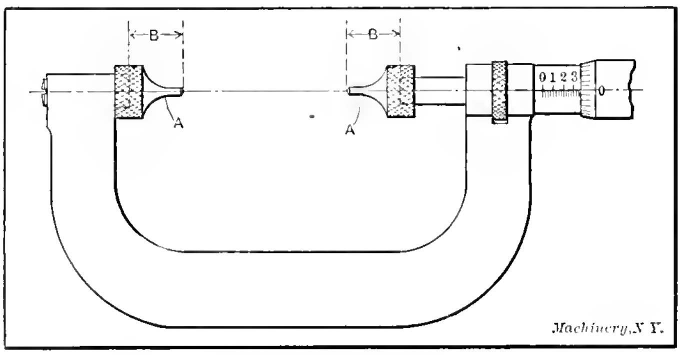

Fig. 26. Micrometer Arranged for Measuring Form Tools of Difficult Shapes

the sides are frequently objectionable and require to be removed. A form tool similar to that shown in Fig. 22 is sometimes used for this purpose. Making a tool of this description produces a form difficult to measure accurately, but by adopting the wire method, the measuring of the tool is somewhat simplified. To proceed with the wire method employed, refer to Fig. 22.

Let D = the largest diameter of the tool,
a = distance from outer edge of largest diameter of tool to bottom of chamfer, on the piece,
w = the width of piece to be chamfered,
ϕ = angle that chamfer makes with vertical line of tool,
b = distance from bottom of chamfer to apex or root of triangle,
C = the root diameter of tool,
R = the radius of wire,
A = distance from center of wire to apex or root of triangle,
E = the diameter over wires.

Then $b = \dfrac{w}{2} \times \cot \phi$; $C = D - 2(a + b)$

$$A = \frac{R}{\sin \phi}; \quad B = A + R; \quad E = C + 2B.$$

The dimension E can be calculated when the tool is being designed and put on the drawing, also giving the size of wire to be used. When the wires are below the part c, the pieces A shown in Fig. 26 can be used for finding dimension E.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

APRIL, 1910

PAID CIRCULATION FOR MARCH, 1910, 25,960 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition, $2.00 per year—coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 300 pages additional reading matter, and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

THE NECESSITY FOR ACCURACY

Quite frequently the complaint that young technical graduates cannot be trusted to do accurate work involving calculations and the keeping of records and data is voiced in the engineering press. It is impossible to say to what extent complaints of that kind are based on general defects inherent in the training of the technical graduate. No doubt in many cases they have been called forth by the work of individuals who do not fairly represent the whole body of young engineers. The experience in this office in the editorial work of revising contributed articles written by a great many young engineers has been that while general formulas are deduced with considerable ability and ingenuity, the arithmetical work in the examples calculated by the deduced formulas to show their application, is very often lacking in accuracy. This is rather a paradoxical condition, but the fact remains that it exists, and it is not difficult to find an explanation.

It is not unusual that engineering students while at the technical colleges are led to believe, by the very training they receive, that the deduction of formulas and a knowledge of their application to practical problems are the most important parts of an engineering education; and that the actual arithmetical work involved in the solution of examples is of minor importance. The engineering student apparently reasons, "I know arithmetic anyway." This habit of inaccuracy and of slighting work requiring only elementary knowledge formed perhaps during the college years, is often the cause of bitter experiences. In practical engineering work accuracy is of prime importance. What practical use is a high order of ability in deducing complicated formulas if, when these formulas are applied, errors appear in the arithmetical work and inaccurate results are obtained for a specific case? The only purpose that formulas serve is the convenience of their practical application in solving problems occurring in everyday engineering work. No matter how ingenious is the work of deducing the formula, errors in calculation involving the numerical values inserted therein render all the previous work of no value. Indeed the value of such formulas becomes even negative, because the result of a calculation based upon a formula known to be correct will command attention and confidence. Its accuracy will be assumed and may, therefore, cause mistakes in design which will entail loss in time and money and, in certain classes of work, danger to human life.

No engineer, regardless of his ability and genius, who is inaccurate in his work even in small and seemingly unimportant details should be trusted to carry out any important problems where his work cannot be readily checked. Indeed it appears that the aversion to young engineering graduates which is rather common among many manufacturers is largely due to the fact that such young men do not usually perform the minor duties which are at first entrusted to them with sufficient care. The average young engineer imagines that such work is not worthy of his superior education and so he slights it. He gets into the habit of carelessness, and unless he awakens to a realization of the necessity for accuracy and care in small matters, and in what he may consider unimportant work, it is likely to hamper his success for many years. The young man of mediocre ability who brings to his work care and diligence is much more likely to win the race than is the brilliantly equipped man who slights details because he considers them unworthy of his ability, and who falls into habits of inaccuracy and carelessness through which he finally loses the confidence of those who might otherwise be in a position to open up to him opportunities for progress.

DESIGNING AND INVENTING

The art of the machine designer is one to which it is difficult to assign a rigid definition. The machine designer is to a certain extent an inventor, but largely he is an adapter; and it seems that his abilities in the latter field are in general far more valuable than in the former. Practical machine designing does not consist so much in inventing radically new devices as in adapting old and well-known mechanisms and principles to new uses and arranging them in different relations to each other so as to perform new functions. Sometimes work of this kind may be classed as invention, but as a rule it is not. Invention is rather the devising of an entirely new mechanism, or an application of mechanical principles in a radically new manner. If inventions are defined as fundamentally new departures, it will be conceded that the machine designer's work is seldom of the nature of invention, but almost entirely a work of adaptation.

This by no means lessens the importance of the work of the machine designer. It is often as difficult, and certainly as important, to be able to apply known and tried devices and methods, to perform new operations, as it is to devise something entirely new which may require considerable experimenting and great expense for its perfection. As an example, in the construction of a machine requiring a friction clutch, the experienced designer could naturally lay out his work so as to employ a clutch of standard make rather than to invent one himself. The adaptation of machines to the use of certain standard parts makes possible the unit system of manufacture which is the most economical method of building machines in large quantities, and at the same time it permits of flexibility in design at small cost. The machine designer who insists upon making original designs of his own for all mechanisms required in his machines is, as a rule, a far less efficient man than one who confines his work to the arrangement and modification of devices already known to give satisfactory service, and thoroughly tried out in practice. The best qualification of a machine designer, therefore, is not always ability to invent, but ability to make proper use of existing inventions as well.

* * *

The abrasive power of grindstones, correctly applied, is second to none, the emery wheel not excepted. The peripheral speed of a grindstone should be from 1,600 to 1,800 feet per minute. The bearings should be self-oiling and self-aligning and the stone should be kept true by use of some truing device that will turn the face smooth and accurate without waste. High spots may be reduced by nicking, causing them to wear more rapidly than the low parts. Water should be applied copiously, but not in a flood, the supply being just sufficient to cover the face with a film that will carry away the heat.

THE INTERNAL COMBUSTION ENGINE

The past fifty years have been remarkable for mechanical development in many lines, and one of the most important improvements of that period was made in the internal combustion engine. This type of prime mover, which comprises gas, gasoline, oil, alcohol and other engines of various descriptions in which the fuel is burned in the work cylinder, dates from the introduction of the crude Lenoir engine in 1860. This was the first gas motor brought before the public, although by no means the first actually built. Since that date there has been a steady improvement in design and growth in size, until to-day there are in use gas engines of four thousand horse-power, or more, driving dynamos with the regularity and smoothness which characterize the best steam engines.

Although essentially simple, the simplicity of the gas engine is more apparent than real. Possessed of but few parts, there are nevertheless many defects likely to affect the gas engine that never trouble the steam engine. Poor ignition, back firing, carbon deposits, poor compression and short circuits are a few of the troubles that have played havoc with its reputation as a reliable motive power. The simplicity of its mechanism is in part responsible for these troubles. Not sufficient care was taken in the design and construction and the conditions of operation often were notoriously bad. But the advent of the motor boat and automobile has been followed by a great improvement in design and construction. The number of users has greatly increased, and their requirements for uninterrupted service have made imperative the elimination of the ordinary faults inherent in the earlier designs. The battery system of ignition, for example, has been largely superseded in automobile design by the magneto apparatus, so simple and reliable in certain makes that it will work immediately after submersion in water.

The gas engine has been an attractive subject to machinists, having been even more popular with them than the steam engine as a model for home construction. Many a machinist has procured the rough castings and other parts for a few dollars, and by working nights has built an engine with which as the motive power he started a humble repair shop of his own, with perhaps a lathe, drill and grinder as his principal tool equipment. From these humble beginnings have developed thriving manufacturing industries, and many of the minor improvements in the gas engine have been made by these unknown mechanics in building model engines. The success of the aeroplane may be largely attributed to the work of machinists—amateurs in the gas engine art—who built motors after their own ideas.

The steam engine is rapidly passing for small stationary plants, and it is practically out of the automobile field. The competition between it and the gas engine as the motive power of the automobile resulted in a complete victory for the latter. Its simpler construction, compactness, great power, superior economy and other valuable characteristics have won for it the leading place, and the trend is toward the use of gas engines as the motive power for all purposes. The modern gas producer and the improved gas engine are for manufacturing plants practically as simple to operate as the steam engine, and the cost of fuel and labor is less. Cheap fuel can be used; there is no boiler to explode, no tubes to leak, no trouble with water supply and little or no waste of fuel after the engine is stopped. The number of machine shops driven by gas engines is large and is growing, but the great users of the future will be the farmers, to whom the coming of reliable gas power means a new era in agriculture in which power-driven machinery will play a still greater part in the emancipation of farm labor than has the horse-drawn machinery of the past and present.

* * *

An idea of the enormous amount of labor represented by a battleship may be formed by the fact that the breaking up or taking apart of an old obsolete British battleship, the *Thunderer*, built in 1877, will require the work of 100 men for nearly two years. During the thirty-three years of existence this battleship has never appeared in war, its usefulness apparently having been limited to that of "insuring peace."

LIGHT AND RELIABLE GAS ENGINES

By A. S. ATKINSON

In the evolution of the gas engine, little attention was given to the weight of the motor per horsepower until it had reached a stage which made it reliable and adapted it to wide fields of usefulness. The chief question which first concerned the designers and manufacturers was how much power it was possible to obtain from a single engine working under economical loads, and how reliable it could be made under continuous operation. The first gas engines were comparatively small, and it was not believed that large ones could be built; but to-day mammoth gas engines are constructed without difficulty, the twin-tandem, double-acting motors of the new Gary steel mills having 3600 horsepower capacity each.

The question of reducing the weight of gas engines arose when builders of boats and airships began to experiment with this form of motive power. The elimination of superfluous metal in the gas engine is following the lines of development of the steam engine. A hundred years ago a steam engine which produced ten horsepower weighed some ten to twenty tons, including engine, boiler and all equipment. Similarly, the early gas engines were heavy and unnecessarily clumsy. Even those first used in automobiles were so large, heavy and clumsy that when mounted on trucks they left apparently little room for passengers or freight. The systematic cutting down of weight has progressed rapidly, and to-day designers are confronted with the question of how light a reliable gas motor can be made.

In marine engines weight and bulk have always been of more concern than for stationary engines. A factory plant cares less about weight and size of the motive power than of the capacity, reliability and cost of operation. Designers have consequently emphasized these points for all stationary work, and as a result many engines are installed on land which carry a great surplus of metal. The marine engineer, however, had to study the bulk and weight of the motor very much as the pioneers in the automobile and airship industries did. In light, frail torpedo boats, the weight of the engines per horsepower was a vital question from the first, and when it came to equipping the small motor boats with gas engines the same subject was forced to the front. The swift motor boat built for racing purposes had to carry high-speed engines in which every ounce of superfluous metal was whittled off.

The designers of motors for airships and aeroplanes had even more difficult problems to solve. The engine that proved suitable for the motor boat or automobile was far too heavy for the flying machine. The reduction in weight furthermore had to be accompanied by an increase in speed. The automobile or marine engine making 800 revolutions per minute proved satisfactory, but the aeroplane motor had to make from 1,000 to 1,400 revolutions per minute. A speed of twenty or thirty miles on the land or water was satisfactory, but the airship had to attain a speed of approximately thirty-five miles to keep up in the air.

The systematic study of reduction of weight of gas motors per horsepower was therefore undertaken by designers of engines for flying machines, and to them we owe much of our knowledge of this subject. In the race for light motors, however, it is undoubtedly true that reliability has in most instances been sacrificed for speed and lightness. Every aeronaut to-day agrees that the greatest problem of flight awaiting solution is that of a light and reliable motor. The problem of flying has been solved but not the problem of the motor. Nearly all of the mishaps and troubles in flying are caused by the motor skipping, missing fire, or breaking down at some critical moment. When the modern airship is once in the air, it can fly as long as the motor runs and the fuel lasts.

The weight of the motor to-day with its magneto equals about one-fifth of the whole weight of the aeroplane. The aim is to whittle these motors down to the minimum and then construct them so that they will be absolutely reliable. The goal apparently is one pound of metal per horsepower, which to say the least is a rather startling proposition to

* Address: P. O. Box 1189, New York City.

those accustomed to heavier machinery. The inventors and designers of the leading types of airships are indefatigable workers in developing and perfecting their motors, and the secrets of this part of the equipment are jealously guarded. The new Herring-Curtiss motor weighs only fifty-two pounds and generates on a solid foundation approximately 24 horsepower. Some of the French motors for aeroplanes weigh 125 pounds, and generate thirty and forty horsepower. There are as many varieties of motors for airships as there are types of flying machines, and they often differ in many minor points and in some of the more vital ones. The horsepower varies from 25 in the Curtiss and 30 in the Wright machine up to 50 in the Antoinette monoplane. The American motors are mostly of the four-cylinder type, while some of the French motors run up to a dozen or more cylinders. The different airship motors are both air-cooled and water-cooled.

Taking the airships as a whole the average power generated is about twenty-five horsepower, and the approximate weight is three pounds to the horsepower. One firm, however, is now claiming that it can make good reliable motors which will weigh only one and a half pounds per horsepower generated, while another is making an 80-horsepower motor with a total weight of 300 pounds. This motor has eight cylinders grouped in pairs around a center crank chamber which contains a two-throw crank. Two carburetors and two magnetos are used; the piston bore is 3.54 inches and the combined stroke is 6.3 inches. Another modern high-powered light, reliable gas engine weighs 176 pounds and generates 40 horsepower. In all of these light engines designed for aeroplanes, high speed is, of course, as essential as lightness. A motor weighing one and a half to two or three pounds per horsepower running at 1,200 to 1,400 revolutions per minute, and mounted on a very flexible foundation, must of necessity be a remarkably delicate piece of machinery. It is the flexible base which gives designers of airship motors most trouble. It has been found by actual experience that the motor loses about 30 per cent of its power when mounted on the aeroplane. This loss must therefore be considered in testing the engines for actual use.

In the effort to solve the airship motor problem designers have turned their attention again and again to the gas turbine. If an efficient gas turbine could be constructed that would be suitable in other respects, the matter of revolutions would no longer present difficulties. Fifteen hundred revolutions per minute, which is now considered extremely high for the reciprocating motor, would be comparatively slow for an efficient gas turbine; but this would require in addition to a continuous force a perfect balancing of the whole engine, and this must be worked out better than it has been so far on the aeroplane.

The lack of reliability of gas engines designed for aeroplanes has been taken up by manufacturers of motors in general, and they are trying to solve the problems which the pioneer aeronauts have failed in. Probably every gas engine manufacturer to-day is experimenting with light high-speed motors, even though they do not advertise them or even put them on the market. They realize that for certain kinds of work these motors will prove of the greatest value. They will be suitable for speed crafts, hydroplanes, and possibly very light torpedo boats as well as for flying machines. Even very small boats such as skiffs and canoes will be greatly improved by having light high-speed motors.

Incidentally the question comes up for consideration as to whether the engines of extreme types have not been reduced in weight too much for practical and reliable work. Is it possible to design and construct a reliable and efficient high-speed gas motor that will weigh only a pound or two per horsepower? Not a few of the leading manufacturers agree that the craze for lightness in motors has handicapped the flying question, and that matters would be greatly improved if the aeronauts would accept a heavier machine which would run smoothly and easily for a long time. Motors for automobiles and boats can be run indefinitely without a stop or a miss, and if the airship expects to attain similar endurance the motor must be made heavier and more reliable.

It would be difficult to set absolutely the lowest weight of a motor for a given speed and horsepower, for in the past it has frequently been demonstrated that the triumphs of one generation have been easily eclipsed by those of the next. Apparently, however, a pound of metal per horsepower would seem to be the ultimate goal.

The air-cooled engine has an advantage over the water-cooled motor for airships if other things are equal, for the body of water which the latter must carry in the jacket must be taken into consideration in considering weight. But there are many difficulties in the way of designing light, speedy engines which can be practically cooled by air, and a motor that gets too hot after a short run in the airship is a decided failure. It cannot be stopped in mid-air to cool off as might be the case in a boat or automobile. It must keep on working at all times in order to keep the ship floating. A few skips or a short stop from overheating means an inglorious descent.

A type of air-cooled engine for flying machines which represents some of the greatest advances in designing is the French motor used in the Petleris airship which won a short distance prize last November. The specifications of these motors are as follows:

Horsepower	Number of Cylinders	Speed	Weight in pounds
20-25	5	1000 R.P.M.	115
35-40	7	1000 R.P.M.	150
40-50	10	1000 R.P.M.	216

The pistons of these engines are of turned steel, and the cylinders are placed fan-like; but these motors, like all others designed for airships, have their rating based upon actual work on a solid foundation. In all of these light-weight motors running at high speed there must be ample cooling surface, generous bearing surfaces in the wearing parts, perfect magneto ignition, and forced lubrication which will not get out of order.

* * *

THE NITER PROCESS FOR BLUING IRON AND STEEL

Attention is called in the *Brass World* to the niter process for bluing iron and steel. This process was first brought to the notice of the public in a paper read before the American Society of Mechanical Engineers, by Mr. William H. Weightman in 1886. This method produces a beautiful color and may, therefore, be of general interest. The process is very simple, the niter (nitrate of potash, often called saltpeter) is melted in an iron pot and heated to about 600 degrees F. The articles to be blued are cleaned and polished and then immersed in the molten niter, in which they are allowed to remain until the desired color has been obtained in a uniform manner. Only a few seconds are required, or, in general, only the length of time necessary for the articles to arrive at the heat of the niter. The articles are then removed and allowed to cool, after which they are immersed in water and the adhering niter washed off. Articles which will not warp or twist may be immersed in water immediately after having been removed from the niter. After the cleaning process the articles are dried in sawdust and then oiled with suitable oil, such as linseed, to prevent them from rusting. If a uniform color is to be attained continuously, a pyrometer should be used to control the temperature of the heated niter, because a higher heat than 600 degrees F. will produce a dark color, while a lower heat will make the objects light.

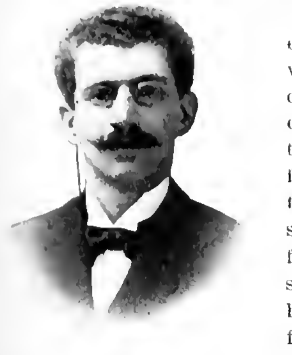
The niter process can scarcely be called suitable for small articles on account of its cost. Niter itself is not expensive, but the pieces must be dipped carefully in order to obtain the desired color and the handling in washing them off afterwards and drying them makes the cost per piece high. It is, therefore, used mostly for medium-sized and large work.

* * *

The German Post Office Department has adopted a letter-registering machine by means of which, in order to register a letter, all that is necessary to do is to insert it in a slot in the lid, which closes automatically as soon as the letter is dropped, and to turn a handle. This operation stamps the letter with the name of the post office, the date and a number, and delivers a receipt similarly printed. How the registration fee is collected by this device is not explained in the description published in an English contemporary, from which this information is obtained

THE DESIGN OF A PLATE GIRDER*

By MARTIN JOACHIMSON†



Martin Joachimson‡

While the design of plate girders does not strictly belong to the work of the mechanical engineer or draftsman, they are often called upon to carry out work of this character. Girders under uniform load, or with one concentrated load in the middle of the span, may readily be selected from tables in the handbooks issued by the steel manufacturers, but even these do not always conform to the building laws of the various cities, and their economy of steel is not always the greatest. Girders carrying a uniform load and a number of concentrated loads must be designed for their specific purpose, but this is a comparatively simple problem, as the following example shows.

The problem here given will be to design a plate girder to span an opening of 30 feet in a brick wall of 12 inches thickness; the wall above the girder, including roof and floor loads which it carries, produces a uniform load of 2,000 pounds per foot of girder. Besides this, provision should be made for two hangers to support shop trolleys at points 9 and 11 feet from the sides of the opening and each capable of sustaining a total load of 5 tons.

Dimensions of Girder

The depth of a plate girder may be taken as 1/12 of its span which gives 30 inches as the depth. The girder should rest on the wall on both sides for a distance of ½ its depth, which gives a total length of 32 feet 6 inches. The length used in the calculations is taken from center to center of pressure and equals 31 feet 3 inches.

To determine the effective depth of the girder and its weight, the sizes of material to be used must be assumed. As the wall above the girder is 12 inches thick the cover plates will be of this width, and the horizontal flanges of the angles will be made 5 inches, as the two angles and web included will then nearly come to the same width as the cover plates. The other flange of the angles may be 3 or 3½ inches, as only one row of rivets will have to be used. The web of the girder will tentatively be made ⅜ inch thick by 30 inches deep. This gives the weight as follows:

Weight of four $5 \times 3\frac{1}{2} \times \frac{1}{2}$ inch angles $= 4 \times 13.6 = 54.4$ pounds per foot.

The value 13.6 in the above calculation is found from the accompanying Data Sheet Supplement. The lengths of the legs are first added ($5 + 3\frac{1}{2} = 8\frac{1}{2}$), and then the weight is found in the section corresponding to the sum of the lengths of the legs and opposite the thickness, which in this case is ½ inch.

Weight of 2 cover plates, $12 \times \frac{1}{2}$ inch $= 2 \times 6 \times 3.4 = 40.8$ pounds per foot.

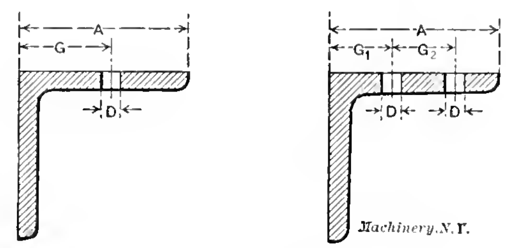
The factor 3.4 in the above calculation is the weight of a steel bar one square inch in section and one foot long.

Weight of web plate, $30 \times \frac{3}{8}$ inch $= 30 \times 0.375 \times 3.4 = 38.25$ pounds per foot.

Total weight per foot $= 54.4 + 40.8 + 38.25 = 133.45$ pounds, or with details, about 140 pounds.

The effective depth of the girder is the depth between the lines of centers of gravity of the flange angles. The location of the center of gravity for structural shapes is given in the steel manufacturers' handbooks, and for an angle $5 \times 3\frac{1}{2} \times \frac{1}{2}$ inch is at a distance of 0.91 inch from back of longer leg. In the example given, we have a web of 30 inches depth; the angles generally protrude from ⅛ to ¼ inch on both sides of the web which will give a distance from back to back of angles of, say, 30½ inches. Deducting from this $2 \times 0.91 = 1.82$ inch, we have an effective depth of $30.5 - 1.82 = 28.68$. We have now to find the combined bending moment of the concentrated and uniform loads. We lay out, in Fig. 1, the dimensions of the girder which we have found, to scale (say ¼ inch = 1 foot), and the bending moment of the concentrated loads can be found graphically by drawing, to the same scale as used for Fig. 1, the force polygon of these two loads (A and B) using a definite length as pole distance (say 100 inches), as shown in Fig. 2. If we use a scale of forces of 10,000 pounds = 1 inch, for the two loads, we will derive our bending moment in a scale of 100 inches × 10,000 pounds = 1,000,000 inch-pounds = 1 inch. We draw a vertical line cd (representing load A) equal to 1 inch or 10,000 pounds, and de (representing B) equal to 1 inch or 10,000 pounds. From d draw horizontally do equal to 100 inches to scale of Fig. 1, and connect c and e with o, which completes the force polygon.

TABLE I. RIVET SPACING IN ANGLES



One Row of Rivets

Length of Leg	Distance to Center of Rivet	Max. Size of Rivets	Length of Leg	Distance to Center of Rivet	Max. Size of Rivets	Length of Leg	Distance to Center of Rivet	Max. Size of Rivets
A	G	D	A	G	D	A	G	D
8	4½	⅞	3½	2	⅞	2	1⅛	⅝
7	4	⅞	3	1¾	⅞	1¾	1	½

Returning to Fig. 1, we start from a vertical line through one of the points of support R and draw lines P, T, and S parallel to lines co, do, and eo of the force polygon and connect the ends of the lines P and S by a line V. Any vertical distance between lines P, T, or S and line V represents the bending moment due to the loads A and B at that point to the selected scale of 1,000,000 inch-pounds = 1 inch. We find that this moment in the center of the girder is 1,320,000 inch-pounds by scaling the vertical distance between the lines T and V at this point. The line of (Fig. 2) drawn parallel to line V divides ce into the two reactions R_a nearest load A and R_b nearest load B. The bending moment of the

* With Data Sheet Supplement.
† Address 518 West 156th St., New York City.
‡ Martin Joachimson was born in Breslau, Germany, in 1867, and received his general education at the high-school of his native town, and his theoretical technical training in a four-year course at the College of Technology in Berlin. He served a four-year apprenticeship in an instrument-making and general machine shop in Breslau, and has since been engaged with the Ludwig Loewe & Co., Siemens & Halske, the Union Electric Co., and the General Electric Co. of Germany. Upon coming to America Mr. Joachimson was first employed by the American Sugar Refining Co., and then by R. Hoe & Co. He is now in the employ of the city of New York in the Department of Bridges. He has worked as machinist, foreman, draftsman and mechanical engineer, and his specialty is machine design and the systematizing of shop work; some electromedical apparatuses have been designed and patented by him. Besides MACHINERY, Mr. Joachimson has contributed articles to the *Electrical World*, the *Engineering News* and the *Technologist*.

uniform load for the center of the girder is computed by the formula

$$M = \frac{wl^2}{8}$$

where w equals load per foot,

l equals length between supports.

From the given data and the computations already made, we have:

$w = 2140$ pounds (including weight of girder),

$l = 31$ feet 3 inches.

Hence:

$$M = \frac{2140 \times 31.25^2 \times 12}{8} = 3{,}135{,}000 \text{ inch-pounds.}$$

The variation of this moment is indicated by the ordinates of a parabola whose vertex is the maximum moment or 3,135,000 inch-pounds in the scale of moments already adopted (1,000,000 inch-pounds = 1 inch). We can draw this parabola by pointing off on the center line of the girder points C and L, 3.135 inches apart; draw horizontal lines through these points, divide the lines DC, DF, CE and EG into an equal number of parts, say 10, and draw horizontal and vertical lines through these divisions, numbering them respectively 1, 2, 3, etc., and I, II, III, etc., as shown. Draw, now, lines radiating from C to I, II, III, etc. The points of intersection of these radiating lines with the corresponding vertical lines are points of the parabola. After the curve is drawn through these points, lay off the vertical distances of the moment diagram of the concentrated loads above the parabola, which results in the com-

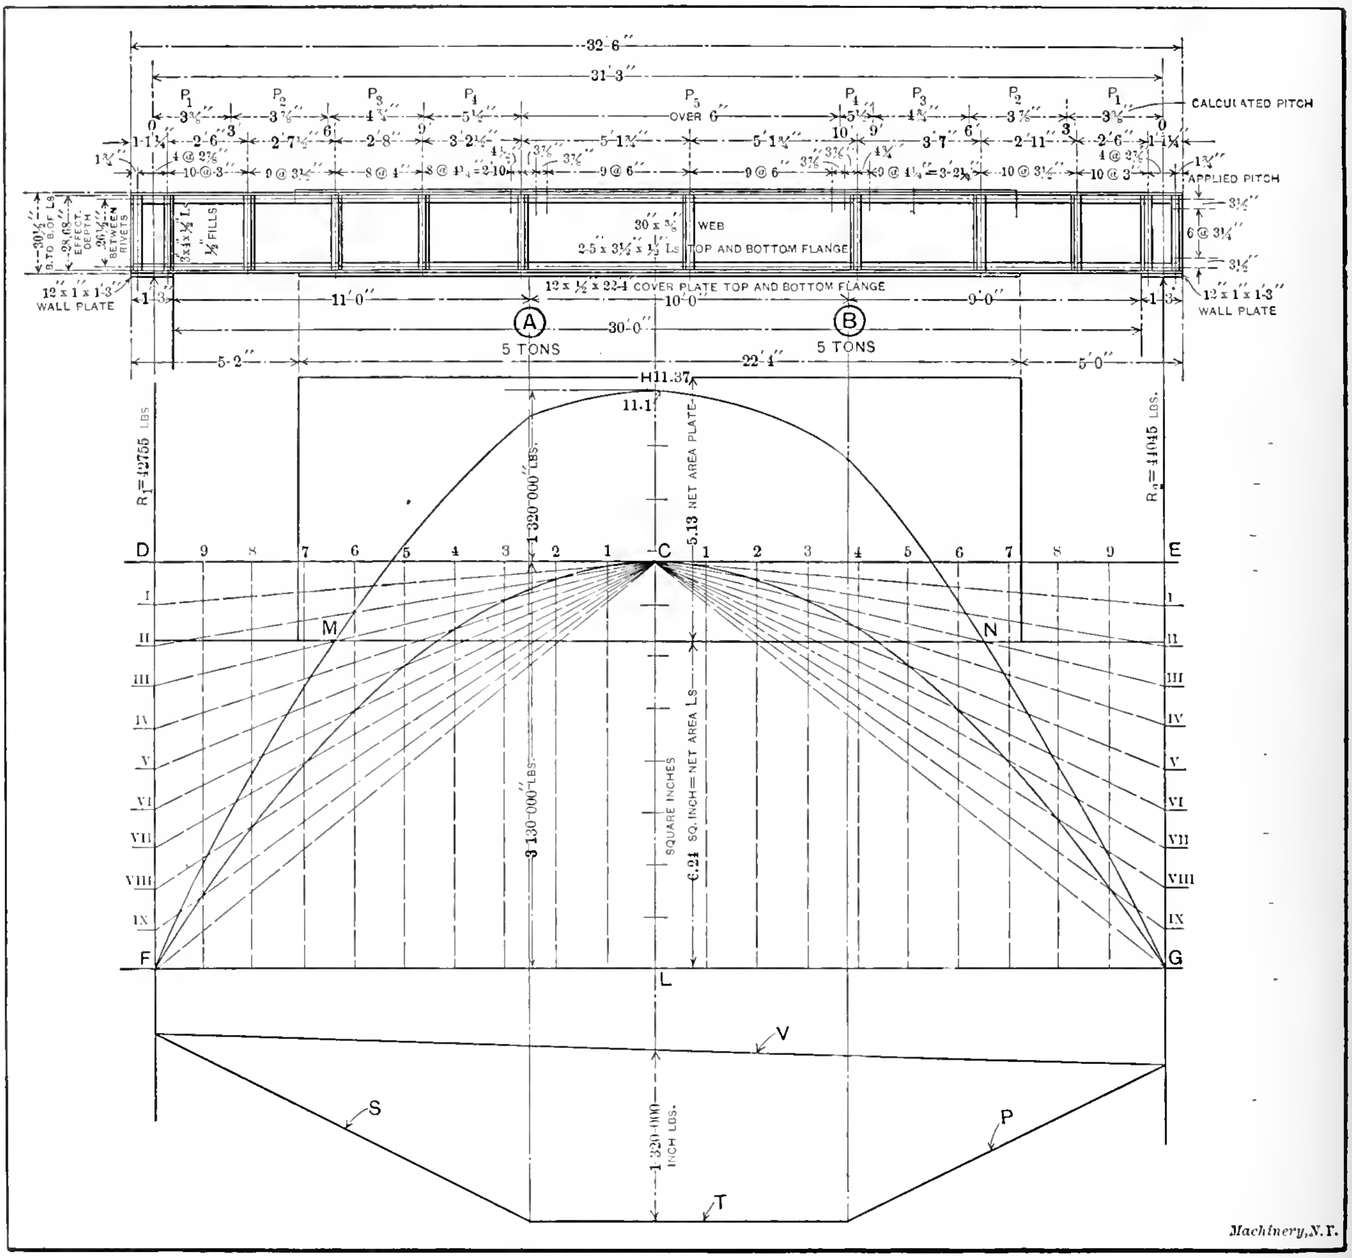

Fig. 1. Plate Girder and Graphical Construction for Obtaining the Bending Moments

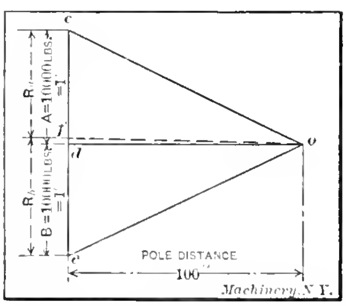

Fig. 2. Auxiliary Diagram for Obtaining Bending Moment Diagram in Fig. 1

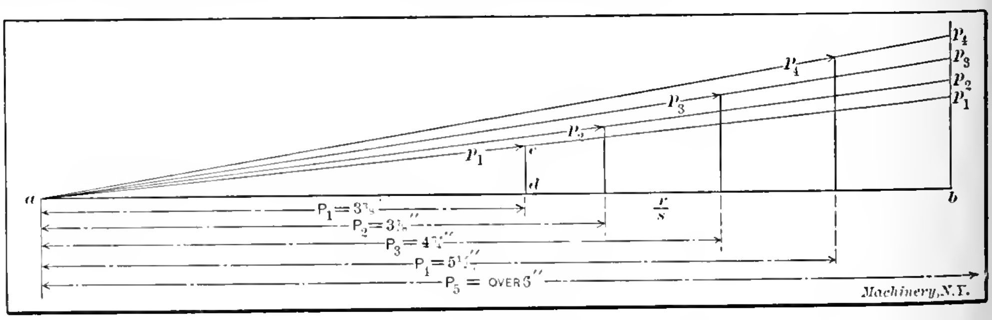

Fig. 3. Diagram for Aacertaining the Pitch of Rivets

bined moment curve FHG. The maximum bending moment in the center of the girder is represented by line LH and equals 4,450,000 inch-pounds.

We can now determine the flange area and length of the cover plates. The net flange area F_a, in square inches, is:

$$F_a = \frac{M}{df}.$$

where M = bending moment in inch-pounds,
d = effective depth of girder in inches,

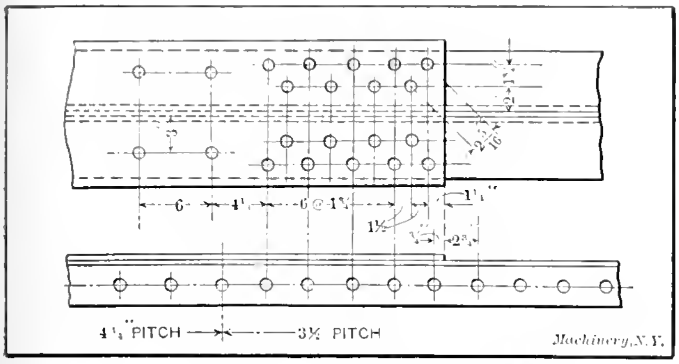

Fig. 4. Arrangement of Rivets and Ends of Cover Plate

f = permissible stress per square inch.

The New York City building law permits f = 14,000 pounds.

$$\text{Therefore } F_a = \frac{4,450,000}{28.68 \times 14,000} = 11.1 \text{ square inches.}$$

We divide now the distance HL, representing the maximum bending moment, in 11.1 parts, representing square inches of flange area. One-half of the flange area (5.55 square inches) should be included in the two angles. From the Data Sheet Supplement we find that the net area of a 5 × 3½ × ½-inch angle with two ¾-inch rivet holes deducted equals 3.12 square inches, and for two such angles the area is 6.24 square inches. A 12 × ½-inch cover plate has a gross area of 6 square inches from which two holes for ¾-inch rivets in ½-inch metal must be deducted. (The hole must be taken ⅛-inch larger than the diameter of the rivet.) The Data Sheet gives 0.87 square inch as the area to be deducted, and we have the net flange area:

Angles = 6.24 square inches
Plate = 5.13 square inches

Total flange area = 11.37 square inches

An inspection will show that a 5 × 3 × ½-inch angle would not give the desired area.

To determine the length of cover plates we point off in our diagram from L on line LH, 6.24 parts for the area of the angles, and continue the divisions above H to 11.37, drawing horizontal lines through both points. The theoretical length of the cover plate extends from M to N, the intersections with the curve of moments. The actual length of the plate is extended one foot on both sides or to 4 feet 6½ inches from the left and 4 feet 4½ inches from the right center of support.

We can now proceed to design the web plate of the girder, which must sustain the maximum shearing stress without buckling. The reactions at the supports are:

Reaction R_1:

From uniform load: $2140 \times 15.625 = 33,400$ pounds

From load A: $\dfrac{10,000 \times 19.625}{31.25} = 6,280$ pounds

From load B: $\dfrac{10,000 \times 9.625}{31.25} = 3,075$ pounds

Total $R_1 = 42,755$ pounds

Reaction R_2:

From uniform load: $2140 \times 15.625 = 33,400$ pounds

From load A: $\dfrac{10,000 \times 11.625}{31.25} = 3,720$ pounds

From load B: $\dfrac{10,000 \times 21.625}{31.25} = 6,925$ pounds

Total $R_2 = 44,045$ pounds

Our web plate will be 30 inches deep and we will try the assumed thickness of ⅜ inch for strength. The permissible shearing strain according to the New York City building law is 9,000 pounds per square inch for web plates.

The gross area of the web is 30 × 0.375 = 11.25 square inches. Assuming that 9 rivets, ¾ inch in diameter, connect the end stiffeners to the web, we must deduct 9 × 0.33 = 2.97 square inches (see Data Sheet), which leaves a net area of 8.28 square inches. This area will stand a shearing strain of 8.28 × 9000 = 74,520 pounds, which is ample, as the maximum required is 44,045 pounds.

TABLE II. CENTER DISTANCES C FOR STAGGERED RIVETS

2 3/8	2 1/2	2 9/16	2 5/8	2 11/16	2 3/4	2 13/16	2 7/8	2 15/16	3	3 1/8	3 3/16	3 1/4	3 3/8	3 7/16
2 1/2	2 5/8	2 11/16	2 3/4	2 13/16	2 7/8	2 15/16	3	3 1/16	3 1/8	3 3/16	3 1/4	3 3/8	3 7/16	3 9/16

Note: Values below or to the right of upper zigzag lines are large enough for ¾ rivets
Values below or to the right of lower zigzag lines are large enough for ⅞ rivets

We must now investigate for safety against buckling. Stiffeners must be used at proper intervals along the girder if the shearing strain exceeds

$$S = \frac{11,000}{1 + \dfrac{l^2}{3000t^2}}$$

where l = distance between upper and lower rivet lines,
t = thickness of web.

The distance back to back of the angles is 30½ inches, and the distance from back of angle to the rivet for a 3½-inch leg

is 2 inches, as given in Table I. This gives the distance between rivet lines $26\frac{1}{2}$ inches, and the safe strain against buckling per square inch

$$S = \frac{11{,}000}{1 + \dfrac{26.5^2}{3000\, t^2}} = \frac{11{,}000}{2.665} = 4{,}130 \text{ pounds per square inch,}$$

while the shearing stress equals

$$\frac{44{,}045}{8.28} = 5{,}320 \text{ pounds per square inch.}$$

Thus the web is not safe against buckling.

We require therefore either a thicker web or stiffeners at the ends of the girder, at the concentrated loads, and at regular intervals. These intervals should be about equal to the depth of the girder at the ends, getting larger toward the center, but never more than 6 feet.

Rivet Spacing

Enough rivets must be provided in the end stiffeners to transmit the end shear from the web plate to the supports. The permissible shearing strain for rivets is 10,000 pounds per square inch, and the bearing pressure 20,000 pounds per square inch. Tables giving values for different rivet sizes will be found in all the steel manufacturers' handbooks. A ¾-inch rivet in double shear will resist 8,836 pounds, but bearing in a ⅜-inch plate only 5,625 pounds, which, therefore, is the critical value in this case. Hence we find that $\frac{44{,}045}{5{,}625} =$ 7.8, or, say, 8 rivets are required. It is customary to provide two end stiffeners for girders resting on walls, at each end of the girder, and we will select 4 × 3 × ½-inch angles for this purpose, with 3 × ½-inch fillers between the flange angles. When determining the pitch of the rivets, we will find that the best arrangement is to place nine rivets in each stiffener, making six spaces of $3\frac{1}{4}$ inches and two of $3\frac{1}{2}$ inches, or a total of $26\frac{1}{2}$ inches.

The rivets in all stiffeners are generally spaced alike and should have the same or nearly the same pitch as the flange angles at that point, which makes the pitch of the end stiffeners governing all others.

The rivets connecting the flange angles to the web must transmit the horizontal shear. Their pitch is determined by the formula

$$p = \frac{r \times d_1}{S}$$

where r = value of one rivet = 5,625 pounds,
d_1 = distance between rivet lines = $26\frac{1}{2}$ inches,
S = horizontal shear.

The horizontal shear at any point is equal to the nearest end reaction, minus all the loads between the point and this reaction. We will determine the pitch at points 3, 6, 9 and 10 feet from R_2, the larger reaction.

Distance from R_2, Feet	Load between Point and R_2, Pounds	Horizontal Shear, Pounds S	Pitch $p = \frac{r \times d_1}{S}$ Inches	Corrected Pitch from Diagram Fig. 3
0	0	44,045	$3.38 = p_1$	$3\frac{3}{8} = P_1$
3	6,420	37,625	$3.96 = p_2$	$3\frac{7}{8} = P_2$
6	12,840	31,205	$4.78 = p_3$	$4\frac{3}{4} = P_3$
9	19,260	24,785	$5.60 = p_4$	$5\frac{1}{2} = P_4$
10	21,400 + 10,000	12,645	$11.80 = p_5$	over 6 $= P_5$

The rivets in the upper flange carry the direct load of the wall besides the horizontal shear, and the pitch must be corrected for this additional load, which is best done graphically.

Find the load s per 1 inch of the upper flange, which in this case equals $\frac{2000}{12} = 166.67$ pounds. In Fig. 3, line ab, drawn to any convenient scale, represents $\frac{r}{s} = \frac{5625}{166.67} = 33.75$, lines bp_1, bp_2, etc., are the pitches at the points required. If we lay out on line ap_1 to a larger scale the value of the pitch in the first 3 feet, as shown, the line cd perpendicular to ab cuts off distance ad, which is the corrected pitch P_1 in the first 3 feet. The same method is repeated for P_2, P_3, etc., for which the corrected pitch P_1 to P_5 is given in the foregoing table.

The rivets connecting the cover plates can be spaced 16 times the thickness of the outside plate or 16 × ½ = 8 inches apart, but 6 inches is the maximum pitch for any rivet spacing, which governs in this case as well as for the rivets in the flange angles between the two concentrated loads. At the ends of the cover plates enough rivets must be placed to develop their full strength, and the pitch of the rivets must be the closest possible. The full strength of the cover plates is their net area, times 14,000, or

12″ × ½″ — 2 holes for ¾-inch rivets = 5.125 square inches ×
14,000 pounds = 71,750 pounds,

which must be taken by the rivets which are in single shear.

Then $\frac{71{,}750}{4{,}418} = 17.3$, or, say, 18 rivets are required. Their closest spacing may be three times their diameters or $2\frac{1}{4}$ inches. These rivets will be "staggered" in two rows, and their position will be governed by the gage lines for 5-inch angles, the rivets in the vertical legs of the same angles, the minimum stagger, and the minimum distance from the edge of plate. The minimum distance of a rivet from the edge of a plate or angle is usually $1\frac{1}{2}$ times the diameter of the rivet, but is generally made $1\frac{1}{4}$-inch for a ¾-inch rivet, and $1\frac{1}{2}$-inch for a ⅞-inch rivet. The position of the rivets is shown in Fig. 4. The gage lines for 5-inch angles are 2 and $3\frac{3}{4}$ inches from back of the angle respectively (see Table I). Table II for the staggering of rivets gives $1\frac{1}{2}$ inch as minimum pitch for ¾-inch rivets and $1\frac{3}{4}$-inch distance of gage lines with 2 5/16 inches distance between centers of rivets. This can be adopted for the first two spaces but the pitch in the vertical ($3\frac{1}{2}$-inch) leg of the angle is $3\frac{1}{2}$ inches, and some of the other rivets would interfere. For this reason the pitch must be made $1\frac{3}{4}$ inch for the rest of the rivets.

The bearing plates at the ends of the girder must be large enough to transmit the end reaction to the wall. Generally a stone is placed beneath them and their size depends on the pressure this stone is able to sustain. For bluestone the building law permits 2,000 pounds per square inch. A plate 12 × 15 inches would be the smallest that could be used. The thickness of the plate should be double the thickness of the flange angles or 1 inch. For practical purposes the upper cover plate is carried to the ends of the girder to give an even bed for the wall.

* * *

SPOT ELECTRIC WELDING

A method of electric welding has been developed within a few years that differs from the common electric welding process in one important essential. It is known as "spot" welding and virtually amounts to electric riveting. The process is employed for joining thin metal plates that ordinarily would be united with iron or copper rivets and which are not required to make a watertight joint. The electrodes are pressed against the sheet metal pieces assembled in the desired relation and almost instantly the metal of both plates fuses and joins at the point of application. The union is of the most permanent nature, being much stronger than ordinary riveting because with the ordinary rivet the strength is generally limited to the shearing resistance of the heads, this usually being unequal to the tensile strength of the body. In the electric form of rivet the cross-section of metal in the spot is the measure of strength unless the metal is very thin, in which case the heads would shear out of the plate, of course. The number of applications in spot riveting depends on the area of the pieces joined, and the need for firm union. The process being rapid, the spot rivets may be thickly set at comparatively low cost.

* * *

It is stated in the *Brass World* that metals and alloys cast in chilled molds sometimes will have their tensile strength doubled by this process as compared with their strength when they are cast in sand.

THE FIRST AVIATION MEET IN AMERICA

A RECORD OF THE PERFORMANCES AND A DESCRIPTION OF THE MACHINES

By LEROY W. ALLISON*

Aeroplane development within the past year has been remarkable. The recent aviation contests, the first of their kind in this country, held at Dominquez, fourteen miles from Los Angeles, Cal., has brought forcibly to mind that we are now embarking upon an era of aerial navigation and that aeroplanes are to be a coming means of locomotion; one thing is self-evident, the flying-machine has great possibilities and the time is not far distant when it will enjoy much of the popularity now accorded the automobile.

This event was the second of its character to be officially recognized by the International Aeronautical Association (the first being at Rheims, France, in August, 1909). It served to elucidate to the American people many of the enigmatical problems surrounding the various types of air-craft. The climatic conditions of this section offer advantages to aerial work found in few other parts of the world, and records were made at this meet which only superior motor and controlling power in improved models of future aeroplanes can eradicate. The success of the exhibition far exceeded the expectations of the promoters, for during the eleven days, January 10 to January 20, there were over 176,000 paid admissions to the field, and fully 200,000 people, including press representatives, etc., witnessed the contests. The seating capacity of the grand stand was 26,000; it was set at the side of the inclosure, directly in front of a large marked-out square, which designated the starting point for the machines to leave the ground. To the rear of this square, for about one hundred yards, the ground was leveled to afford smooth running previous to flight.

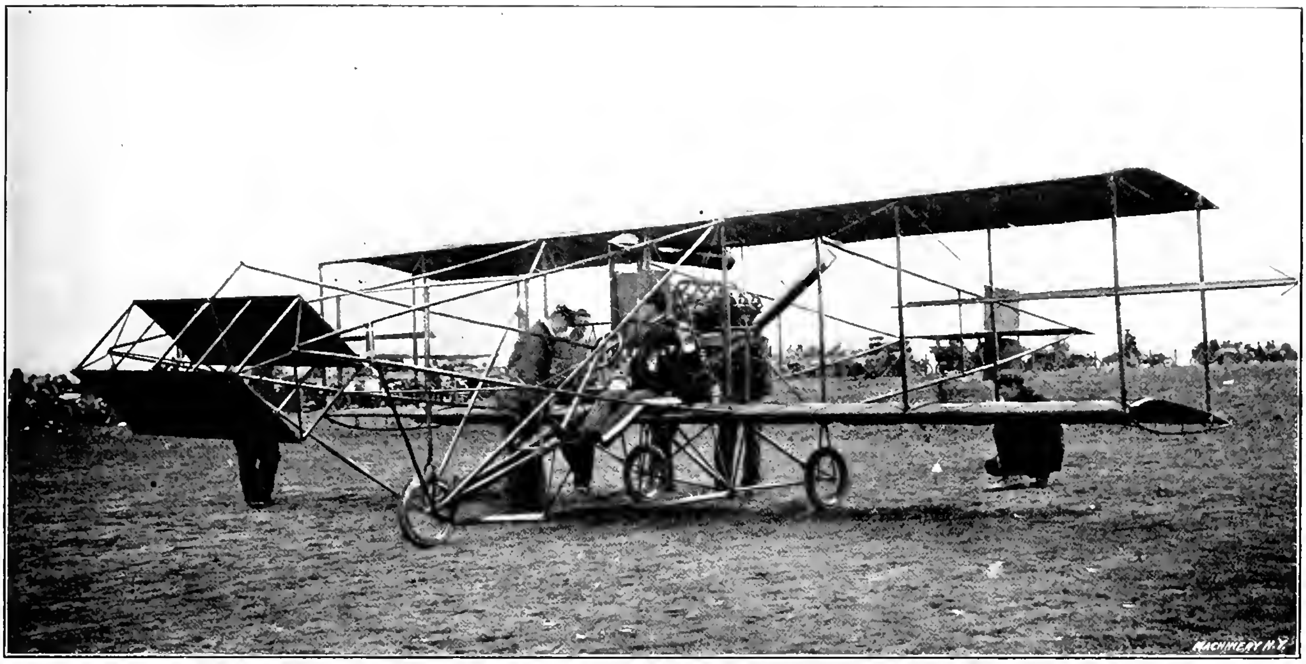

Fig. 1. Sixty-horsepower Curtiss Biplane

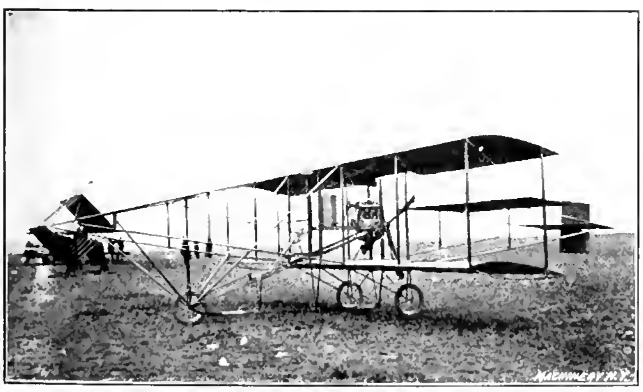

Fig. 2. Twenty-five-horsepower Curtiss Biplane

The course was hexagonal in shape, a lap measuring 1.61 mile. While proving a greater test of skill than a more extended circuit, it was evident that this lap was far too short to permit of possible speed records, and that one of twice this size would offer bigger advantages. At the Rheims meet, mentioned above, a lap was 6.21 miles, nearly four times this size. Conditions governing the prizes provided that they could be contested for any day during the event. Each contestant had to cover one lap each day when trying for a prize or forfeit a percentage of credit. To qualify for each lap, the aviator had to cross the line at the judges' stand off the ground at start and finish; should he touch the ground at any time during flight he was disqualified. The posts marking the circuit had to be encircled outside, and any contestant passed in flight was allowed the inside course. Notable in aerial circles and officiating as judges were Cortlandt Field Bishop, President of the Aero Club of America and Vice-President of the International Aeronautical Association, and Prof. H. LaV. Twining, President of the Aero Club of California.

Ten important machines were entered. Of the Herring-Curtiss models there were three different types, piloted by Glenn H. Curtiss, Charles K. Hamilton, Clifford B. Harmon, Hillery Beachy and Charles F. Willard (who has more successful flights in this country credited to him than any other aviator). Louis Paulhan, heading a French syndicate, entered four machines, two models of Voisin-Farman biplanes, and two of the Bleriot No. 11 monoplanes.

The 60-horsepower Curtiss Biplane

The 60-horsepower Curtiss biplane, piloted by the inventor, (Fig. 1) is the machine which holds the speed record and with which Mr. Curtiss won the international cup at Rheims. It weighs, complete, about 600 pounds, with a supporting surface of only 250 square feet in the main planes; this gives a weight factor of 2.4 pounds per square foot of surface. In the main planes the framework is of spruce, supported by laminated ribs, forming a parabolic curve of about 4 1/4 inch spring. The angle of the planes so formed is decreased when the machine is in flight. Verticals of the same material support the upper plane, which are of elliptical section with the long axis (about 2 1/4 inches) turned in a transverse direction; their connection with the frames of the main planes is by means of a socket joint, very similar to that used in standard motorcycles. The planes are 29 feet long by 4 feet 9 inches wide, and are divided, as shown in the illustration, into five panels, the middle one containing the power plant;

* Address: 1353 West 30th St., Los Angeles, Cal.

they are covered with Baldwin's patent cloth, a sort of rubberized silk fabric, very light in texture. Featherbone is used to fasten it to the ribs. In each of these planes, at the rear, a cut is made to allow for the swing of the propeller. Central between the main planes are two 6 feet by 2 feet balancing planes; these are hinged at the end strut, with a projection of 33 inches inward and 39 inches outward beyond the planes. These movable surfaces act in harmony; that is, when one moves upward the other moves downward a corresponding distance. Through the medium of these planes equilibrium is maintained and aid is afforded in making turns. The framework and covering is similar to that of the larger planes.

As shown in the engraving, the horizontal tail-surface and rudder at the rear are supported by a V-shaped framework formed of bamboo, with intermediate laterals of galvanized wire. The vertical rudder, 2 feet by 3 feet, is for steering, being under the control of the handwheel in front of the operator's seat; the horizontal plane, which passes through it by means of a slit, is for stability. The front control is supported by a framework of similar construction to that of the rear frame, a more elaborate system of bracing, however, being required. The planes are about 2 feet by 6 feet, spaced 2 feet apart, with their axis a little over 4 feet from the ground level.

The most interesting features of the Curtiss machine are the control and the power plant; the minor devices of the former are ingenious and surpass those of any other aeroplane. The handwheel and front planes are joined by a long rod of bamboo, while the back rudder is connected by a wire cord which passes, by means of pulleys, completely around the wheel. This affords the operator control of the front and rear at any time in flight. By pushing or pulling the wheel, the front planes are directed to guide the altitude; by rotating the wheel the rear rudder is regulated to suit the course. Involuntarily the aviator maintains the lateral stability of the machine by means of a frame or yoke which fits around his shoulders; this frame is made of light tubing and is connected to the ailerons, as the movable planes are called by wires so that as he swings from side to side against the inclination of the aeroplane, balance is maintained. The operator's feet rest against two small levers; the right one is for speed control, and is connected to the throttle valve; the other acts upon the magneto and a brake upon the front chassis wheel, by which the machine is immediately stopped when on the ground. The engine can also be stopped by means of a switch, located under the seat and acting upon the magneto circuit.

The power plant is of the Curtiss design, and is patterned after that found in the smaller Curtiss machines. The engine has eight 4 x 4 inch cylinders; it is of the four-cycle type, and is rated at 60 horsepower. The cylinders are placed in a V-shaped manner, as shown; they are water cooled by means of a small pump. The lubricating oil is located in a three-gallon tank under the crank case. The bearings are lubricated through a hollow cam-shaft; a small pump, operated by the foot, is arranged to supply additional lubrication as required. A thirteen-gallon gasoline tank is carried above the engine, close to the upper plane. The entire motor weighs about 200 pounds; it is mounted on a frame, of ash, rigidly braced to the machine. The propeller is 7 feet in diameter; it is made of spruce, and has two straight-pitched blades with an average width of a little over 6 inches; it is flanged to the crankshaft direct, offering a simple form of drive.

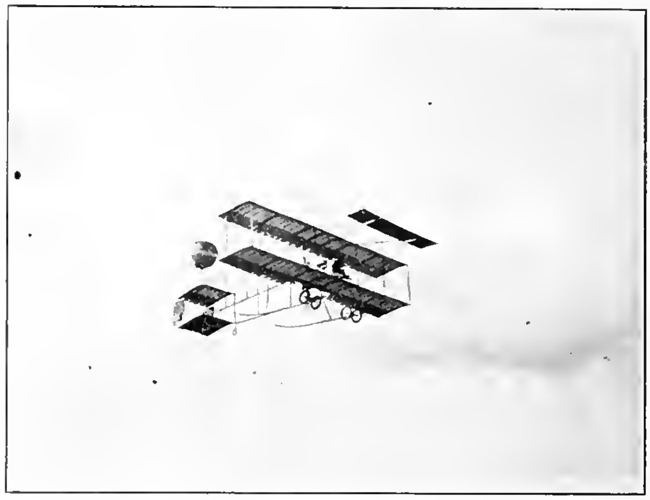

Fig. 4. Paulhan in Flight—Second Farman Biplane

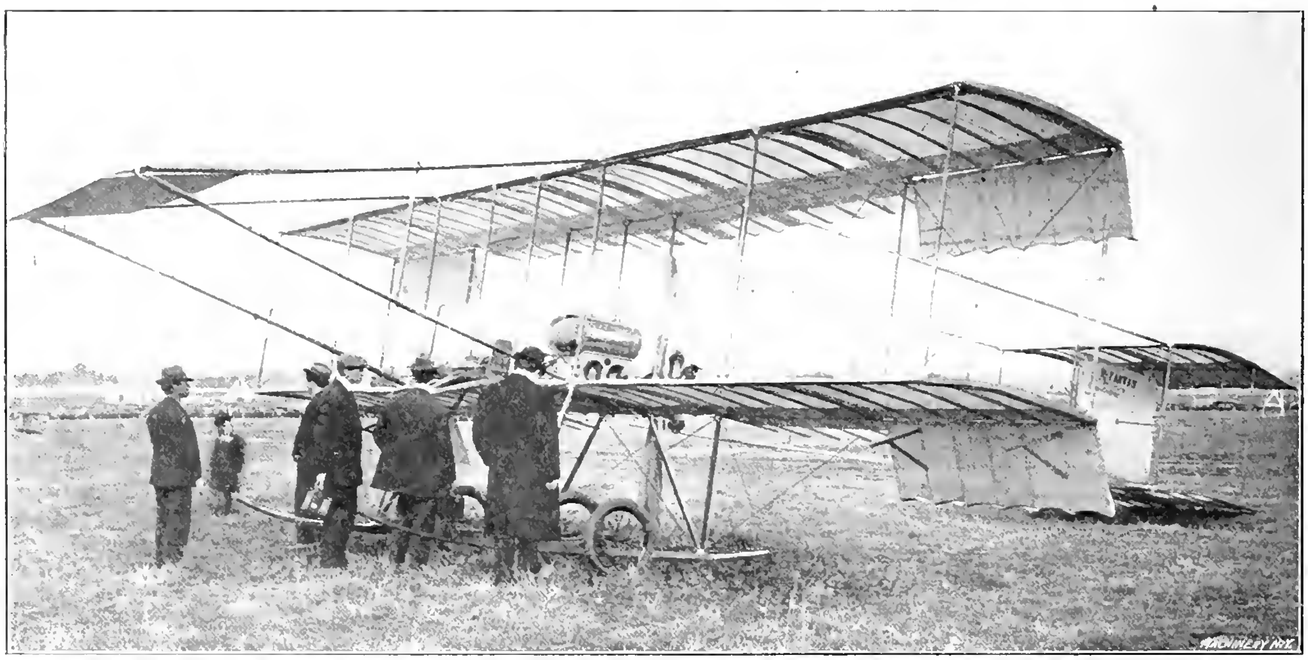

Fig. 3. Biplane of the Farman Type

The chassis is mounted on three 20-inch pneumatic-tired wheels, supported on rigid axles; this allows it to run on the ground in starting. When the machine is on the ground the height to the upper plane is about 7 feet.

The 25-horsepower Curtiss Biplane

As will be noticed by referring to the engraving, Fig. 2, the Curtiss machines of smaller sizes are of the same general type and dimensions as the one described in the foregoing, except in the power plant and a few minor instances. These are the smallest models of American aeroplanes which have proved successful; the Santos-Dumont creation, known as "La Demoiselle," is the smallest aeroplane on record—it is a monoplane and has found great favor in France.

In the power plant of these 25 horsepower Curtiss biplanes, the engine is four-cylinder, four-cycle, of $3\frac{3}{4}$-inch bore and 4-inch stroke. It is water cooled by a circulating pump driven from the cam-shaft. The heads are of the hemispherical pattern, and contain the inlet and exhaust valves, each set of which is operated by a rocker arm and a connection rod from the cam-shaft. The cylinders are of cast iron; a copper jacket extends around each cylinder, and is brazed to it, which incloses both the head and the body. The Curtiss type of carburetor is used. The magneto is gear-driven from the cam-shaft; this shaft also drives the force pump for oiling, the tank for which is situated below the engine. The overflow of oil from the aluminum crank-case is by way of two pipes, connecting with the tank at either end. A three-gallon fuel tank is located above the engine. The radiator is of the common type used in automobiles; it has a capacity of seven quarts and is placed in front of the engine, as shown in Figs. 1 and 2. All material used for piping is of brass and copper. The crankshaft is of steel alloy, and the piston, piston rods, valve arms, etc., of composition metal. The mechanism throughout is simple, and the design makes prac-

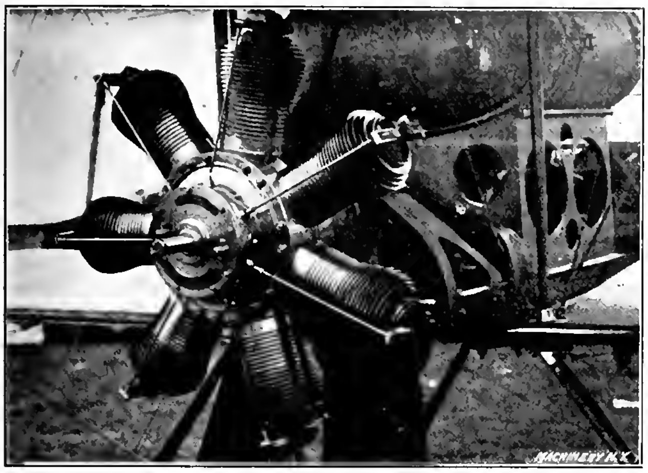

Fig. 5. Gnome Rotary Aeronautic Engine

tically all parts readily accessible. The engine develops a pull of 160 pounds; it runs at about 1,100 revolutions per minute and its weight is close to 100 pounds. The entire power plant ready for operation weighs about 150 pounds. The propeller and method of mounting is identical with that of the 60 horsepower machine. The machine shown in Fig. 2 had the only four-blade propeller on the field. This propeller is of the same general dimensions as the double-blade type.

The Gill-Dosh Biplane

The Gill-Dosh machine, operated by Hillery Beachy, is a Curtiss biplane with a standard automobile motor (the only

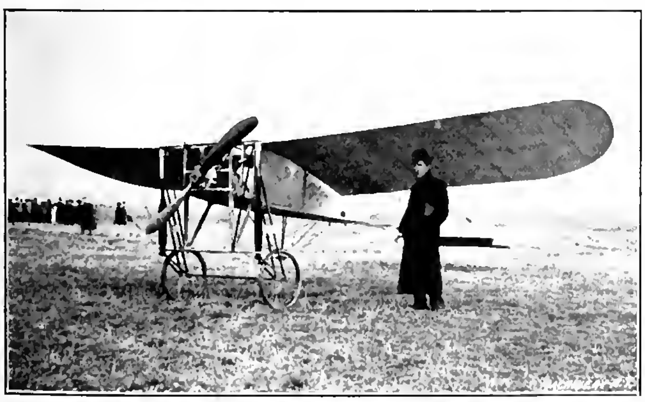

Fig. 6. Bleriot No. 11 Monoplane

one of its kind at the contests), and a propeller of the Gill-Dosh design, from which latter the machine derives its name. The engine was the well-known British-American with four 4 x 4 inch cylinders, four-cycle, of 26 horsepower. It was lightened by using copper jackets. This engine developed a pull of 200 pounds, or about 40 pounds more than the Curtiss engine of almost like rating. Like this latter engine, it is water cooled. The planes are covered with Baldwin "balloon cloth." This machine had the misfortune of being wrecked in the early days of the meet.

The Farman Biplanes

A modification of the first Farman aeroplane of the Voisin model is shown in Fig. 3. In Fig. 4 the second Farman ma-

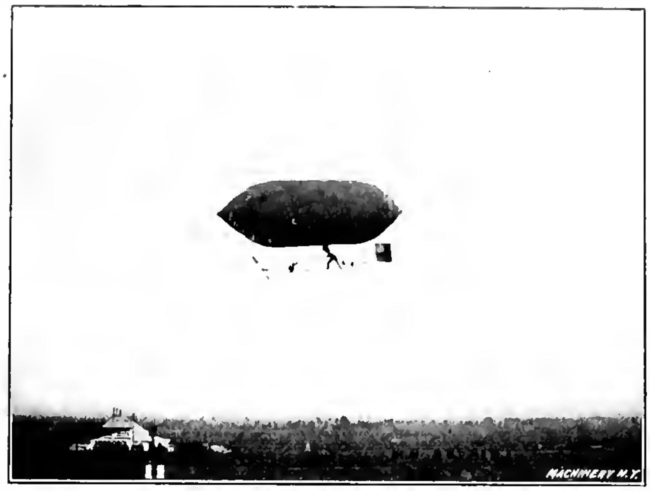

Fig. 7. Roy Knabenshue in His Dirigible

chine is shown in flight (the balloon seen in the illustration should not be confused with the biplane; it was in evidence throughout the meet, representing a local daily). Both of these machines were used at the Rheims exhibition and this was their first appearance in America. In the Voisin Brothers' model, the box-kite element is more evident than in any other type of flying-machine. The planes are about 33 feet wide, over all, three feet less than the Wright Brothers' model, and a little short of seven feet more than the Curtiss inventions. In length, these machines are much larger than either the Wright or Curtiss. The tail is also more prominent in the Farman aeroplanes than in other types. The weight of the aeroplanes in Figs. 3 and 4 is 800 and 1100 pounds respectively. As they are almost identical in construction, save for a few minor instances, only one will be described.

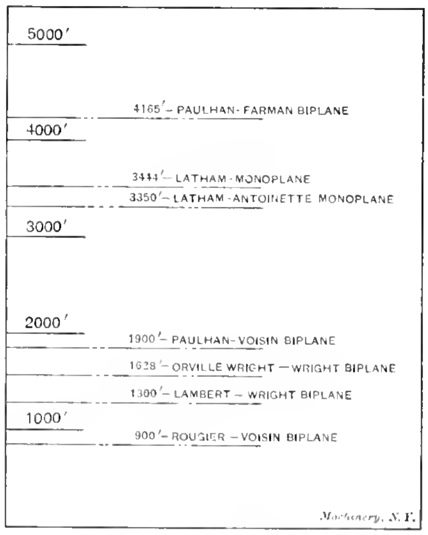

Fig. 8. Diagram showing Height Records

The framework of the second model illustrated is of steel tubing, and the ribs are of wood, covered with rubberized cloth. As mentioned, the planes are 33 feet; they are covered with Continental silk fabric. The upper plane is situated about $6\frac{1}{2}$ feet above the lower. To take the place of the movable balancing planes seen in the Curtiss models, at both sides of the main planes, at the rear, are hinged four stabilizing wings, two at each level; these planes are under the control of the operator by means of a hand-lever, and can be made to assume any angle. The framework at the rear is mounted upon two small wheels. The tail renders great stability to the main body, being located nearly 20 feet from the large planes. The two horizontal planes are square, measuring $6\frac{1}{2}$ feet along each edge. As seen in the illustration, Fig. 4, there are two vertical rudders, situated at either end of the horizontals; they are the steering apparatus for the machine. These are operated by the feet of the aviator, which rest on a pivoted lever connected to the rudders by wires; these latter act only in turning the biplanes to either side. The rudders are held up by the action of the wind to which they suit them-

selves. As will be noticed, the two Farman machines shown in the illustrations differ in the tail construction.

The front framework, which is built on the cantilever system, supports at the end a horizontal rudder 13 feet wide; this rudder is under the control of a hand lever and as in the other types, it is for regulating the height. In the former Farman machines, a handwheel controlled the front and rear rudders; this has given way to a hand-lever, controlling the front plane, while the rear planes are now acted upou by the feet of the aviator. This lever is pivoted, being capable of movement in all directions. While the previous Farman models had but two chassis wheels, this type has four, with the addition of skids; the chassis is supported on heavy rubber cushions, for eliminating shocks.

The Gnome Rotary Engine

The Gnome rotary engine, with which the two Farman aeroplanes are equipped, is a remarkable motor; it is one of the

Fig. 9. Curtiss Biplane with Mr. Curtiss and Lieut. Beck, U. S. A.

lightest (weighing 170 pounds) and most capable aeroplane engines yet invented, and it is the first of its kind to be used on flying-machines. This engine, which is shown in Fig. 5, develops 50 horsepower at 1,200 revolutions per minute and it is of four-cycle type. The seven cylinders are cast in one piece. The cylinders rotate around the crankshaft, while the pistons move in a circle about the crank pin, which is eccentric by half the length of a stroke ($4\frac{3}{4}$) to the center of rotation. This cylinder arrangement gives the advantage of a balance wheel effect without the additional weight of a fly-wheel and gearing, and eliminates to a great extent, the vibration current with reciprocating engines. The cylinders are air cooled by their own motion. The valve-rods travel over fixed cams, the centrifugal force making the action of the valves positive, without the necessity of springs. For ignition, the spark plugs each touch a common contact point as the cylinder turns into position, no separate leads being required in the magneto system. The Gnome motor holds the record for distance—118 miles made by Farman at Rheims.

The Bleriot No. 11 Monoplane

In Fig. 6 is shown the famous cross-Channel type monoplane, perfected by Louis Bleriot during the early part of last year, and known as the Bleriot No. 11 monoplane. It is probably more dangerous than the other dynamic machines. In flight the machine is more bird-like than any of the other biplanes; it also greatly resembles a dragon-fly.

The weight of the machine is 550 pounds, which, with a supporting surface of 240 square feet, gives a weight factor of 2.3 pounds. In over-all dimensions, the machine is approximately 28 feet square. The framework of the main planes is of ash supported by alternate aluminum and wood ribs, curved to suit the inclination of the wings, which are of unit pattern, being detachable from the body of the machine, and secured thereto, when in use, by means of a socket. These planes are about 6 feet wide and are rounded at each end as seen in the illustration; they are securely trussed with wires, and both sides are covered with Continental silk fabric, like that used on the Farman planes; this double thickness gives great stability. The socket joint mentioned above is arranged to keep the wings from interference with the motor.

As seen in the illustration, the body of the machine is of a sort of girder type. It is made of ash, with a little poplar, and trussed with steel wires. At the sides are the wing attachments, at the front is the space for the power plant, while at the rear the tail and rudder are connected. The tail is composed of three horizontal planes; one is a large fixed plane fastened to the tail frame, while two small planes are pivoted and act independently of each other. Above the main plane mentioned, a small rudder is placed, pivoted at the front edge; it is under the control of the operator's foot. The tail frame is mounted on a single pneumatic-tired wheel, (it is behind the man in the engraving). The two small pivoted wings mentioned are to the monoplane what the front rudders are to the other machines described, that is they are for altitude. In using these planes in connection with the main wings for balancing, the latter planes can be warped to suit the action of the wind. Paulhan, the French aviator, however, owing to the Wright brothers' injunction issued against the "wing warping" device, claiming an infringement, removed the apparatus from the machine, and used the rear control alone, thereby greatly handicapping the performances of the monoplane at this meet. As seen, the monoplane has no supporting surface in front. The propeller is located to act in "new" air, thus making the machine pull itself instead of pushing, as in the other machines illustrated.

The pilot's seat is located behind the motor between the main planes at the rear. All mechanism is visible from this position. The steering gear is in the form of a lever with a base of hemispherical shape attached to the main frame by a movable joint; to this latter the wires are attached for controlling the small hinged planes of the tail; it also formerly governed the wing warping. Neither the Farman nor Bleriot machine was equipped with wheel brakes.

The engine is of the reciprocating type, of Anzani design; it is three cylinder, four-cycle, size about $4\frac{3}{8} \times 6\frac{1}{4}$-inch, and air cooled. The inlet valves act automatically, and the exhaust valves perform mechanically. The engine is rated at about 25 horsepower and runs at 1,100 revolutions per minute. The ignition system is of ordinary design. Splash lubrication is used. The propeller is plainly seen in the illustration; it is constructed of walnut, variable-pitched, being composed of various sections glued together. It is fastened directly to the crankshaft, with a flanged reinforcement.

Great refinement of parts is more noticeable in the Bleriot monoplane than in any other type of machine shown at this meet; they are essentially a one-passenger machine (the Bleriot XII type is, I believe, suited for two passengers). In the model here shown, M. Bleriot made his famous flight across the English Channel, winning the $5,000 prize offered by the *Daily Mail*.

Other Aeroplanes

Lack of space will permit only mention of a few further models seen. A multiplane, a triplane and an "aerofoil" were entered. The former was composed of five main planes, patterned after a flight of steps, with the main body, very small
